The following code sets the value of `Message` using `TempData`:

C#

```
public class CreateDotModel : PageModel
{
    private readonly AppDbContext _db;

    public CreateDotModel(AppDbContext db)
```

```
    {
        _db = db;
    }

    [TempData]
    public string Message { get; set; }

    [BindProperty]
    public Customer Customer { get; set; }

    public async Task<IActionResult> OnPostAsync()
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }

        _db.Customers.Add(Customer);
        await _db.SaveChangesAsync();
        Message = $"Customer {Customer.Name} added";
        return RedirectToPage("./Index");
    }
}
```

The following markup in the `Pages/Customers/Index.cshtml` file displays the value of `Message` using `TempData`.

CSHTML

```
<h3>Msg: @Model.Message</h3>
```

The `Pages/Customers/Index.cshtml.cs` page model applies the `[TempData]` attribute to the `Message` property.

C#

```
[TempData]
public string Message { get; set; }
```

For more information, see TempData.

Multiple handlers per page

The following page generates markup for two handlers using the `asp-page-handler` Tag Helper:

CSHTML

```
@page
@model CreateFATHModel

<html>
<body>
    <p>
        Enter your name.
    </p>
    <div asp-validation-summary="All"></div>
    <form method="POST">
        <div><label>Name: <input asp-for="Customer.Name" /></label></div>
        <!-- <snippet_Handlers> -->
        <input type="submit" asp-page-handler="JoinList" value="Join" />
        <input type="submit" asp-page-handler="JoinListUC" value="JOIN UC"
/>
        <!-- </snippet_Handlers> -->
    </form>
</body>
</html>
```

The form in the preceding example has two submit buttons, each using the `FormActionTagHelper` to submit to a different URL. The `asp-page-handler` attribute is a companion to `asp-page`. `asp-page-handler` generates URLs that submit to each of the handler methods defined by a page. `asp-page` isn't specified because the sample is linking to the current page.

The page model:

C#

```
using System.Threading.Tasks;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using RazorPagesContacts.Data;

namespace RazorPagesContacts.Pages.Customers
{
    public class CreateFATHModel : PageModel
    {
        private readonly AppDbContext _db;

        public CreateFATHModel(AppDbContext db)
        {
            _db = db;
        }

        [BindProperty]
        public Customer Customer { get; set; }

        public async Task<IActionResult> OnPostJoinListAsync()
```

```
        {
            if (!ModelState.IsValid)
            {
                return Page();
            }

            _db.Customers.Add(Customer);
            await _db.SaveChangesAsync();
            return RedirectToPage("/Index");
        }

        public async Task<IActionResult> OnPostJoinListUCAsync()
        {
            if (!ModelState.IsValid)
            {
                return Page();
            }
            Customer.Name = Customer.Name?.ToUpperInvariant();
            return await OnPostJoinListAsync();
        }
    }
}
```

The preceding code uses *named handler methods*. Named handler methods are created by taking the text in the name after `On<HTTP Verb>` and before `Async` (if present). In the preceding example, the page methods are OnPost**JoinList**Async and OnPost**JoinListUC**Async. With *OnPost* and *Async* removed, the handler names are `JoinList` and `JoinListUC`.

CSHTML

```
<input type="submit" asp-page-handler="JoinList" value="Join" />
<input type="submit" asp-page-handler="JoinListUC" value="JOIN UC" />
```

Using the preceding code, the URL path that submits to `OnPostJoinListAsync` is `https://localhost:5001/Customers/CreateFATH?handler=JoinList`. The URL path that submits to `OnPostJoinListUCAsync` is `https://localhost:5001/Customers/CreateFATH?handler=JoinListUC`.

Custom routes

Use the `@page` directive to:

- Specify a custom route to a page. For example, the route to the About page can be set to `/Some/Other/Path` with `@page "/Some/Other/Path"`.

- Append segments to a page's default route. For example, an "item" segment can be added to a page's default route with `@page "item"`.
- Append parameters to a page's default route. For example, an ID parameter, `id`, can be required for a page with `@page "{id}"`.

A root-relative path designated by a tilde (`~`) at the beginning of the path is supported. For example, `@page "~/Some/Other/Path"` is the same as `@page "/Some/Other/Path"`.

If you don't like the query string `?handler=JoinList` in the URL, change the route to put the handler name in the path portion of the URL. The route can be customized by adding a route template enclosed in double quotes after the `@page` directive.

CSHTML

```
@page "{handler?}"
@model CreateRouteModel

<html>
<body>
    <p>
        Enter your name.
    </p>
    <div asp-validation-summary="All"></div>
    <form method="POST">
        <div><label>Name: <input asp-for="Customer.Name" /></label></div>
        <input type="submit" asp-page-handler="JoinList" value="Join" />
        <input type="submit" asp-page-handler="JoinListUC" value="JOIN UC"
/>
    </form>
</body>
</html>
```

Using the preceding code, the URL path that submits to `OnPostJoinListAsync` is `https://localhost:5001/Customers/CreateFATH/JoinList`. The URL path that submits to `OnPostJoinListUCAsync` is `https://localhost:5001/Customers/CreateFATH/JoinListUC`.

The `?` following `handler` means the route parameter is optional.

Collocation of JavaScript (JS) files

Collocation of JavaScript (JS) files for pages and views is a convenient way to organize scripts in an app.

Collocate JS files using the following filename extension conventions:

- Pages of Razor Pages apps and views of MVC apps: `.cshtml.js`. Examples:

- `Pages/Index.cshtml.js` for the `Index` page of a Razor Pages app at `Pages/Index.cshtml`.
- `Views/Home/Index.cshtml.js` for the `Index` view of an MVC app at `Views/Home/Index.cshtml`.

Collocated JS files are publicly addressable using the ***path to the file in the project***:

- Pages and views from a collocated scripts file in the app:

  `{PATH}/{PAGE, VIEW, OR COMPONENT}.{EXTENSION}.js`

  - The `{PATH}` placeholder is the path to the page, view, or component.
  - The `{PAGE, VIEW, OR COMPONENT}` placeholder is the page, view, or component.
  - The `{EXTENSION}` placeholder matches the extension of the page, view, or component, either `razor` or `cshtml`.

  Razor Pages example:

  A JS file for the `Index` page is placed in the `Pages` folder (`Pages/Index.cshtml.js`) next to the `Index` page (`Pages/Index.cshtml`). In the `Index` page, the script is referenced at the path in the `Pages` folder:

  ```
  razor

  @section Scripts {
    <script src="~/Pages/Index.cshtml.js"></script>
  }
  ```

The default layout `Pages/Shared/_Layout.cshtml` can be configured to include collocated JS files, eliminating the need to configure each page individually:

```
razor

<script asp-src-include="@(ViewContext.View.Path).js"></script>
```

The sample download uses the preceding code snippet to include collocated JS files in the default layout.

When the app is published, the framework automatically moves the script to the web root. In the preceding example, the script is moved to `bin\Release\{TARGET FRAMEWORK MONIKER}\publish\wwwroot\Pages\Index.cshtml.js`, where the `{TARGET FRAMEWORK MONIKER}` placeholder is the Target Framework Moniker (TFM). No change is required to the script's relative URL in the `Index` page.

When the app is published, the framework automatically moves the script to the web root. In the preceding example, the script is moved to `bin\Release\{TARGET FRAMEWORK MONIKER}\publish\wwwroot\Components\Pages\Index.razor.js`, where the `{TARGET FRAMEWORK MONIKER}` placeholder is the Target Framework Moniker (TFM). No change is required to the script's relative URL in the `Index` component.

- For scripts provided by a Razor class library (RCL):

  `_content/{PACKAGE ID}/{PATH}/{PAGE, VIEW, OR COMPONENT}.{EXTENSION}.js`

  - The `{PACKAGE ID}` placeholder is the RCL's package identifier (or library name for a class library referenced by the app).
  - The `{PATH}` placeholder is the path to the page, view, or component. If a Razor component is located at the root of the RCL, the path segment isn't included.
  - The `{PAGE, VIEW, OR COMPONENT}` placeholder is the page, view, or component.
  - The `{EXTENSION}` placeholder matches the extension of page, view, or component, either `razor` or `cshtml`.

Advanced configuration and settings

The configuration and settings in following sections is not required by most apps.

To configure advanced options, use the AddRazorPages overload that configures RazorPagesOptions:

C#

```
using Microsoft.EntityFrameworkCore;
using RazorPagesContacts.Data;
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages(options =>
{
    options.RootDirectory = "/MyPages";
    options.Conventions.AuthorizeFolder("/MyPages/Admin");
});

builder.Services.AddDbContext<CustomerDbContext>(options =>
    options.UseInMemoryDatabase("name"));

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}
```

```
app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

Use the RazorPagesOptions to set the root directory for pages, or add application model conventions for pages. For more information on conventions, see Razor Pages authorization conventions.

To precompile views, see Razor view compilation.

Specify that Razor Pages are at the content root

By default, Razor Pages are rooted in the */Pages* directory. Add WithRazorPagesAtContentRoot to specify that your Razor Pages are at the content root (ContentRootPath) of the app:

C#

```
using Microsoft.EntityFrameworkCore;
using RazorPagesContacts.Data;
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages(options =>
{
    options.Conventions.AuthorizeFolder("/MyPages/Admin");
})
  .WithRazorPagesAtContentRoot();

builder.Services.AddDbContext<CustomerDbContext>(options =>
    options.UseInMemoryDatabase("name"));

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();
```

```
app.UseRouting();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

Specify that Razor Pages are at a custom root directory

Add WithRazorPagesRoot to specify that Razor Pages are at a custom root directory in the app (provide a relative path):

C#

```
using Microsoft.EntityFrameworkCore;
using RazorPagesContacts.Data;
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages(options =>
{
    options.Conventions.AuthorizeFolder("/MyPages/Admin");
})
  .WithRazorPagesRoot("/path/to/razor/pages");

builder.Services.AddDbContext<CustomerDbContext>(options =>
    options.UseInMemoryDatabase("name"));

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

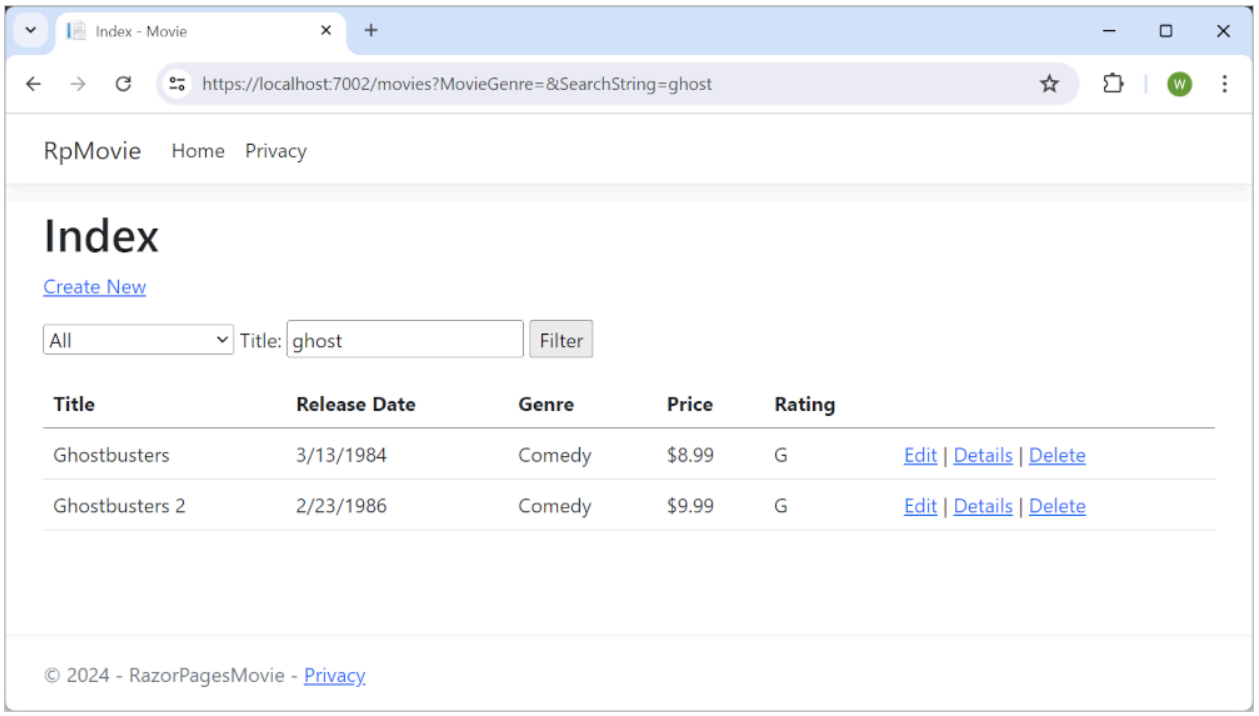
Tutorial: Create a Razor Pages web app with ASP.NET Core

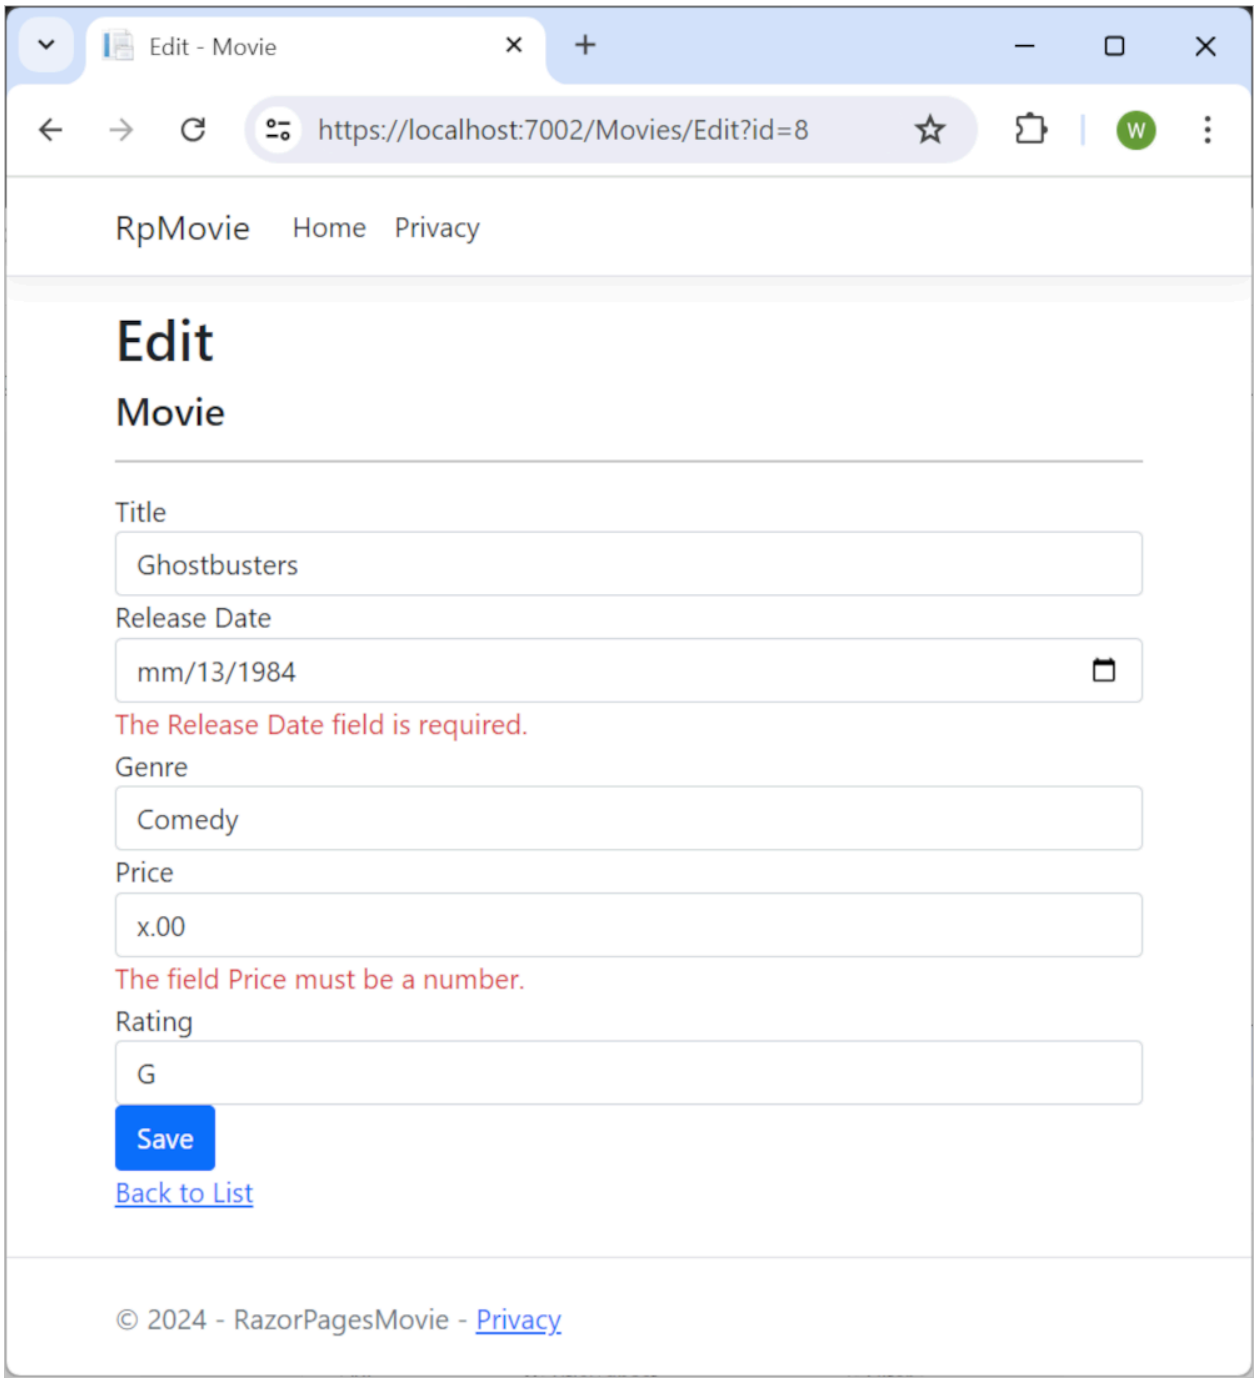
Article • 06/23/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This series of tutorials explains the basics of building a Razor Pages web app.



For a more advanced introduction aimed at developers who are familiar with controllers and views, see Introduction to Razor Pages in ASP.NET Core.



If you're new to ASP.NET Core development and are unsure of which ASP.NET Core web UI solution will best fit your needs, see Choose an ASP.NET Core UI.

This series includes the following tutorials:

1. Create a Razor Pages web app
2. Add a model to a Razor Pages app
3. Scaffold (generate) Razor pages
4. Work with a database
5. Update Razor pages
6. Add search
7. Add a new field
8. Add validation

At the end, you'll have an app that can display and manage a database of movies.

>
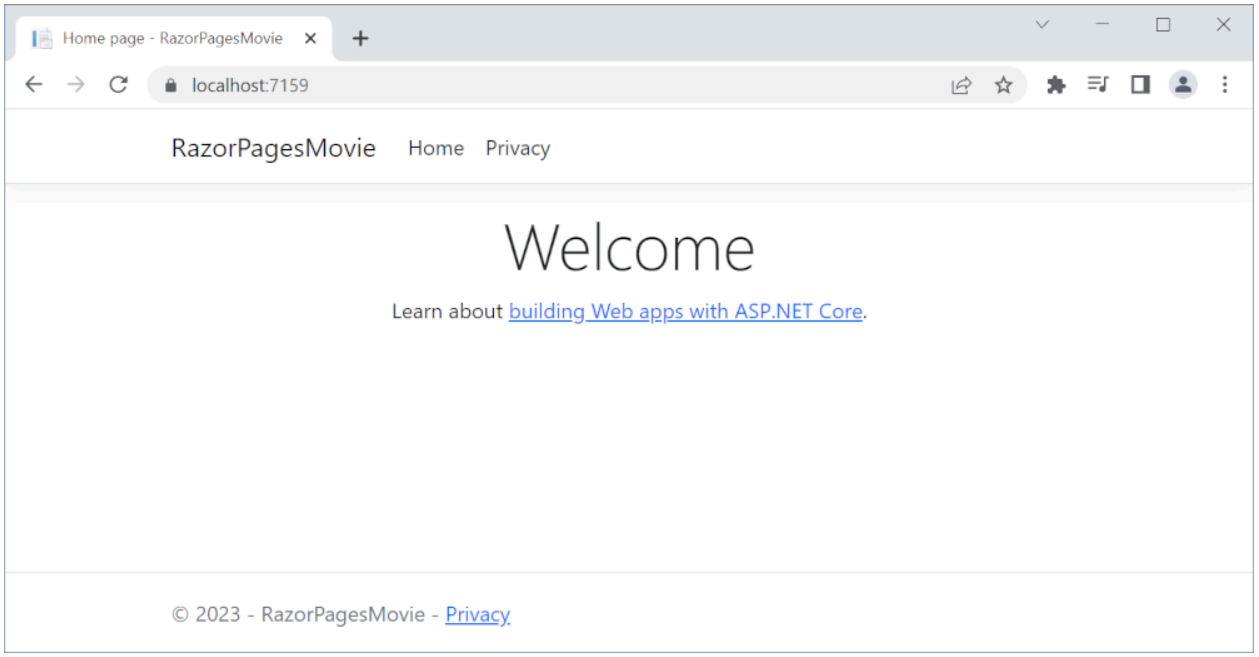
> For the current release, see the **.NET 8 version of this article**.

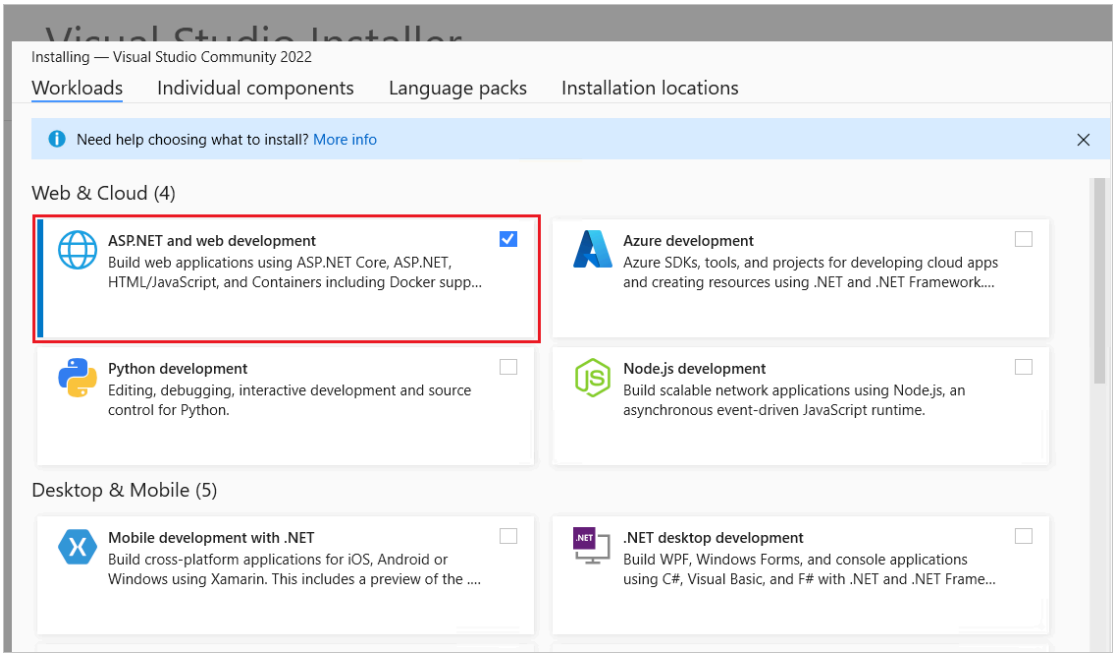


By Rick Anderson

This is the first tutorial of a series that teaches the basics of building an ASP.NET Core Razor Pages web app.

For a more advanced introduction aimed at developers who are familiar with controllers and views, see Introduction to Razor Pages. For a video introduction, see Entity Framework Core for Beginners.

If you're new to ASP.NET Core development and are unsure of which ASP.NET Core web UI solution will best fit your needs, see Choose an ASP.NET Core UI.

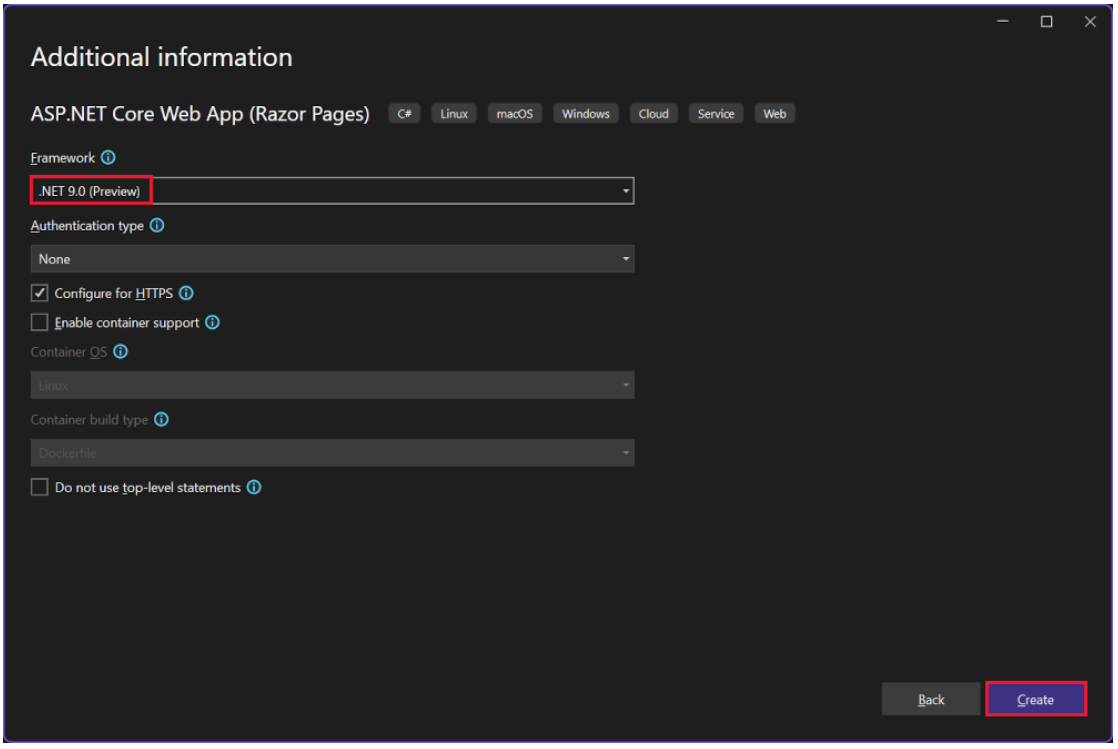


At the end of this tutorial, you'll have a Razor Pages web app that manages a database of movies.

Prerequisites

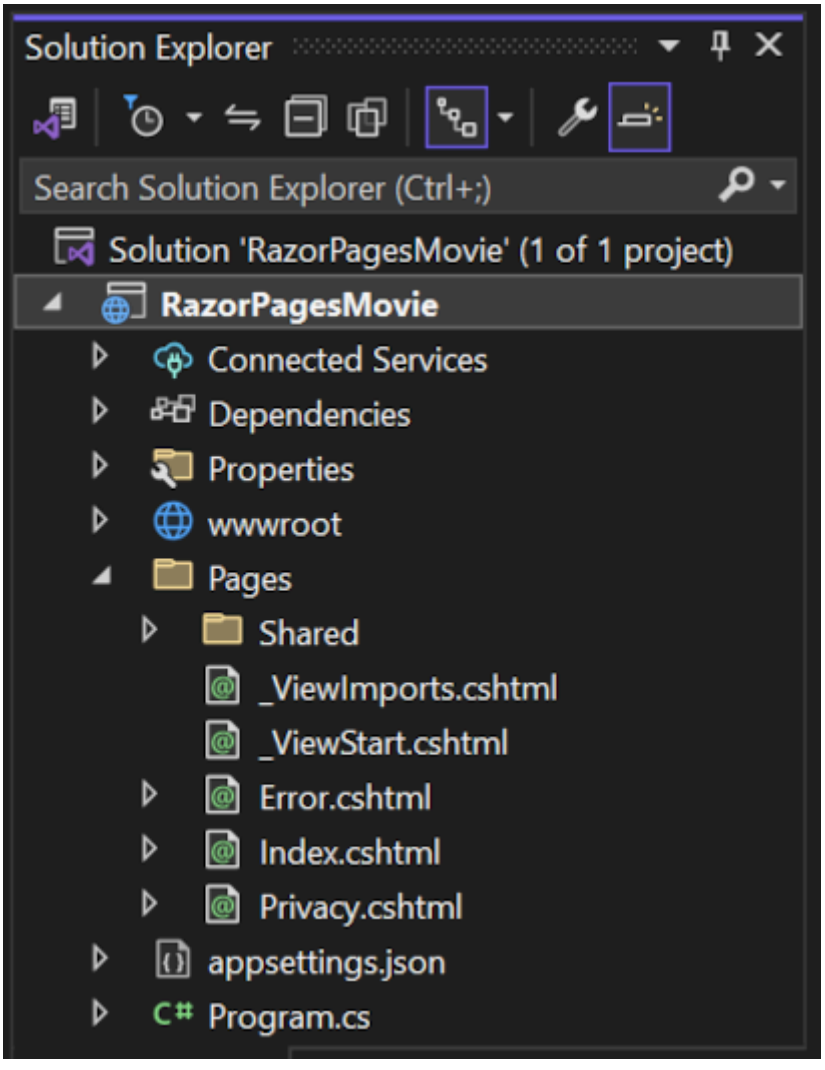
Visual Studio

- Visual Studio 2022 Preview with the **ASP.NET and web development** workload.



Create a Razor Pages web app

Visual Studio

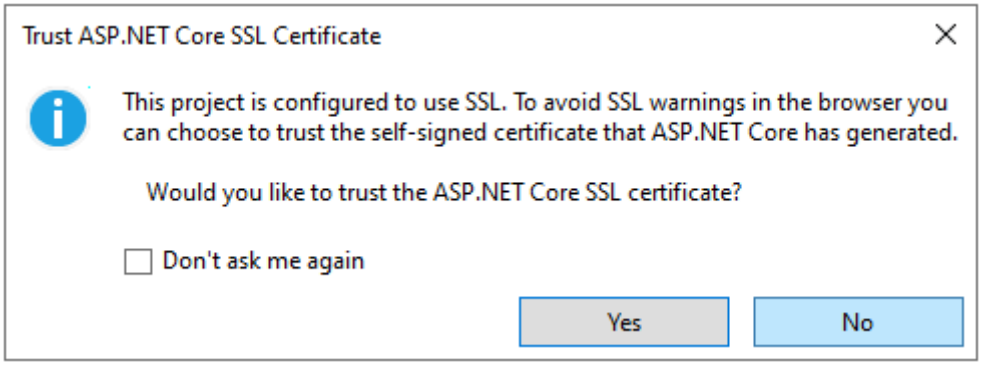


- Start Visual Studio and select **New project**.
- In the **Create a new project** dialog, select **ASP.NET Core Web App (Razor Pages)** > **Next**.
- In the **Configure your new project** dialog, enter `RazorPagesMovie` for **Project name**. It's important to name the project **RazorPagesMovie**, including matching the capitalization, so the namespaces will match when you copy and paste example code.
- Select **Next**.
- In the **Additional information** dialog:
  - Select **.NET 9.0 (Preview)**.

- Verify: **Do not use top-level statements** is unchecked.

- Select **Create**.

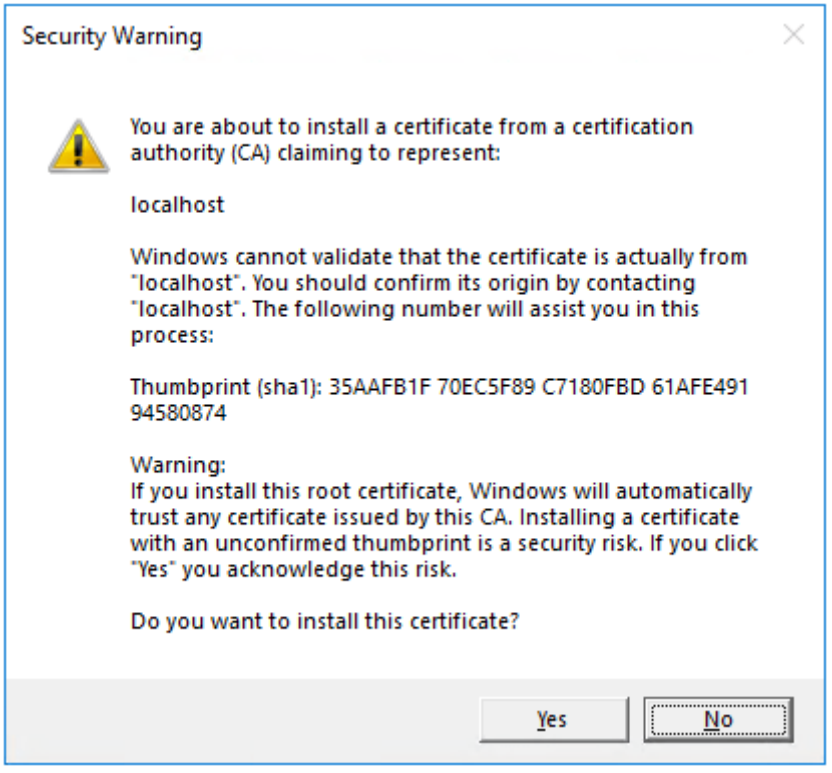
The following starter project is created:



For alternative approaches to create the project, see Create a new project in Visual Studio.

Run the app

Visual Studio



Select **RazorPagesMovie** in **Solution Explorer**, and then press `Ctrl`+`F5` to run the app without the debugger.

Visual Studio displays the following dialog when a project is not yet configured to use SSL:

Select **Yes** if you trust the IIS Express SSL certificate.

The following dialog is displayed:

Select **Yes** if you agree to trust the development certificate.

For information on trusting the Firefox browser, see Firefox SEC_ERROR_INADEQUATE_KEY_USAGE certificate error.

Visual Studio:

- Runs the app, which launches the Kestrel server.
- Launches the default browser at `https://localhost:<port>`, which displays the apps UI. `<port>` is the random port that is assigned when the app was created.

Close the browser window.

Examine the project files

The following sections contain an overview of the main project folders and files that you'll work with in later tutorials.

Pages folder

Contains Razor pages and supporting files. Each Razor page is a pair of files:

- A `.cshtml` file that has HTML markup with C# code using Razor syntax.
- A `.cshtml.cs` file that has C# code that handles page events.

Supporting files have names that begin with an underscore. For example, the `_Layout.cshtml` file configures UI elements common to all pages. `_Layout.cshtml` sets up the navigation menu at the top of the page and the copyright notice at the bottom of the page. For more information, see Layout in ASP.NET Core.

wwwroot folder

Contains static assets, like HTML files, JavaScript files, and CSS files. For more information, see Static files in ASP.NET Core.

`appsettings.json`

Contains configuration data, like connection strings. For more information, see Configuration in ASP.NET Core.

Program.cs

Contains the following code:

```
C#
```

```
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.AddRazorPages();

var app = builder.Build();

// Configure the HTTP request pipeline.
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    // The default HSTS value is 30 days. You may want to change this for
production scenarios, see https://aka.ms/aspnetcore-hsts.
    app.UseHsts();
}

app.UseHttpsRedirection();

app.UseRouting();

app.UseAuthorization();

app.MapStaticAssets();
app.MapRazorPages();

app.Run();
```

The following lines of code in this file create a `WebApplicationBuilder` with preconfigured defaults, add Razor Pages support to the Dependency Injection (DI) container, and builds the app:

```
C#
```

```
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.AddRazorPages();

var app = builder.Build();
```

The developer exception page is enabled by default and provides helpful information on exceptions. Production apps should not be run in development mode because the developer exception page can leak sensitive information.

The following code sets the exception endpoint to `/Error` and enables HTTP Strict Transport Security Protocol (HSTS) when the app is ***not*** running in development mode:

```
C#
```

```
// Configure the HTTP request pipeline.
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    // The default HSTS value is 30 days. You may want to change this for
production scenarios, see https://aka.ms/aspnetcore-hsts.
    app.UseHsts();
}
```

For example, the preceding code runs when the app is in production or test mode. For more information, see Use multiple environments in ASP.NET Core.

The following code enables various Middleware:

- `app.UseHttpsRedirection();` : Redirects HTTP requests to HTTPS.
- `app.UseRouting();` : Adds route matching to the middleware pipeline. For more information, see Routing in ASP.NET Core.
- `app.UseAuthorization();` : Authorizes a user to access secure resources. This app doesn't use authorization, therefore this line could be removed.
- `app.MapRazorPages();`: Configures endpoint routing for Razor Pages.
- `app.MapStaticAssets();` : Optimize the delivery of static assets in an app such as such as HTML, CSS, images, and JavaScript to be served. For more information, see What's new in ASP.NET Core 9.0.
- `app.Run();` : Runs the app.

Troubleshooting with the completed sample

If you run into a problem you can't resolve, compare your code to the completed project. View or download completed project (how to download).

Next steps

Next: Add a model

Part 2, add a model to a Razor Pages app in ASP.NET Core

Article • 10/29/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

In this tutorial, classes are added for managing movies in a database. The app's model classes use Entity Framework Core (EF Core) to work with the database. EF Core is an object-relational mapper (O/RM) that simplifies data access. You write the model classes first, and EF Core creates the database.

The model classes are known as POCO classes (from "**P**lain-**O**ld **C**LR **O**bjects") because they don't have a dependency on EF Core. They define the properties of the data that are stored in the database.

Add a data model

Visual Studio

1. In **Solution Explorer**, right-click the *RazorPagesMovie* project > **Add** > **New Folder**. Name the folder `Models`.
2. Right-click the `Models` folder. Select **Add** > **Class**. Name the class *Movie*.
3. Add the following properties to the `Movie` class:

C#

```
using System.ComponentModel.DataAnnotations;

namespace RazorPagesMovie.Models;

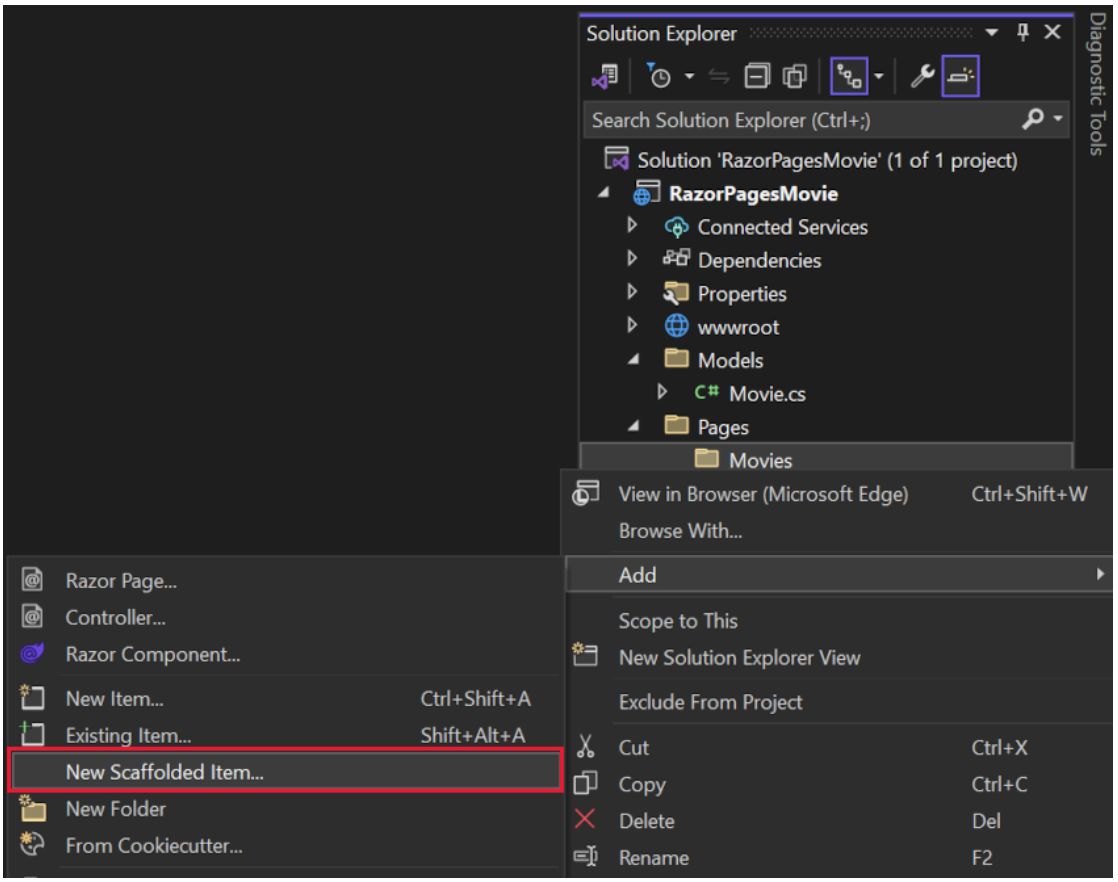
public class Movie
{
    public int Id { get; set; }
```

```
    public string? Title { get; set; }
    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }
    public string? Genre { get; set; }
    public decimal Price { get; set; }
}
```

The `Movie` class contains:

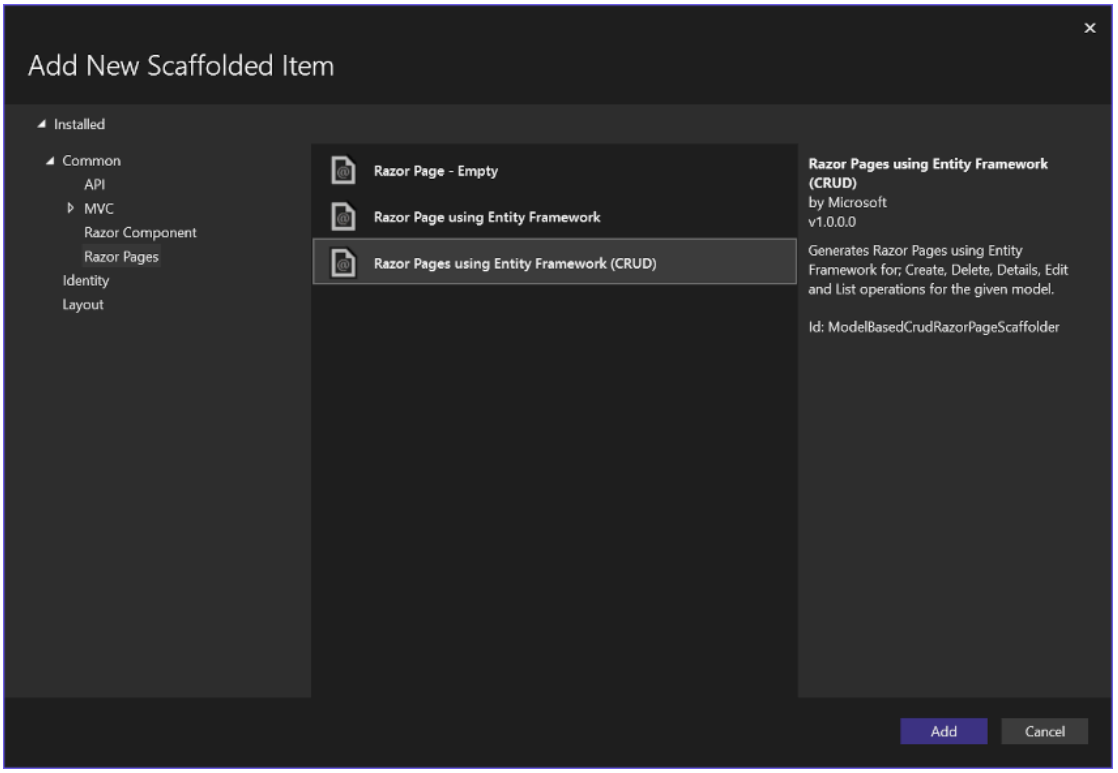
- The `ID` field is required by the database for the primary key.
- A [DataType] attribute that specifies the type of data in the `ReleaseDate` property. With this attribute:
  - The user isn't required to enter time information in the date field.
  - Only the date is displayed, not time information.
- The question mark after `string` indicates that the property is nullable. For more information, see Nullable reference types.

DataAnnotations are covered in a later tutorial.



Build the project to verify there are no compilation errors.

Scaffold the movie model

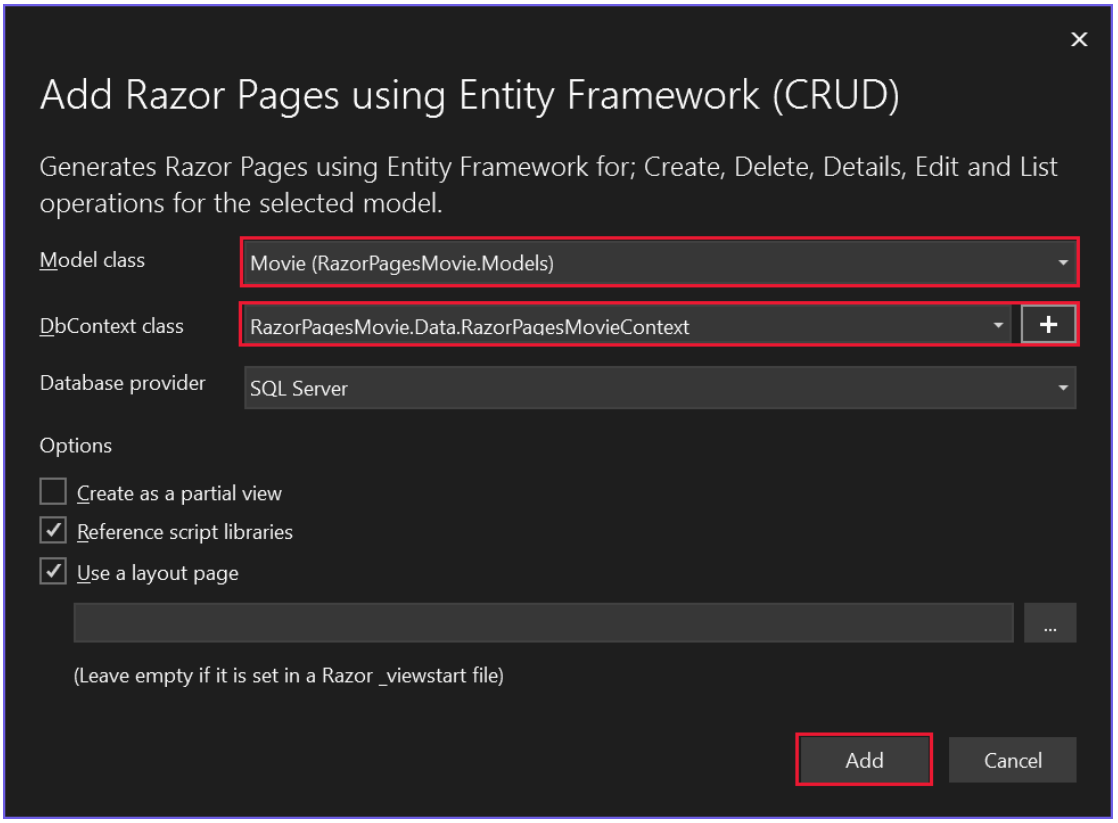


In this section, the movie model is scaffolded. That is, the scaffolding tool produces pages for Create, Read, Update, and Delete (CRUD) operations for the movie model.

Visual Studio

1. Create the *Pages/Movies* folder:
   a. Right-click on the *Pages* folder > **Add** > **New Folder**.
   b. Name the folder *Movies*.
2. Right-click on the *Pages/Movies* folder > **Add** > **New Scaffolded Item**.

3. In the **Add New Scaffold** dialog, select **Razor Pages using Entity Framework (CRUD)** > **Add**.



4. Complete the **Add Razor Pages using Entity Framework (CRUD)** dialog:
   a. In the **Model class** drop down, select **Movie (RazorPagesMovie.Models)**.
   b. In the **Data context class** row, select the + (plus) sign.

i. In the **Add Data Context** dialog, the class name `RazorPagesMovie.Data.RazorPagesMovieContext` is generated.

ii. In the **Database provider** drop down, select **SQL Server**.

c. Select **Add**.

The `appsettings.json` file is updated with the connection string used to connect to a local database.

> ⚠ **Warning**
>
> This article uses a local database that doesn't require the user to be authenticated. Production apps should use the most secure authentication flow available. For more information on authentication for deployed test and production apps, see Secure authentication flows.

Files created and updated

The scaffold process creates the following files:

- *Pages/Movies*: Create, Delete, Details, Edit, and Index.
- `Data/RazorPagesMovieContext.cs`

The created files are explained in the next tutorial.

The scaffold process adds the following highlighted code to the `Program.cs` file:

Visual Studio

C#

```
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;
using RazorPagesMovie.Data;
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.AddRazorPages();
builder.Services.AddDbContext<RazorPagesMovieContext>(options =>

options.UseSqlServer(builder.Configuration.GetConnectionString("RazorPag
esMovieContext") ?? throw new InvalidOperationException("Connection
string 'RazorPagesMovieContext' not found.")));

var app = builder.Build();

// Configure the HTTP request pipeline.
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    // The default HSTS value is 30 days. You may want to change this
for production scenarios, see https://aka.ms/aspnetcore-hsts.
    app.UseHsts();
}

app.UseHttpsRedirection();

app.UseRouting();

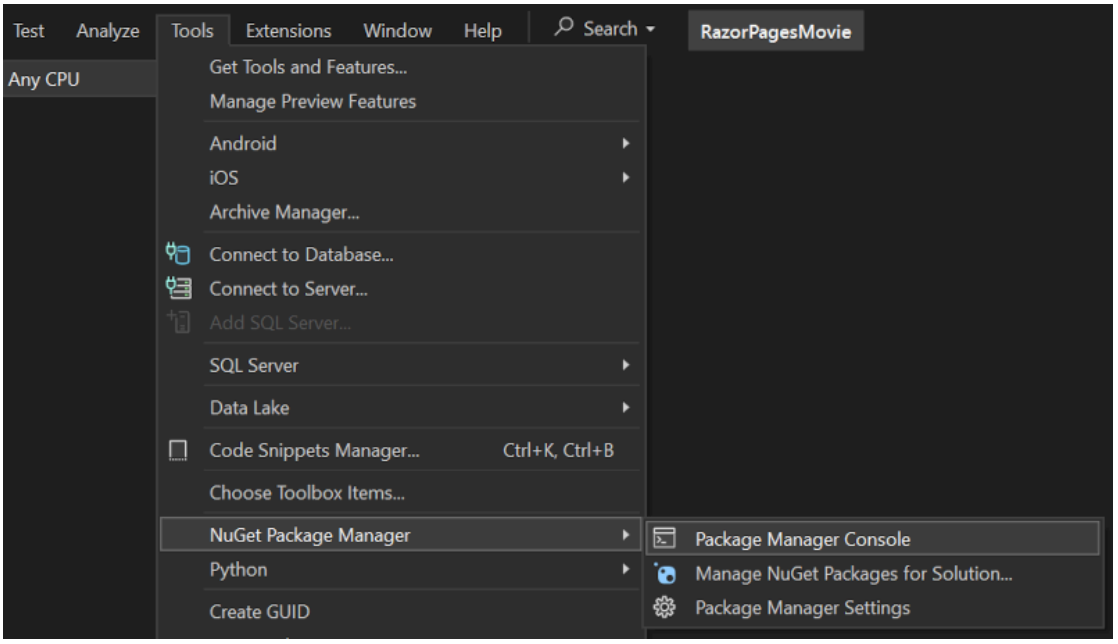
app.UseAuthorization();

app.MapStaticAssets();
app.MapRazorPages();

app.Run();
```

The `Program.cs` changes are explained later in this tutorial.

Create the initial database schema using EF's migration feature



The migrations feature in Entity Framework Core provides a way to:

- Create the initial database schema.
- Incrementally update the database schema to keep it in sync with the app's data model. Existing data in the database is preserved.

Visual Studio

In this section, the **Package Manager Console** (PMC) window is used to:

- Add an initial migration.
- Update the database with the initial migration.
- From the **Tools** menu, select **NuGet Package Manager** > **Package Manager Console**.

- In the PMC, enter the following command:

```
PowerShell

Add-Migration InitialCreate
```

- The `Add-Migration` command generates code to create the initial database schema. The schema is based on the model specified in `DbContext`. The `InitialCreate` argument is used to name the migration. Any name can be used, but by convention a name is selected that describes the migration.

The following warning is displayed, which is addressed in a later step:

> No type was specified for the decimal column 'Price' on entity type 'Movie'. This will cause values to be silently truncated if they do not fit in the default

> precision and scale. Explicitly specify the SQL server column type that can accommodate all the values using 'HasColumnType()'.

- In the PMC, enter the following command:

```
PowerShell
```

```
Update-Database
```

The `Update-Database` command runs the `Up` method in migrations that have not been applied. In this case, the command runs the `Up` method in the `Migrations/<time-stamp>_InitialCreate.cs` file, which creates the database.

The data context `RazorPagesMovieContext`:

- Derives from Microsoft.EntityFrameworkCore.DbContext.
- Specifies which entities are included in the data model.
- Coordinates EF Core functionality, such as Create, Read, Update and Delete, for the `Movie` model.

The `RazorPagesMovieContext` class in the generated file `Data/RazorPagesMovieContext.cs`:

```
C#
```

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.EntityFrameworkCore;
using RazorPagesMovie.Models;

namespace RazorPagesMovie.Data
{
    public class RazorPagesMovieContext : DbContext
    {
        public RazorPagesMovieContext
(DbContextOptions<RazorPagesMovieContext> options)
            : base(options)
        {
        }

        public DbSet<RazorPagesMovie.Models.Movie> Movie { get; set; } =
default!;
    }
}
```

The preceding code creates a DbSet<Movie> property for the entity set. In Entity Framework terminology, an entity set typically corresponds to a database table. An entity corresponds to a row in the table.

The name of the connection string is passed in to the context by calling a method on a DbContextOptions object. For local development, the Configuration system reads the connection string from the `appsettings.json` file.

Test the app

1. Run the app and append `/Movies` to the URL in the browser (`http://localhost:port/movies`).

   If you receive the following error:

   Console

   ```
   SqlException: Cannot open database "RazorPagesMovieContext-GUID"
   requested by the login. The login failed.
   Login failed for user 'User-name'.
   ```

   You missed the migrations step.

2. Test the **Create New** link.

> **Note**
>
> You may not be able to enter decimal commas in the `Price` field. To support jQuery validation for non-English locales that use a comma (",") for a decimal point and for non US-English date formats, the app must be globalized. For globalization instructions, see this GitHub issue.

3. Test the **Edit**, **Details**, and **Delete** links.

The next tutorial explains the files created by scaffolding.

Examine the context registered with dependency injection

ASP.NET Core is built with dependency injection. Services, such as the EF Core database context, are registered with dependency injection during application startup. Components that require these services (such as Razor Pages) are provided via constructor parameters. The constructor code that gets a database context instance is shown later in the tutorial.

The scaffolding tool automatically created a database context and registered it with the dependency injection container. The following highlighted code is added to the `Program.cs` file by the scaffolder:

Visual Studio

C#

```
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;
using RazorPagesMovie.Data;
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.AddRazorPages();
builder.Services.AddDbContext<RazorPagesMovieContext>(options =>

options.UseSqlServer(builder.Configuration.GetConnectionString("RazorPag
esMovieContext") ?? throw new InvalidOperationException("Connection
string 'RazorPagesMovieContext' not found.")));

var app = builder.Build();

// Configure the HTTP request pipeline.
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    // The default HSTS value is 30 days. You may want to change this
for production scenarios, see https://aka.ms/aspnetcore-hsts.
    app.UseHsts();
}

app.UseHttpsRedirection();

app.UseRouting();

app.UseAuthorization();

app.MapStaticAssets();
app.MapRazorPages();

app.Run();
```

Troubleshooting with the completed sample

If you run into a problem you can't resolve, compare your code to the completed project. View or download completed project (how to download).

By Rick Anderson

This tutorial examines the Razor Pages created by scaffolding in the previous tutorial.

The Create, Delete, Details, and Edit pages

Examine the `Pages/Movies/Index.cshtml.cs` Page Model:

C#

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using RazorPagesMovie.Data;
using RazorPagesMovie.Models;
using Microsoft.AspNetCore.Mvc.Rendering;

namespace RazorPagesMovie.Pages.Movies
{
    public class IndexModel : PageModel
    {
        private readonly RazorPagesMovie.Data.RazorPagesMovieContext
_context;

        public IndexModel(RazorPagesMovie.Data.RazorPagesMovieContext
context)
        {
            _context = context;
        }
```

```
        public IList<Movie> Movie { get;set; } = default!;

        public async Task OnGetAsync()
        {
            Movie = await _context.Movie.ToListAsync();
        }
    }
}
```

Razor Pages are derived from PageModel. By convention, the `PageModel` derived class is named `PageNameModel`. For example, the Index page is named `IndexModel`.

The constructor uses dependency injection to add the `RazorPagesMovieContext` to the page:

C#

```
public class IndexModel : PageModel
{
    private readonly RazorPagesMovie.Data.RazorPagesMovieContext _context;

    public IndexModel(RazorPagesMovie.Data.RazorPagesMovieContext context)
    {
        _context = context;
    }
```

See Asynchronous code for more information on asynchronous programming with Entity Framework.

When a `GET` request is made for the page, the `OnGetAsync` method returns a list of movies to the Razor Page. On a Razor Page, `OnGetAsync` or `OnGet` is called to initialize the state of the page. In this case, `OnGetAsync` gets a list of movies and displays them.

When `OnGet` returns `void` or `OnGetAsync` returns `Task`, no return statement is used. For example, examine the Privacy Page:

C#

```
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace RazorPagesMovie.Pages
{
    public class PrivacyModel : PageModel
    {
        private readonly ILogger<PrivacyModel> _logger;
```

```
        public PrivacyModel(ILogger<PrivacyModel> logger)
        {
            _logger = logger;
        }

        public void OnGet()
        {
        }
    }

}
```

When the return type is IActionResult or `Task<IActionResult>`, a return statement must be provided. For example, the `Pages/Movies/Create.cshtml.cs OnPostAsync` method:

C#

```
public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    _context.Movie.Add(Movie);
    await _context.SaveChangesAsync();

    return RedirectToPage("./Index");
}
```

Examine the `Pages/Movies/Index.cshtml` Razor Page:

CSHTML

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-page="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Title)
```

```
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].ReleaseDate)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Genre)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Price)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
@foreach (var item in Model.Movie) {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.Title)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.ReleaseDate)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Genre)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Price)
            </td>
            <td>
                <a asp-page="./Edit" asp-route-id="@item.Id">Edit</a> |
                <a asp-page="./Details" asp-route-id="@item.Id">Details</a>
|
                <a asp-page="./Delete" asp-route-id="@item.Id">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

Razor can transition from HTML into C# or into Razor-specific markup. When an `@` symbol is followed by a Razor reserved keyword, it transitions into Razor-specific markup, otherwise it transitions into C#.

The @page directive

The `@page` Razor directive makes the file an MVC action, which means that it can handle requests. `@page` must be the first Razor directive on a page. `@page` and `@model` are examples of transitioning into Razor-specific markup. See Razor syntax for more information.

The @model directive

```cshtml
@page
@model RazorPagesMovie.Pages.Movies.IndexModel
```

The `@model` directive specifies the type of the model passed to the Razor Page. In the preceding example, the `@model` line makes the `PageModel` derived class available to the Razor Page. The model is used in the `@Html.DisplayNameFor` and `@Html.DisplayFor` HTML Helpers on the page.

Examine the lambda expression used in the following HTML Helper:

```cshtml
@Html.DisplayNameFor(model => model.Movie[0].Title)
```

The DisplayNameFor HTML Helper inspects the `Title` property referenced in the lambda expression to determine the display name. The lambda expression is inspected rather than evaluated. That means there is no access violation when `model`, `model.Movie`, or `model.Movie[0]` is `null` or empty. When the lambda expression is evaluated, for example, with `@Html.DisplayFor(modelItem => item.Title)`, the model's property values are evaluated.

The layout page

Select the menu links **RazorPagesMovie**, **Home**, and **Privacy**. Each page shows the same menu layout. The menu layout is implemented in the `Pages/Shared/_Layout.cshtml` file.

Open and examine the `Pages/Shared/_Layout.cshtml` file.

Layout templates allow the HTML container layout to be:

- Specified in one place.
- Applied in multiple pages in the site.

Find the `@RenderBody()` line. `RenderBody` is a placeholder where all the page-specific views show up, *wrapped* in the layout page. For example, select the **Privacy** link and the `Pages/Privacy.cshtml` view is rendered inside the `RenderBody` method.

ViewData and layout

Consider the following markup from the `Pages/Movies/Index.cshtml` file:

CSHTML

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
}
```

The preceding highlighted markup is an example of Razor transitioning into C#. The `{` and `}` characters enclose a block of C# code.

The `PageModel` base class contains a `ViewData` dictionary property that can be used to pass data to a View. Objects are added to the `ViewData` dictionary using a ***key value*** pattern. In the preceding sample, the `Title` property is added to the `ViewData` dictionary.

The `Title` property is used in the `Pages/Shared/_Layout.cshtml` file. The following markup shows the first few lines of the `_Layout.cshtml` file.

CSHTML

```
<!DOCTYPE html>
<html lang="en">
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - RazorPagesMovie</title>
    <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.css" />
    <link rel="stylesheet" href="~/css/site.css" asp-append-version="true"
/>
    <link rel="stylesheet" href="~/RazorPagesMovie.styles.css" asp-append-
version="true" />
```

Update the layout

1. Change the `<title>` element in the `Pages/Shared/_Layout.cshtml` file to display **Movie** rather than **RazorPagesMovie**.

   CSHTML

   ```
   <!DOCTYPE html>
   <html lang="en">
   <head>
   ```

```
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-
scale=1.0" />
    <title>@ViewData["Title"] - Movie</title>
```

2. Find the following anchor element in the `Pages/Shared/_Layout.cshtml` file.

```
CSHTML

<a class="navbar-brand" asp-area="" asp-
page="/Index">RazorPagesMovie</a>
```

3. Replace the preceding element with the following markup:

```
CSHTML

<a class="navbar-brand" asp-page="/Movies/Index">RpMovie</a>
```

   The preceding anchor element is a Tag Helper. In this case, it's the Anchor Tag Helper. The `asp-page="/Movies/Index"` Tag Helper attribute and value creates a link to the `/Movies/Index` Razor Page. The `asp-area` attribute value is empty, so the area isn't used in the link. See Areas for more information.

4. Save the changes and test the app by selecting the **RpMovie** link. See the _Layout.cshtml file in GitHub if you have any problems.

5. Test the **Home**, **RpMovie**, **Create**, **Edit**, and **Delete** links. Each page sets the title, which you can see in the browser tab. When you bookmark a page, the title is used for the bookmark.

> **Note**
>
> You may not be able to enter decimal commas in the `Price` field. To support jQuery validation for non-English locales that use a comma (",") for a decimal point, and non US-English date formats, you must take steps to globalize the app. See this GitHub issue 4076 for instructions on adding decimal comma.

The `Layout` property is set in the `Pages/_ViewStart.cshtml` file:

```
CSHTML

@{
    Layout = "_Layout";
```

```
}
```

The preceding markup sets the layout file to `Pages/Shared/_Layout.cshtml` for all Razor files under the *Pages* folder. See Layout for more information.

The Create page model

Examine the `Pages/Movies/Create.cshtml.cs` page model:

C#

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.AspNetCore.Mvc.Rendering;
using RazorPagesMovie.Data;
using RazorPagesMovie.Models;

namespace RazorPagesMovie.Pages.Movies
{
    public class CreateModel : PageModel
    {
        private readonly RazorPagesMovie.Data.RazorPagesMovieContext
_context;

        public CreateModel(RazorPagesMovie.Data.RazorPagesMovieContext
context)
        {
            _context = context;
        }

        public IActionResult OnGet()
        {
            return Page();
        }

        [BindProperty]
        public Movie Movie { get; set; } = default!;

        // To protect from overposting attacks, see
https://aka.ms/RazorPagesCRUD
        public async Task<IActionResult> OnPostAsync()
        {
            if (!ModelState.IsValid)
            {
                return Page();
            }
```

```
            _context.Movie.Add(Movie);
            await _context.SaveChangesAsync();

            return RedirectToPage("./Index");
        }
    }
}
```

The `OnGet` method initializes any state needed for the page. The Create page doesn't have any state to initialize, so `Page` is returned. Later in the tutorial, an example of `OnGet` initializing state is shown. The `Page` method creates a `PageResult` object that renders the `Create.cshtml` page.

The `Movie` property uses the [BindProperty] attribute to opt-in to model binding. When the Create form posts the form values, the ASP.NET Core runtime binds the posted values to the `Movie` model.

The `OnPostAsync` method is run when the page posts form data:

C#

```
public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    _context.Movie.Add(Movie);
    await _context.SaveChangesAsync();

    return RedirectToPage("./Index");
}
```

If there are any model errors, the form is redisplayed, along with any form data posted. Most model errors can be caught on the client-side before the form is posted. An example of a model error is posting a value for the date field that cannot be converted to a date. Client-side validation and model validation are discussed later in the tutorial.

If there are no model errors:

- The data is saved.
- The browser is redirected to the Index page.

The Create Razor Page

Examine the `Pages/Movies/Create.cshtml` Razor Page file:

CSHTML

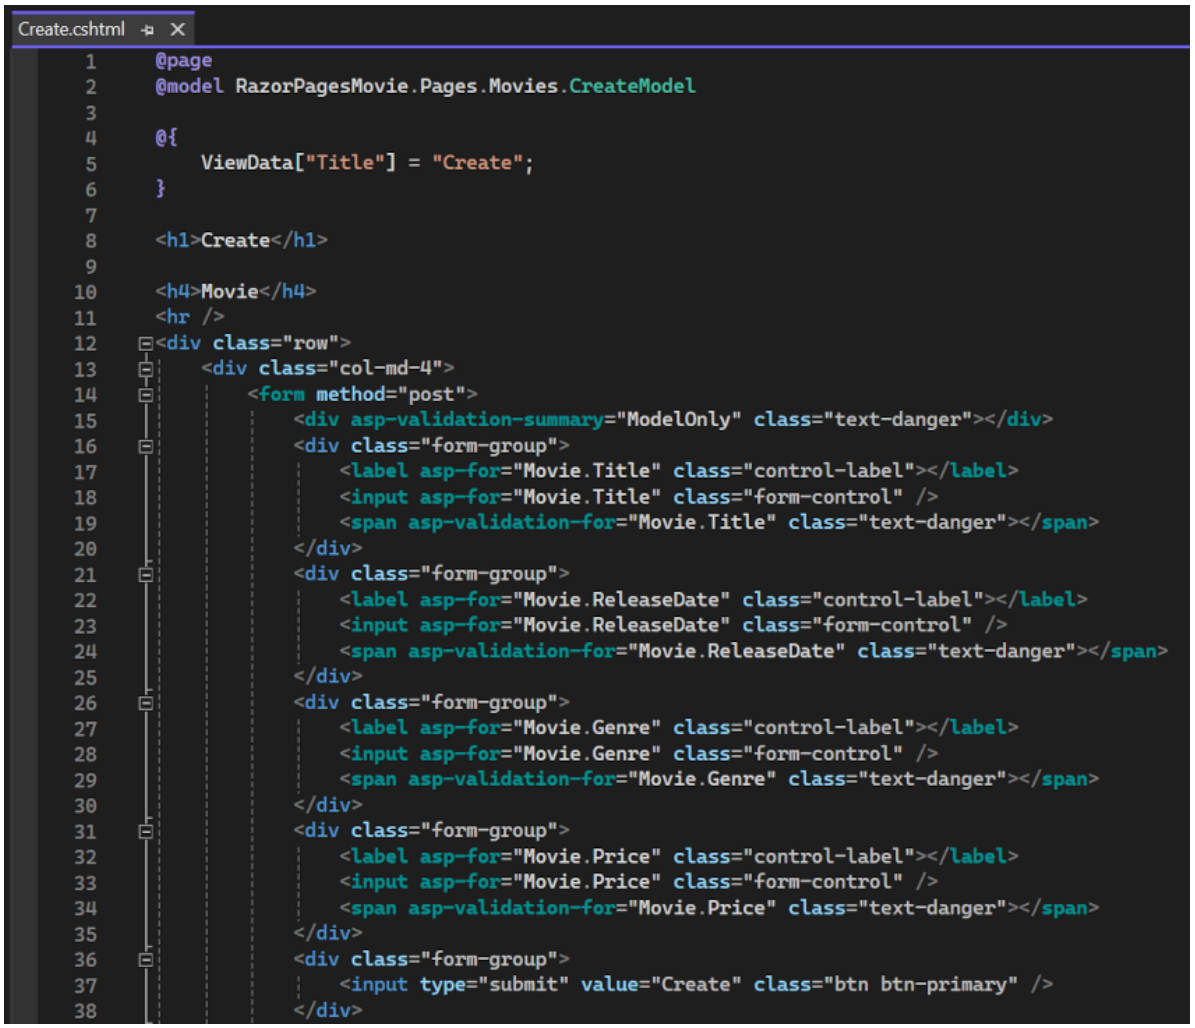
```
@page
@model RazorPagesMovie.Pages.Movies.CreateModel

@{
    ViewData["Title"] = "Create";
}

<h1>Create</h1>

<h4>Movie</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger">
</div>
            <div class="form-group">
                <label asp-for="Movie.Title" class="control-label"></label>
                <input asp-for="Movie.Title" class="form-control" />
                <span asp-validation-for="Movie.Title" class="text-danger">
</span>
            </div>
            <div class="form-group">
                <label asp-for="Movie.ReleaseDate" class="control-label">
</label>
                <input asp-for="Movie.ReleaseDate" class="form-control" />
                <span asp-validation-for="Movie.ReleaseDate" class="text-
danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Movie.Genre" class="control-label"></label>
                <input asp-for="Movie.Genre" class="form-control" />
                <span asp-validation-for="Movie.Genre" class="text-danger">
</span>
            </div>
            <div class="form-group">
                <label asp-for="Movie.Price" class="control-label"></label>
                <input asp-for="Movie.Price" class="form-control" />
                <span asp-validation-for="Movie.Price" class="text-danger">
</span>
            </div>
            <div class="form-group">
                <input type="submit" value="Create" class="btn btn-primary"
/>
            </div>
        </form>
    </div>
</div>

<div>
```



```
    <a asp-page="Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

Visual Studio

Visual Studio displays the following tags in a distinctive bold font used for Tag Helpers:

- `<form method="post">`
- `<div asp-validation-summary="ModelOnly" class="text-danger"></div>`
- `<label asp-for="Movie.Title" class="control-label"></label>`
- `<input asp-for="Movie.Title" class="form-control" />`
- `<span asp-validation-for="Movie.Title" class="text-danger"></span>`

The `<form method="post">` element is a Form Tag Helper. The Form Tag Helper automatically includes an antiforgery token.

The scaffolding engine creates Razor markup for each field in the model, except the ID, similar to the following:

CSHTML

```
<div asp-validation-summary="ModelOnly" class="text-danger"></div>
<div class="form-group">
    <label asp-for="Movie.Title" class="control-label"></label>
    <input asp-for="Movie.Title" class="form-control" />
    <span asp-validation-for="Movie.Title" class="text-danger"></span>
</div>
```

The Validation Tag Helpers (`<div asp-validation-summary` and `<span asp-validation-for`) display validation errors. Validation is covered in more detail later in this series.

The Label Tag Helper (`<label asp-for="Movie.Title" class="control-label"></label>`) generates the label caption and `[for]` attribute for the `Title` property.

The Input Tag Helper (`<input asp-for="Movie.Title" class="form-control">`) uses the DataAnnotations attributes and produces HTML attributes needed for jQuery Validation on the client-side.

For more information on Tag Helpers such as `<form method="post">`, see Tag Helpers in ASP.NET Core.

By Joe Audette

The `RazorPagesMovieContext` object handles the task of connecting to the database and mapping `Movie` objects to database records. The database context is registered with the Dependency Injection container in `Program.cs`:

Visual Studio

C#

```
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;
using RazorPagesMovie.Data;
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.AddRazorPages();
builder.Services.AddDbContext<RazorPagesMovieContext>(options =>

options.UseSqlServer(builder.Configuration.GetConnectionString("RazorPag
esMovieContext") ?? throw new InvalidOperationException("Connection
string 'RazorPagesMovieContext' not found.")));
```

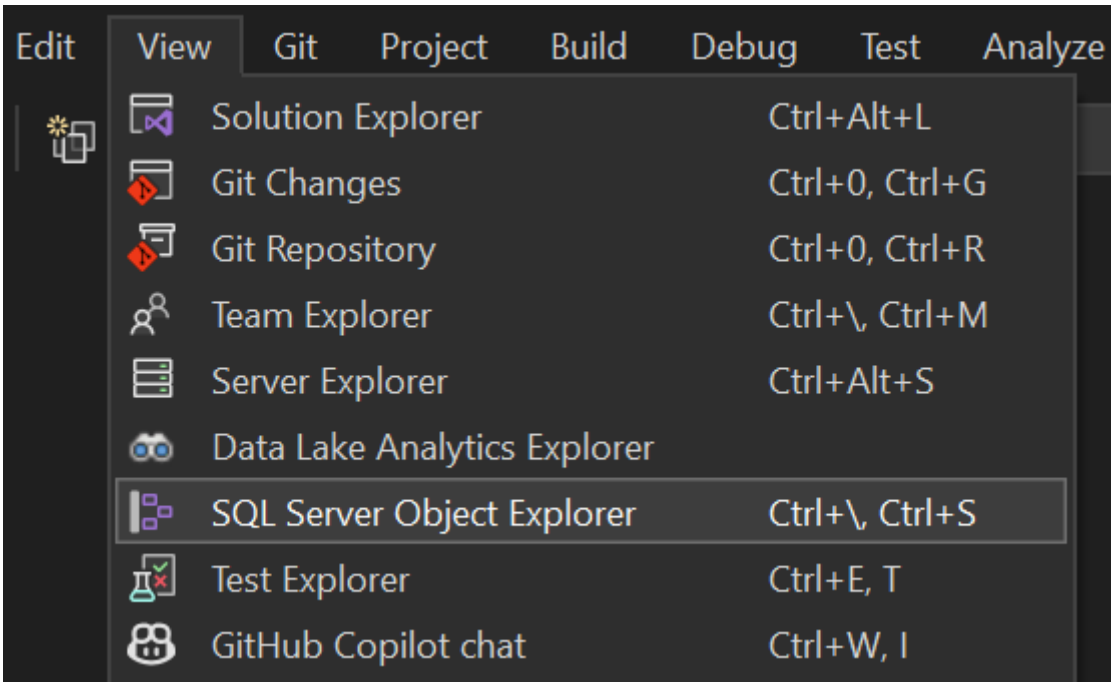
The ASP.NET Core Configuration system reads the `ConnectionString` key. For local development, configuration gets the connection string from the `appsettings.json` file.

Visual Studio

The generated connection string is similar to the following JSON:

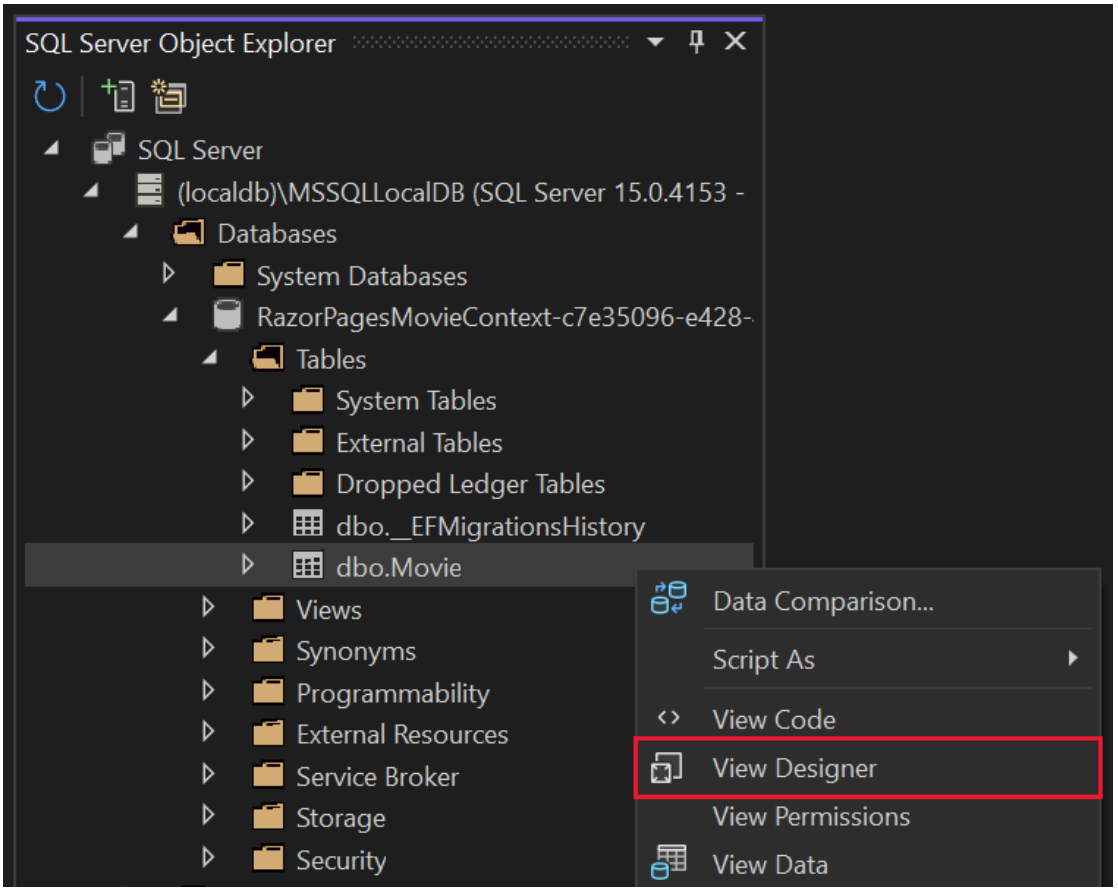
JSON

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft.AspNetCore": "Warning"
    }
  },
  "AllowedHosts": "*",
  "ConnectionStrings": {
    "RazorPagesMovieContext": "Server=
(localdb)\\mssqllocaldb;Database=RazorPagesMovieContext-f2e0482c-952d-
4b1c-afe9-
a1a3dfe52e55;Trusted_Connection=True;MultipleActiveResultSets=true"
  }
}
```

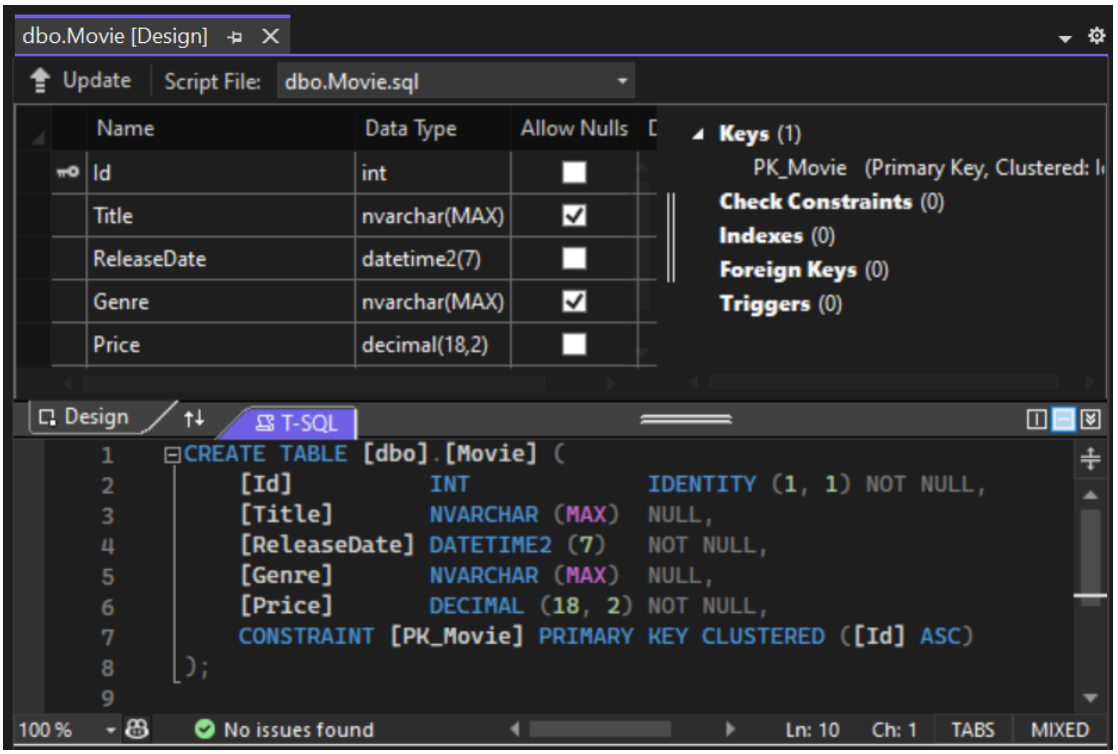


> ⚠ **Warning**
>
> This article uses a local database that doesn't require the user to be authenticated. Production apps should use the most secure authentication flow available. For more information on authentication for deployed test and production apps, see Secure authentication flows.

Visual Studio

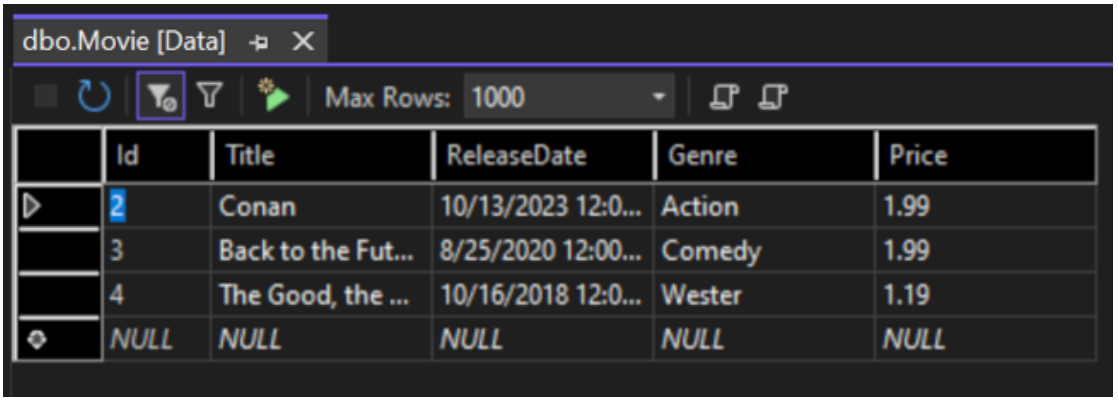


SQL Server Express LocalDB



LocalDB is a lightweight version of the SQL Server Express database engine that's targeted for program development. LocalDB starts on demand and runs in user mode, so there's no complex configuration. By default, LocalDB database creates `*.mdf` files in the `C:\Users\<user>\` directory.

1. From the **View** menu, open **SQL Server Object Explorer** (SSOX).



2. Right-click on the `Movie` table and select **View Designer**:

Note the key icon next to `ID`. By default, EF creates a property named `ID` for the primary key.

3. Right-click on the `Movie` table and select **View Data**:

Seed the database

Create a new class named `SeedData` in the *Models* folder with the following code:

C#

```
using Microsoft.EntityFrameworkCore;
using RazorPagesMovie.Data;

namespace RazorPagesMovie.Models;

public static class SeedData
```

```
{
    public static void Initialize(IServiceProvider serviceProvider)
    {
        using (var context = new RazorPagesMovieContext(
            serviceProvider.GetRequiredService<
                DbContextOptions<RazorPagesMovieContext>>()))
        {
            if (context == null || context.Movie == null)
            {
                throw new ArgumentNullException("Null
RazorPagesMovieContext");
            }

            // Look for any movies.
            if (context.Movie.Any())
            {
                return;   // DB has been seeded
            }

            context.Movie.AddRange(
                new Movie
                {
                    Title = "When Harry Met Sally",
                    ReleaseDate = DateTime.Parse("1989-2-12"),
                    Genre = "Romantic Comedy",
                    Price = 7.99M
                },

                new Movie
                {
                    Title = "Ghostbusters ",
                    ReleaseDate = DateTime.Parse("1984-3-13"),
                    Genre = "Comedy",
                    Price = 8.99M
                },

                new Movie
                {
                    Title = "Ghostbusters 2",
                    ReleaseDate = DateTime.Parse("1986-2-23"),
                    Genre = "Comedy",
                    Price = 9.99M
                },

                new Movie
                {
                    Title = "Rio Bravo",
                    ReleaseDate = DateTime.Parse("1959-4-15"),
                    Genre = "Western",
                    Price = 3.99M
                }
            );
            context.SaveChanges();
        }
```

```
    }
}
```

If there are any movies in the database, the seed initializer returns and no movies are added.

C#

```
if (context.Movie.Any())
{
    return;
}
```

Add the seed initializer

Update the `Program.cs` with the following highlighted code:

Visual Studio

C#

```
using Microsoft.EntityFrameworkCore;
using RazorPagesMovie.Data;
using RazorPagesMovie.Models;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddDbContext<RazorPagesMovieContext>(options =>

options.UseSqlServer(builder.Configuration.GetConnectionString("RazorPag
esMovieContext") ?? throw new InvalidOperationException("Connection
string 'RazorPagesMovieContext' not found.")));

var app = builder.Build();

using (var scope = app.Services.CreateScope())
{
    var services = scope.ServiceProvider;

    SeedData.Initialize(services);
}

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}
```

```
app.UseHttpsRedirection();

app.UseRouting();

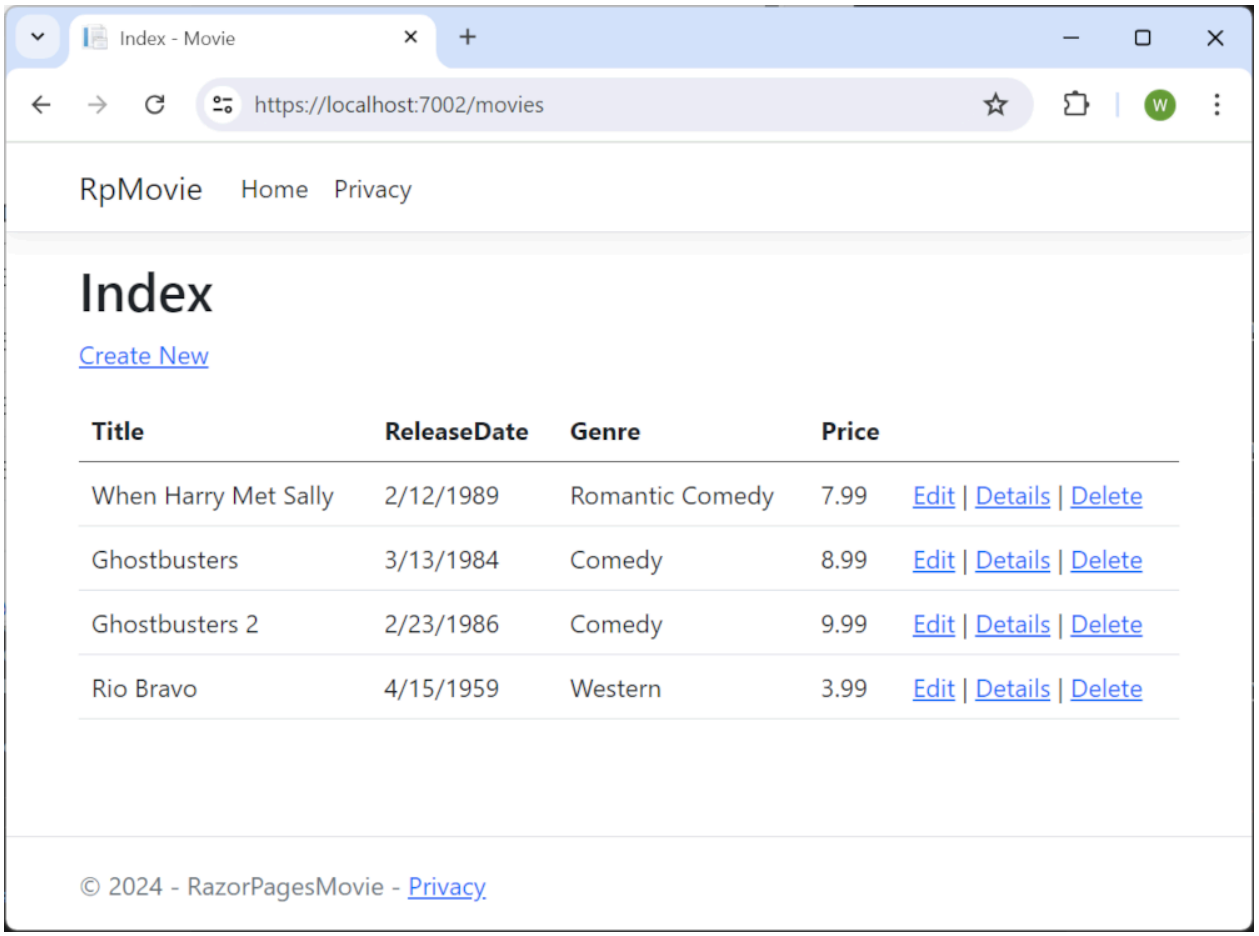
app.UseAuthorization();

app.MapStaticAssets();
app.MapRazorPages();

app.Run();
```

In the previous code, `Program.cs` has been modified to do the following:

- Get a database context instance from the dependency injection (DI) container.
- Call the `seedData.Initialize` method, passing to it the database context instance.
- Dispose the context when the seed method completes. The using statement ensures the context is disposed.



The following exception occurs when `Update-Database` has not been run:

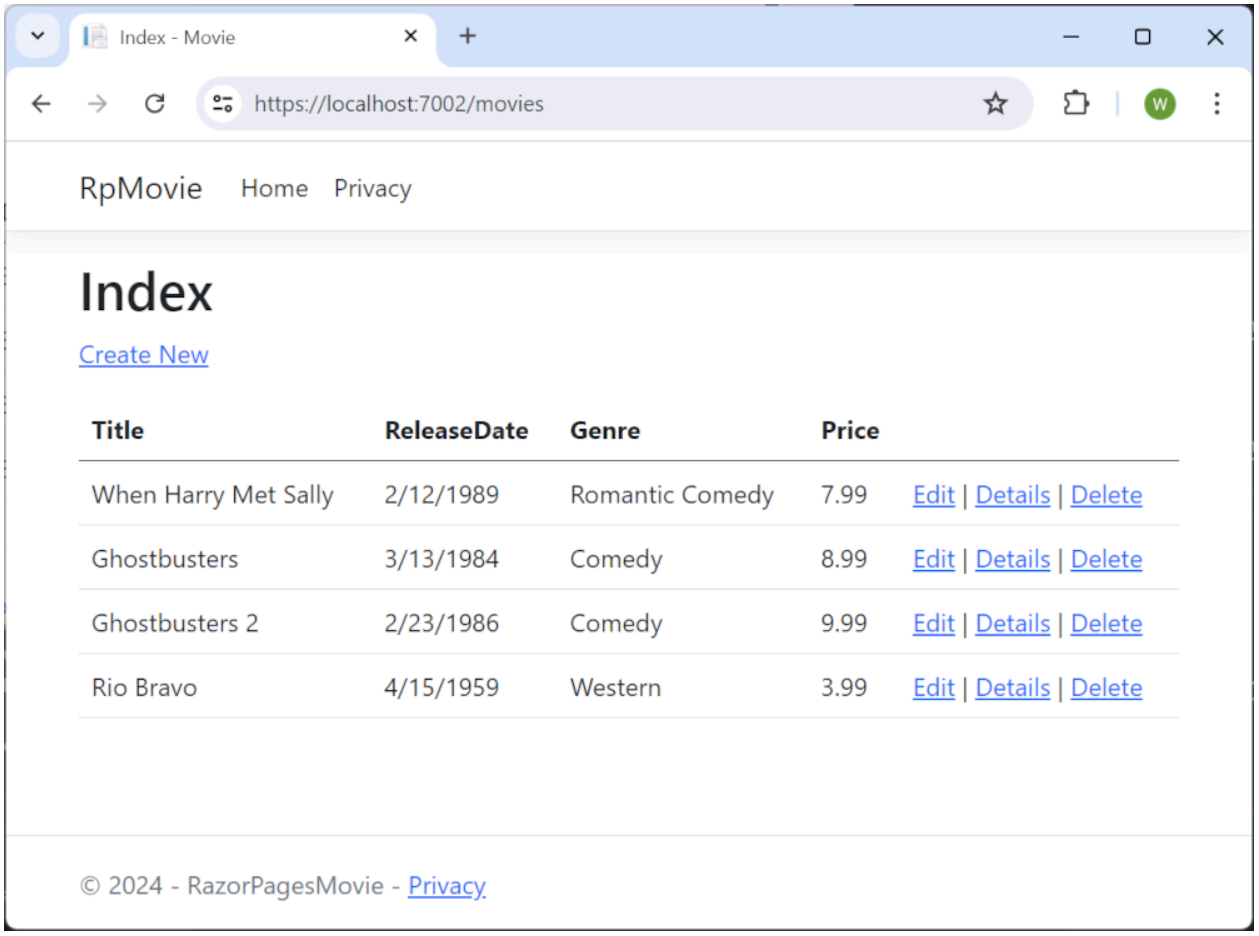
> `SqlException: Cannot open database "RazorPagesMovieContext-" requested by the login. The login failed.` `Login failed for user 'user name'.`

Test the app

Delete all the records in the database so the seed method will run. Stop and start the app to seed the database. If the database isn't seeded, put a breakpoint on `if (context.Movie.Any())` and step through the code.

The app shows the seeded data:

Next steps



Previous: Scaffolded Razor Pages
Next: Update the pages

Part 5, update the generated pages in an ASP.NET Core app

Article • 06/23/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

The scaffolded movie app has a good start, but the presentation isn't ideal. **ReleaseDate** should be two words, **Release Date**.

Update the model

Update `Models/Movie.cs` with the following highlighted code:

C#

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace RazorPagesMovie.Models;

public class Movie
{
    public int Id { get; set; }
    public string Title { get; set; } = string.Empty;

    [Display(Name = "Release Date")]
    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }
    public string Genre { get; set; } = string.Empty;

    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }
}
```

In the previous code:

- The `[Column(TypeName = "decimal(18, 2)")]` data annotation enables Entity Framework Core to correctly map `Price` to currency in the database. For more information, see Data Types.
- The [Display] attribute specifies the display name of a field. In the preceding code, `Release Date` instead of `ReleaseDate`.
- The [DataType] attribute specifies the type of the data (`Date`). The time information stored in the field isn't displayed.

DataAnnotations is covered in the next tutorial.

Browse to *Pages/Movies* and hover over an **Edit** link to see the target URL.

The **Edit**, **Details**, and **Delete** links are generated by the Anchor Tag Helper in the `Pages/Movies/Index.cshtml` file.

CSHTML

```
@foreach (var item in Model.Movie) {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.Title)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.ReleaseDate)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Genre)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Price)
            </td>
            <td>
                <a asp-page="./Edit" asp-route-id="@item.Id">Edit</a> |
                <a asp-page="./Details" asp-route-id="@item.Id">Details</a>
|
                <a asp-page="./Delete" asp-route-id="@item.Id">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

Tag Helpers enable server-side code to participate in creating and rendering HTML elements in Razor files.

In the preceding code, the Anchor Tag Helper dynamically generates the HTML `href` attribute value from the Razor Page (the route is relative), the `asp-page`, and the route identifier (`asp-route-id`). For more information, see URL generation for Pages.

Use **View Source** from a browser to examine the generated markup. A portion of the generated HTML is shown below:

HTML

```
<td>
  <a href="/Movies/Edit?id=1">Edit</a> |
  <a href="/Movies/Details?id=1">Details</a> |
  <a href="/Movies/Delete?id=1">Delete</a>
</td>
```

The dynamically generated links pass the movie ID with a query string. For example, the `?id=1` in `https://localhost:5001/Movies/Details?id=1`.

Add route template

Update the Edit, Details, and Delete Razor Pages to use the `{id:int}` route template. Change the page directive for each of these pages from `@page` to `@page "{id:int}"`. Run the app and then view source.

The generated HTML adds the ID to the path portion of the URL:

HTML

```
<td>
  <a href="/Movies/Edit/1">Edit</a> |
  <a href="/Movies/Details/1">Details</a> |
  <a href="/Movies/Delete/1">Delete</a>
</td>
```

A request to the page with the `{id:int}` route template that does **not** include the integer returns an HTTP 404 (not found) error. For example, `https://localhost:5001/Movies/Details` returns a 404 error. To make the ID optional, append `?` to the route constraint:

CSHTML

```
@page "{id:int?}"
```

Test the behavior of `@page "{id:int?}"`:

1. Set the page directive in `Pages/Movies/Details.cshtml` to `@page "{id:int?}"`.
2. Set a break point in `public async Task<IActionResult> OnGetAsync(int? id)`, in `Pages/Movies/Details.cshtml.cs`.
3. Navigate to `https://localhost:5001/Movies/Details/`.

With the `@page "{id:int}"` directive, the break point is never hit. The routing engine returns HTTP 404. Using `@page "{id:int?}"`, the `OnGetAsync` method returns `NotFound` (HTTP 404):

C#

```
public async Task<IActionResult> OnGetAsync(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var movie = await _context.Movie.FirstOrDefaultAsync(m => m.Id == id);
    if (movie == null)
    {
        return NotFound();
    }
    else
    {
        Movie = movie;
    }
    return Page();
}
```

Review concurrency exception handling

Review the `OnPostAsync` method in the `Pages/Movies/Edit.cshtml.cs` file:

C#

```
public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }
```

```
    _context.Attach(Movie).State = EntityState.Modified;

    try
    {
        await _context.SaveChangesAsync();
    }
    catch (DbUpdateConcurrencyException)
    {
        if (!MovieExists(Movie.Id))
        {
            return NotFound();
        }
        else
        {
            throw;
        }
    }

    return RedirectToPage("./Index");
}

private bool MovieExists(int id)
{
    return _context.Movie.Any(e => e.Id == id);
}
```

The previous code detects concurrency exceptions when one client deletes the movie and the other client posts changes to the movie.

To test the `catch` block:

1. Set a breakpoint on `catch (DbUpdateConcurrencyException)`.
2. Select **Edit** for a movie, make changes, but don't enter **Save**.
3. In another browser window, select the **Delete** link for the same movie, and then delete the movie.
4. In the previous browser window, post changes to the movie.

Production code may want to detect concurrency conflicts. See Handle concurrency conflicts for more information.

Posting and binding review

Examine the `Pages/Movies/Edit.cshtml.cs` file:

C#

```
public class EditModel : PageModel
{
```

```
    private readonly RazorPagesMovie.Data.RazorPagesMovieContext _context;

    public EditModel(RazorPagesMovie.Data.RazorPagesMovieContext context)
    {
        _context = context;
    }

    [BindProperty]
    public Movie Movie { get; set; } = default!;

    public async Task<IActionResult> OnGetAsync(int? id)
    {
        if (id == null)
        {
            return NotFound();
        }

        var movie =  await _context.Movie.FirstOrDefaultAsync(m => m.Id ==
id);
        if (movie == null)
        {
            return NotFound();
        }
        Movie = movie;
        return Page();
    }

    // To protect from overposting attacks, enable the specific properties
you want to bind to.
    // For more details, see https://aka.ms/RazorPagesCRUD.
    public async Task<IActionResult> OnPostAsync()
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }

        _context.Attach(Movie).State = EntityState.Modified;

        try
        {
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateConcurrencyException)
        {
            if (!MovieExists(Movie.Id))
            {
                return NotFound();
            }
            else
            {
                throw;
            }
        }
```

```
            return RedirectToPage("./Index");
        }

        private bool MovieExists(int id)
        {
            return _context.Movie.Any(e => e.Id == id);
        }
```

When an HTTP GET request is made to the Movies/Edit page, for example, `https://localhost:5001/Movies/Edit/3`:

- The `OnGetAsync` method fetches the movie from the database and returns the `Page` method.
- The `Page` method renders the `Pages/Movies/Edit.cshtml` Razor Page. The `Pages/Movies/Edit.cshtml` file contains the model directive `@model RazorPagesMovie.Pages.Movies.EditModel`, which makes the movie model available on the page.
- The Edit form is displayed with the values from the movie.

When the Movies/Edit page is posted:

- The form values on the page are bound to the `Movie` property. The `[BindProperty]` attribute enables Model binding.

  C#

  ```
  [BindProperty]
  public Movie Movie { get; set; }
  ```

- If there are errors in the model state, for example, `ReleaseDate` cannot be converted to a date, the form is redisplayed with the submitted values.
- If there are no model errors, the movie is saved.

The HTTP GET methods in the Index, Create, and Delete Razor pages follow a similar pattern. The HTTP POST `OnPostAsync` method in the Create Razor Page follows a similar pattern to the `OnPostAsync` method in the Edit Razor Page.

Part 6, add search to ASP.NET Core Razor Pages

Article • 06/23/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Rick Anderson

In the following sections, searching movies by *genre* or *name* is added.

Add the following highlighted code to `Pages/Movies/Index.cshtml.cs`:

C#

```
public class IndexModel : PageModel
{
    private readonly RazorPagesMovie.Data.RazorPagesMovieContext _context;

    public IndexModel(RazorPagesMovie.Data.RazorPagesMovieContext context)
    {
        _context = context;
    }

    public IList<Movie> Movie { get;set; }  = default!;

    [BindProperty(SupportsGet = true)]
    public string? SearchString { get; set; }

    public SelectList? Genres { get; set; }

    [BindProperty(SupportsGet = true)]
    public string? MovieGenre { get; set; }
```

In the previous code:

- `SearchString`: Contains the text users enter in the search text box. `SearchString` has the [BindProperty] attribute. `[BindProperty]` binds form values and query

strings with the same name as the property. `[BindProperty(SupportsGet = true)]` is required for binding on HTTP GET requests.

- `Genres`: Contains the list of genres. `Genres` allows the user to select a genre from the list. `SelectList` requires `using Microsoft.AspNetCore.Mvc.Rendering;`
- `MovieGenre`: Contains the specific genre the user selects. For example, "Western".
- `Genres` and `MovieGenre` are used later in this tutorial.

> ⚠ **Warning**
>
> For security reasons, you must opt in to binding `GET` request data to page model properties. Verify user input before mapping it to properties. Opting into `GET` binding is useful when addressing scenarios that rely on query string or route values.
>
> To bind a property on `GET` requests, set the [BindProperty] attribute's `SupportsGet` property to `true`:
>
> C#
>
> ```
> [BindProperty(SupportsGet = true)]
> ```
>
> For more information, see ASP.NET Core Community Standup: Bind on GET discussion (YouTube).

Update the `Movies/Index` page's `OnGetAsync` method with the following code:

C#

```
public async Task OnGetAsync()
{
    var movies = from m in _context.Movie
                 select m;
    if (!string.IsNullOrEmpty(SearchString))
    {
        movies = movies.Where(s => s.Title.Contains(SearchString));
    }

    Movie = await movies.ToListAsync();
}
```

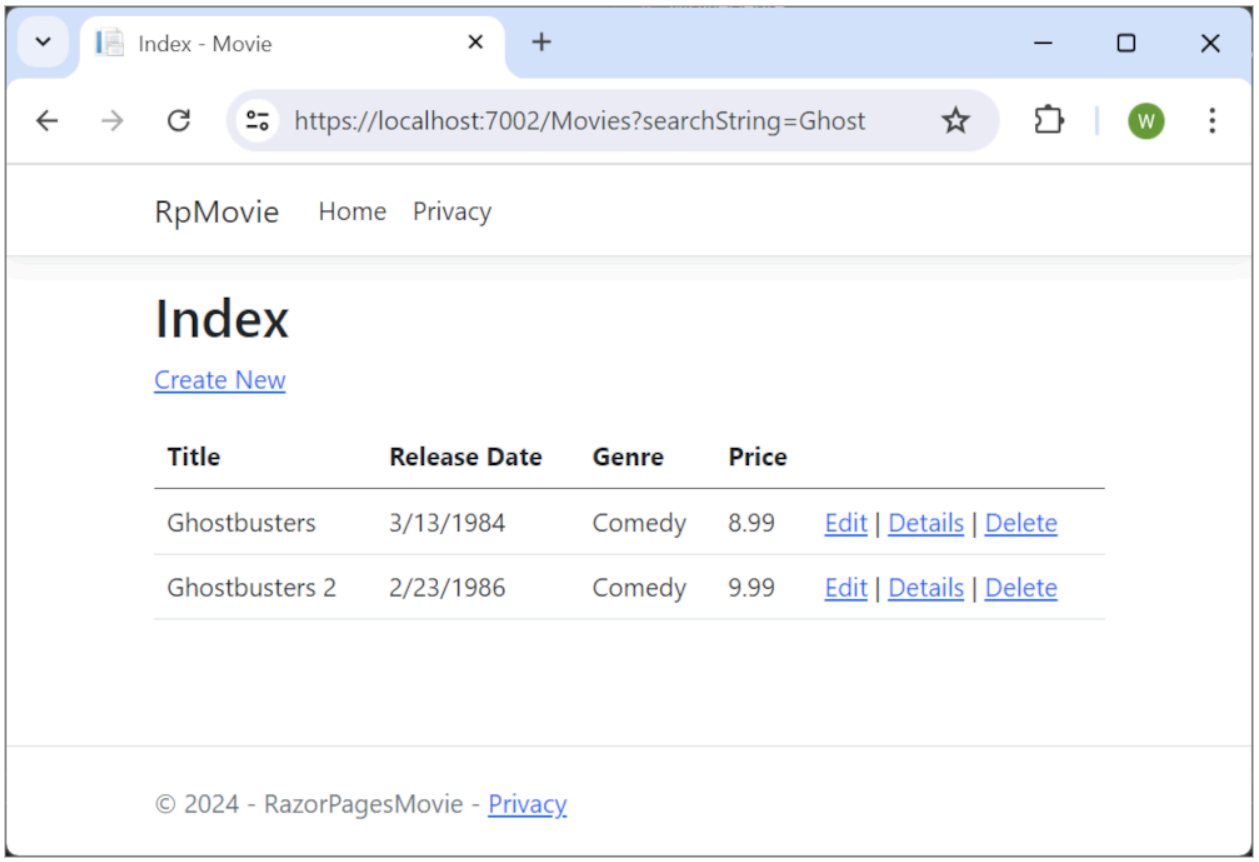
The first line of the `OnGetAsync` method creates a LINQ query to select the movies:

C#

```
var movies = from m in _context.Movie
             select m;
```

The query is only ***defined*** at this point, it has ***not*** been run against the database.

If the `SearchString` property is not `null` or empty, the movies query is modified to filter on the search string:



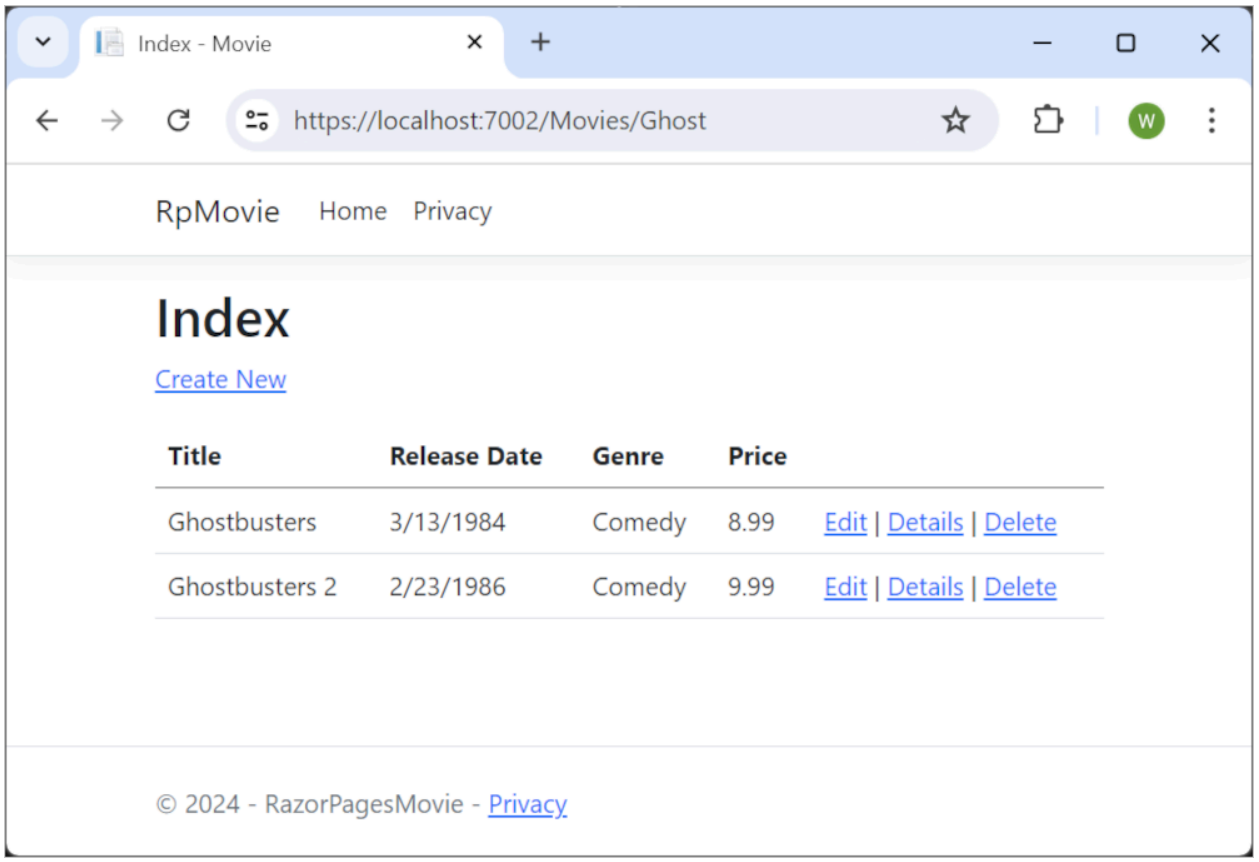
C#

```
if (!string.IsNullOrEmpty(SearchString))
{
    movies = movies.Where(s => s.Title.Contains(SearchString));
}
```

The `s => s.Title.Contains()` code is a Lambda Expression. Lambdas are used in method-based LINQ queries as arguments to standard query operator methods such as the Where method or `Contains`. LINQ queries are not executed when they're defined or when they're modified by calling a method, such as `Where`, `Contains`, or `OrderBy`. Rather, query execution is deferred. The evaluation of an expression is delayed until its realized value is iterated over or the `ToListAsync` method is called. See Query Execution for more information.

> ⓘ Note
>
> The Contains method is run on the database, not in the C# code. The case sensitivity on the query depends on the database and the collation. On SQL Server, `Contains` maps to SQL LIKE, which is case insensitive. SQLite with the default collation is a mixture of case sensitive and case ***IN***sensitive, depending on the query. For information on making case insensitive SQLite queries, see the following:
>
> - How to use case-insensitive query with Sqlite provider? (dotnet/efcore #11414)
> - How to make a SQLite column case insensitive (dotnet/AspNetCore.Docs #22314)
> - Collations and Case Sensitivity

Navigate to the Movies page and append a query string such as `?searchString=Ghost` to the URL. For example, `https://localhost:5001/Movies?searchString=Ghost`. The filtered movies are displayed.



If the following route template is added to the Index page, the search string can be passed as a URL segment. For example, `https://localhost:5001/Movies/Ghost`.

CSHTML

```
@page "{searchString?}"
```

The preceding route constraint allows searching the title as route data (a URL segment) instead of as a query string value. The `?` in `"{searchString?}"` means this is an optional route parameter.

The ASP.NET Core runtime uses model binding to set the value of the `SearchString` property from the query string (`?searchString=Ghost`) or route data (`https://localhost:5001/Movies/Ghost`). Model binding is ***not*** case sensitive.

However, users cannot be expected to modify the URL to search for a movie. In this step, UI is added to filter movies. If you added the route constraint `"{searchString?}"`, remove it.

Open the `Pages/Movies/Index.cshtml` file, and add the markup highlighted in the following code:

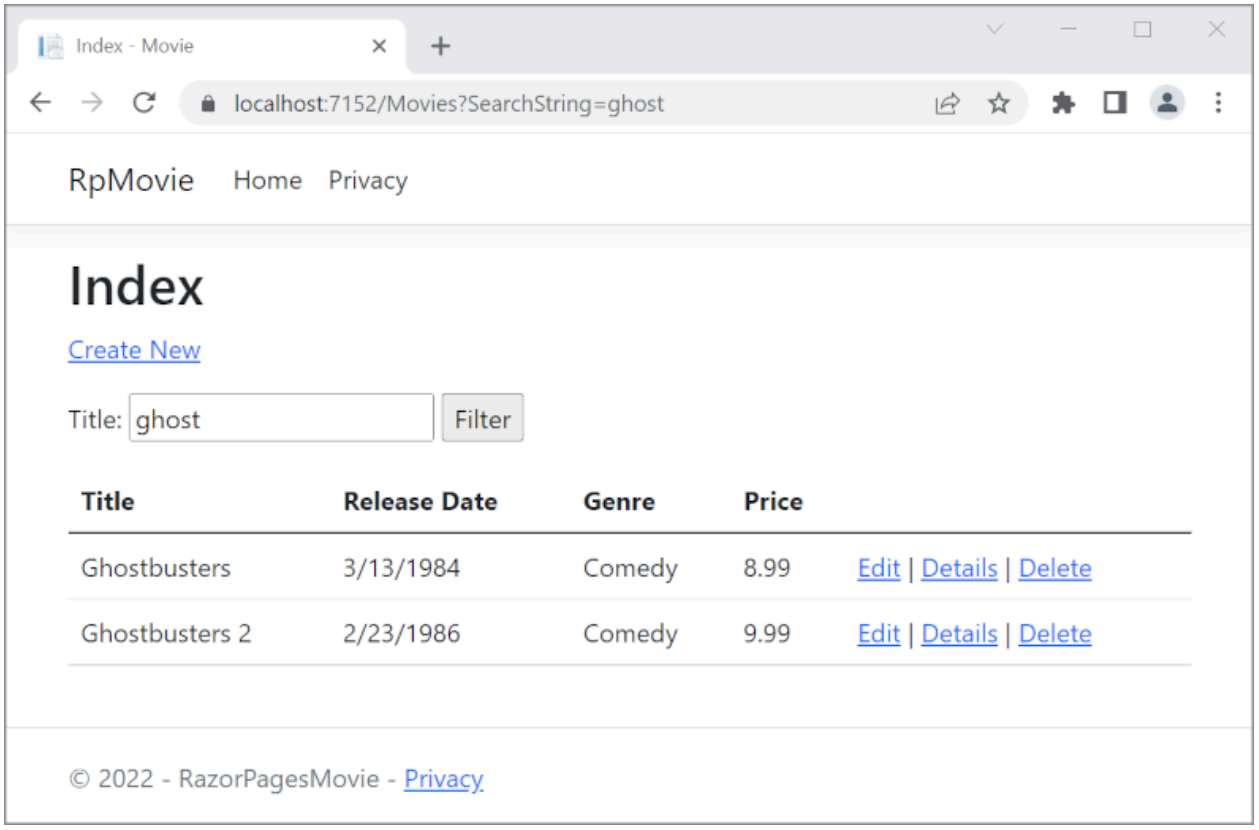
CSHTML

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-page="Create">Create New</a>
</p>
```



```
<form>
    <p>
        Title: <input type="text" asp-for="SearchString" />
        <input type="submit" value="Filter" />
    </p>
</form>
```

```
<table class="table">
    <thead>
```

The HTML `<form>` tag uses the following Tag Helpers:

- Form Tag Helper. When the form is submitted, the filter string is sent to the *Pages/Movies/Index* page via query string.
- Input Tag Helper

Save the changes and test the filter.

Search by genre

Update the `Movies/Index.cshtml.cs` page `OnGetAsync` method with the following code:

C#

```
public async Task OnGetAsync()
{
    // <snippet_search_linqQuery>
```

```
    IQueryable<string> genreQuery = from m in _context.Movie
                                    orderby m.Genre
                                    select m.Genre;
    // </snippet_search_linqQuery>

    var movies = from m in _context.Movie
                 select m;

    if (!string.IsNullOrEmpty(SearchString))
    {
        movies = movies.Where(s => s.Title.Contains(SearchString));
    }

    if (!string.IsNullOrEmpty(MovieGenre))
    {
        movies = movies.Where(x => x.Genre == MovieGenre);
    }

    // <snippet_search_selectList>
    Genres = new SelectList(await genreQuery.Distinct().ToListAsync());
    // </snippet_search_selectList>
    Movie = await movies.ToListAsync();
}
```

The following code is a LINQ query that retrieves all the genres from the database.

C#

```
IQueryable<string> genreQuery = from m in _context.Movie
                                orderby m.Genre
                                select m.Genre;
```

The `SelectList` of genres is created by projecting the distinct genres:

C#

```
Genres = new SelectList(await genreQuery.Distinct().ToListAsync());
```

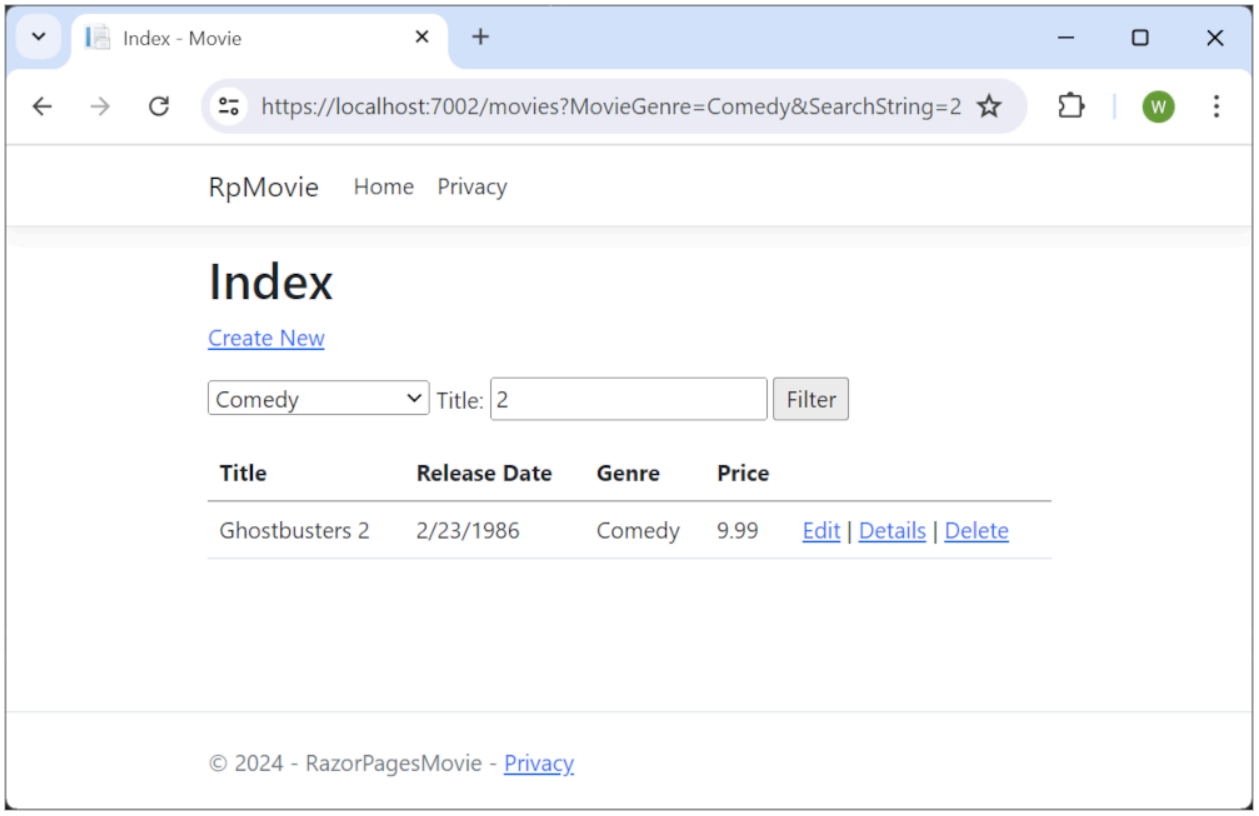
Add search by genre to the Razor Page

Update the `Index.cshtml` <form> element as highlighted in the following markup:

CSHTML

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
```



```
}

<h1>Index</h1>

<p>
    <a asp-page="Create">Create New</a>
</p>

<form>
    <p>
        <select asp-for="MovieGenre" asp-items="Model.Genres">
            <option value="">All</option>
        </select>
        Title: <input type="text" asp-for="SearchString" />
        <input type="submit" value="Filter" />
    </p>
</form>
```

Test the app by searching by genre, by movie title, and by both:

Next steps

Previous: Update the pages
Next: Add a new field

Part 7, add a new field to a Razor Page in ASP.NET Core

Article • 06/23/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Rick Anderson

In this section Entity Framework Core (EF Core) is used to define the database schema based on the app's model class:

- Add a new field to the model.
- Migrate the new field schema change to the database.

The EF Core approach allows for a more agile development process. The developer works on the app's data model directly while the database schema is created and then syncronized, all without the developer having to switch contexts to and from a datbase management tool. For an overview of Entity Framework Core and its benefits, see Entity Framework Core.

Using EF Code to automatically create and track a database:

- Adds an __EFMigrationsHistory table to the database to track whether the schema of the database is in sync with the model classes it was generated from.
- Throws an exception if the model classes aren't in sync with the database.

Automatic verification that the schema and model are in sync makes it easier to find inconsistent database code issues.

Adding a Rating Property to the Movie Model

1. Open the `Models/Movie.cs` file and add a `Rating` property:

```
C#
```

```
public class Movie
{
    public int Id { get; set; }
    public string Title { get; set; } = string.Empty;

    [Display(Name = "Release Date")]
    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }
    public string Genre { get; set; } = string.Empty;

    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }
    public string Rating { get; set; } = string.Empty;
}
```

2. Edit `Pages/Movies/Index.cshtml`, and add a `Rating` field:

CSHTML

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-page="Create">Create New</a>
</p>

<form>
    <p>
        <select asp-for="MovieGenre" asp-items="Model.Genres">
            <option value="">All</option>
        </select>
        Title: <input type="text" asp-for="SearchString" />
        <input type="submit" value="Filter" />
    </p>
</form>

<table class="table">

    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Title)
            </th>
            <th>
                @Html.DisplayNameFor(model =>
model.Movie[0].ReleaseDate)
```

```
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Genre)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Price)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Rating)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Movie)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.Title)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.ReleaseDate)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Genre)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Price)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Rating)
                </td>
                <td>
                    <a asp-page="./Edit" asp-route-
id="@item.Id">Edit</a> |
                    <a asp-page="./Details" asp-route-
id="@item.Id">Details</a> |
                    <a asp-page="./Delete" asp-route-
id="@item.Id">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

3. Update the following pages with a `Rating` field:

- *Pages/Movies/Create.cshtml*.
- *Pages/Movies/Delete.cshtml*.
- *Pages/Movies/Details.cshtml*.
- *Pages/Movies/Edit.cshtml*.

The app won't work until the database is updated to include the new field. Running the app without an update to the database throws a `SqlException`:

```
SqlException: Invalid column name 'Rating'.
```

The `SqlException` exception is caused by the updated Movie model class being different than the schema of the Movie table of the database. There's no `Rating` column in the database table.

There are a few approaches to resolving the error:

1. Have the Entity Framework automatically drop and re-create the database using the new model class schema. This approach is convenient early in the development cycle, it allows developers to quickly evolve the model and database schema together. The downside is that existing data in the database is lost. Don't use this approach on a production database! Dropping the database on schema changes and using an initializer to automatically seed the database with test data is often a productive way to develop an app.
2. Explicitly modify the schema of the existing database so that it matches the model classes. The advantage of this approach is to keep the data. Make this change either manually or by creating a database change script.
3. Use EF Core Migrations to update the database schema.

For this tutorial, use EF Core Migrations.

Update the `SeedData` class so that it provides a value for the new column. A sample change is shown below, but make this change for each `new Movie` block.

C#

```
context.Movie.AddRange(
    new Movie
    {
        Title = "When Harry Met Sally",
        ReleaseDate = DateTime.Parse("1989-2-12"),
        Genre = "Romantic Comedy",
        Price = 7.99M,
        Rating = "R"
    },
```

See the completed SeedData.cs file.

Build the app

Visual Studio

Press `Ctrl`+`Shift`+`B`

Visual Studio

Add a migration for the rating field

1. From the **Tools** menu, select **NuGet Package Manager** > **Package Manager Console**.

2. In the Package Manager Console (PMC), enter the following command:

```
PowerShell

Add-Migration Rating
```

The `Add-Migration` command tells the framework to:

- Compare the `Movie` model with the `Movie` database schema.
- Create code to migrate the database schema to the new model.

The name "Rating" is arbitrary and is used to name the migration file. It's helpful to use a meaningful name for the migration file.

2. In the PMC, enter the following command:

```
PowerShell

Update-Database
```

The `Update-Database` command tells the framework to apply the schema changes to the database and to preserve existing data.

Delete all the records in the database, the initializer will seed the database and include the `Rating` field. Deleting can be done with the delete links in the browser or from Sql Server Object Explorer (SSOX).

Another option is to delete the database and use migrations to re-create the database. To delete the database in SSOX:

1. Select the database in SSOX.

2. Right-click on the database, and select **Delete**.

3. Check **Close existing connections**.

4. Select **OK**.

5. In the PMC, update the database:

```
PowerShell

Update-Database
```

Run the app and verify you can create, edit, and display movies with a `Rating` field. If the database isn't seeded, set a break point in the `SeedData.Initialize` method.

By Rick Anderson

In this section, validation logic is added to the `Movie` model. The validation rules are enforced any time a user creates or edits a movie.

Validation

A key tenet of software development is called DRY ("**D**on't **R**epeat **Y**ourself"). Razor Pages encourages development where functionality is specified once, and it's reflected throughout the app. DRY can help:

- Reduce the amount of code in an app.
- Make the code less error prone, and easier to test and maintain.

The validation support provided by Razor Pages and Entity Framework is a good example of the DRY principle:

- Validation rules are declaratively specified in one place, in the model class.
- Rules are enforced everywhere in the app.

Add validation rules to the movie model

The System.ComponentModel.DataAnnotations namespace provides:

- A set of built-in validation attributes that are applied declaratively to a class or property.
- Formatting attributes like `[DataType]` that help with formatting and don't provide any validation.

Update the `Movie` class to take advantage of the built-in `[Required]`, `[StringLength]`, `[RegularExpression]`, and `[Range]` validation attributes.

C#

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace RazorPagesMovie.Models;

public class Movie
{
    public int Id { get; set; }

    [StringLength(60, MinimumLength = 3)]
    [Required]
    public string Title { get; set; } = string.Empty;

    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }

    [Range(1, 100)]
    [DataType(DataType.Currency)]
    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }

    [RegularExpression(@"^[A-Z]+[a-zA-Z\s]*$")]
    [Required]
    [StringLength(30)]
    public string Genre { get; set; } = string.Empty;

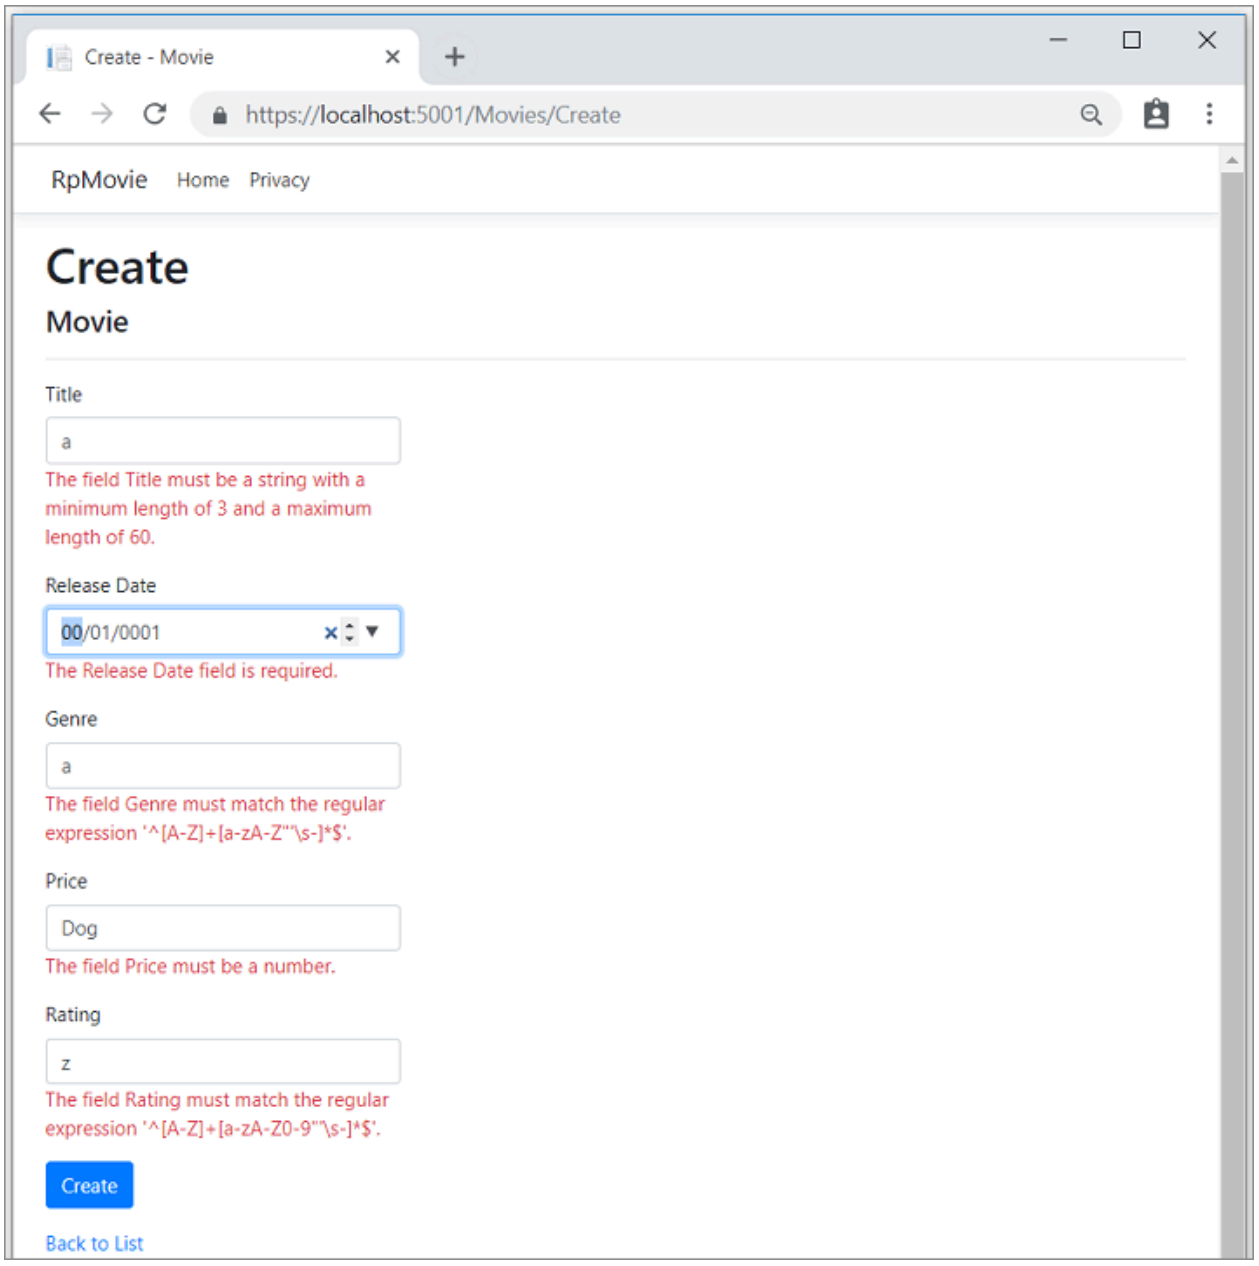
    [RegularExpression(@"^[A-Z]+[a-zA-Z0-9""'\s-]*$")]
    [StringLength(5)]
    [Required]
    public string Rating { get; set; } = string.Empty;
}
```

The validation attributes specify behavior to enforce on the model properties they're applied to:

- The `[Required]` and `[MinimumLength]` attributes indicate that a property must have a value. Nothing prevents a user from entering white space to satisfy this validation.
- The `[RegularExpression]` attribute is used to limit what characters can be input. In the preceding code, `Genre`:
  - Must only use letters.
  - The first letter must be uppercase. White spaces are allowed, while numbers and special characters aren't allowed.

- The `RegularExpression` `Rating`:
  - Requires that the first character be an uppercase letter.
  - Allows special characters and numbers in subsequent spaces. "PG-13" is valid for a rating, but fails for a `Genre`.
- The `[Range]` attribute constrains a value to within a specified range.
- The `[StringLength]` attribute can set a maximum length of a string property, and optionally its minimum length.
- Value types, such as `decimal`, `int`, `float`, `DateTime`, are inherently required and don't need the `[Required]` attribute.

The preceding validation rules are used for demonstration, they are not optimal for a production system. For example, the preceding prevents entering a movie with only two chars and doesn't allow special characters in `Genre`.



Having validation rules automatically enforced by ASP.NET Core helps:

- Make the app more robust.
- Reduce chances of saving invalid data to the database.

Validation Error UI in Razor Pages

Run the app and navigate to Pages/Movies.

Select the **Create New** link. Complete the form with some invalid values. When jQuery client-side validation detects the error, it displays an error message.

> **Note**
>
> You may not be able to enter decimal commas in decimal fields. To support jQuery validation for non-English locales that use a comma (",") for a decimal point, and non US-English date formats, you must take steps to globalize your app. See this GitHub comment 4076 for instructions on adding decimal comma.

Notice how the form has automatically rendered a validation error message in each field containing an invalid value. The errors are enforced both client-side, using JavaScript and jQuery, and server-side, when a user has JavaScript disabled.

A significant benefit is that **no** code changes were necessary in the Create or Edit pages. Once data annotations were applied to the model, the validation UI was enabled. The Razor Pages created in this tutorial automatically picked up the validation rules, using

validation attributes on the properties of the `Movie` model class. Test validation using the Edit page, the same validation is applied.

The form data isn't posted to the server until there are no client-side validation errors. Verify form data isn't posted by one or more of the following approaches:

- Put a break point in the `OnPostAsync` method. Submit the form by selecting **Create** or **Save**. The break point is never hit.
- Use the Fiddler tool.
- Use the browser developer tools to monitor network traffic.

Server-side validation

When JavaScript is disabled in the browser, submitting the form with errors will post to the server.

Optional, test server-side validation:

1. Disable JavaScript in the browser. JavaScript can be disabled using browser's developer tools. If JavaScript cannot be disabled in the browser, try another browser.
2. Set a break point in the `OnPostAsync` method of the Create or Edit page.
3. Submit a form with invalid data.
4. Verify the model state is invalid:

```
C#
```

```
if (!ModelState.IsValid)
{
    return Page();
}
```

Alternatively, Disable client-side validation on the server.

The following code shows a portion of the `Create.cshtml` page scaffolded earlier in the tutorial. It's used by the Create and Edit pages to:

- Display the initial form.
- Redisplay the form in the event of an error.

```
CSHTML
```

```
<form method="post">
    <div asp-validation-summary="ModelOnly" class="text-danger"></div>
    <div class="form-group">
        <label asp-for="Movie.Title" class="control-label"></label>
        <input asp-for="Movie.Title" class="form-control" />
        <span asp-validation-for="Movie.Title" class="text-danger"></span>
    </div>
```

The Input Tag Helper uses the DataAnnotations attributes and produces HTML attributes needed for jQuery Validation on the client-side. The Validation Tag Helper displays validation errors. See Validation for more information.

The Create and Edit pages have no validation rules in them. The validation rules and the error strings are specified only in the `Movie` class. These validation rules are automatically applied to Razor Pages that edit the `Movie` model.

When validation logic needs to change, it's done only in the model. Validation is applied consistently throughout the app, validation logic is defined in one place. Validation in one place helps keep the code clean, and makes it easier to maintain and update.

Use DataType Attributes

Examine the `Movie` class. The `System.ComponentModel.DataAnnotations` namespace provides formatting attributes in addition to the built-in set of validation attributes. The `[DataType]` attribute is applied to the `ReleaseDate` and `Price` properties.

C#

```
[DataType(DataType.Date)]
public DateTime ReleaseDate { get; set; }

[Range(1, 100)]
[DataType(DataType.Currency)]
[Column(TypeName = "decimal(18, 2)")]
public decimal Price { get; set; }
```

The `[DataType]` attributes provide:

- Hints for the view engine to format the data.
- Supplies attributes such as `<a>` for URL's and `<a href="mailto:EmailAddress.com">` for email.

Use the `[RegularExpression]` attribute to validate the format of the data. The `[DataType]` attribute is used to specify a data type that's more specific than the

database intrinsic type. `[DataType]` attributes aren't validation attributes. In the sample app, only the date is displayed, without time.

The `DataType` enumeration provides many data types, such as `Date`, `Time`, `PhoneNumber`, `Currency`, `EmailAddress`, and more.

The `[DataType]` attributes:

- Can enable the app to automatically provide type-specific features. For example, a `mailto:` link can be created for `DataType.EmailAddress`.
- Can provide a date selector `DataType.Date` in browsers that support HTML5.
- Emit HTML 5 `data-`, pronounced "data dash", attributes that HTML 5 browsers consume.
- Do **not** provide any validation.

`DataType.Date` doesn't specify the format of the date that's displayed. By default, the data field is displayed according to the default formats based on the server's `CultureInfo`.

The `[Column(TypeName = "decimal(18, 2)")]` data annotation is required so Entity Framework Core can correctly map `Price` to currency in the database. For more information, see Data Types.

The `[DisplayFormat]` attribute is used to explicitly specify the date format:

```
C#

[DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode =
true)]
public DateTime ReleaseDate { get; set; }
```

The `ApplyFormatInEditMode` setting specifies that the formatting will be applied when the value is displayed for editing. That behavior may not be wanted for some fields. For example, in currency values, the currency symbol is usually not wanted in the edit UI.

The `[DisplayFormat]` attribute can be used by itself, but it's generally a good idea to use the `[DataType]` attribute. The `[DataType]` attribute conveys the semantics of the data as opposed to how to render it on a screen. The `[DataType]` attribute provides the following benefits that aren't available with `[DisplayFormat]`:

- The browser can enable HTML5 features, for example to show a calendar control, the locale-appropriate currency symbol, email links, etc.
- By default, the browser renders data using the correct format based on its locale.

- The `[DataType]` attribute can enable the ASP.NET Core framework to choose the right field template to render the data. The `DisplayFormat`, if used by itself, uses the string template.

Note: jQuery validation doesn't work with the `[Range]` attribute and `DateTime`. For example, the following code will always display a client-side validation error, even when the date is in the specified range:

C#

```
[Range(typeof(DateTime), "1/1/1966", "1/1/2020")]
```

It's a best practice to avoid compiling hard dates in models, so using the `[Range]` attribute and `DateTime` is discouraged. Use Configuration for date ranges and other values that are subject to frequent change rather than specifying it in code.

The following code shows combining attributes on one line:

C#

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace RazorPagesMovie.Models;

public class Movie
{
    public int Id { get; set; }

    [StringLength(60, MinimumLength = 3)]
    public string Title { get; set; } = string.Empty;

    [Display(Name = "Release Date"), DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }

    [RegularExpression(@"^[A-Z]+[a-zA-Z\s]*$"), Required, StringLength(30)]
    public string Genre { get; set; } = string.Empty;

    [Range(1, 100), DataType(DataType.Currency)]
    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }

    [RegularExpression(@"^[A-Z]+[a-zA-Z0-9""'\s-]*$"), StringLength(5)]
    public string Rating { get; set; } = string.Empty;
}
```

Get started with Razor Pages and EF Core shows advanced EF Core operations with Razor Pages.

Apply migrations

The DataAnnotations applied to the class changes the schema. For example, the DataAnnotations applied to the `Title` field:

C#

```
[StringLength(60, MinimumLength = 3)]
[Required]
public string Title { get; set; } = string.Empty;
```

- Limits the characters to 60.
- Doesn't allow a `null` value.

The `Movie` table currently has the following schema:

SQL

```
CREATE TABLE [dbo].[Movie] (
    [ID]          INT             IDENTITY (1, 1) NOT NULL,
    [Title]       NVARCHAR (MAX)  NULL,
    [ReleaseDate] DATETIME2 (7)   NOT NULL,
    [Genre]       NVARCHAR (MAX)  NULL,
    [Price]       DECIMAL (18, 2) NOT NULL,
    [Rating]      NVARCHAR (MAX)  NULL,
    CONSTRAINT [PK_Movie] PRIMARY KEY CLUSTERED ([ID] ASC)
);
```

The preceding schema changes don't cause EF to throw an exception. However, create a migration so the schema is consistent with the model.

Visual Studio

From the **Tools** menu, select **NuGet Package Manager** > **Package Manager Console**. In the PMC, enter the following commands:

PowerShell

```
Add-Migration New_DataAnnotations
Update-Database
```

`Update-Database` runs the `Up` method of the `New_DataAnnotations` class.

Examine the `Up` method:

C#

```
public partial class New_DataAnnotations : Migration
{
    /// <inheritdoc />
    protected override void Up(MigrationBuilder migrationBuilder)
    {
        migrationBuilder.AlterColumn<string>(
            name: "Title",
            table: "Movie",
            type: "nvarchar(60)",
            maxLength: 60,
            nullable: false,
            oldClrType: typeof(string),
            oldType: "nvarchar(max)");

        migrationBuilder.AlterColumn<string>(
            name: "Rating",
            table: "Movie",
            type: "nvarchar(5)",
            maxLength: 5,
            nullable: false,
            oldClrType: typeof(string),
            oldType: "nvarchar(max)");

        migrationBuilder.AlterColumn<string>(
            name: "Genre",
            table: "Movie",
            type: "nvarchar(30)",
            maxLength: 30,
            nullable: false,
            oldClrType: typeof(string),
            oldType: "nvarchar(max)");
    }
```

The updated `Movie` table has the following schema:

SQL

```
CREATE TABLE [dbo].[Movie] (
    [ID]          INT             IDENTITY (1, 1) NOT NULL,
    [Title]       NVARCHAR (60)   NOT NULL,
    [ReleaseDate] DATETIME2 (7)   NOT NULL,
    [Genre]       NVARCHAR (30)   NOT NULL,
    [Price]       DECIMAL (18, 2) NOT NULL,
    [Rating]      NVARCHAR (5)    NOT NULL,
    CONSTRAINT [PK_Movie] PRIMARY KEY CLUSTERED ([ID] ASC)
);
```

Publish to Azure

For information on deploying to Azure, see Tutorial: Build an ASP.NET Core app in Azure with SQL Database.

Thanks for completing this introduction to Razor Pages. Get started with Razor Pages and EF Core is an excellent follow up to this tutorial.

Filter methods for Razor Pages in ASP.NET Core

Article • 04/10/2024

By Rick Anderson

Razor Page filters IPageFilter and IAsyncPageFilter allow Razor Pages to run code before and after a Razor Page handler is run. Razor Page filters are similar to ASP.NET Core MVC action filters, except they can't be applied to individual page handler methods.

Razor Page filters:

- Run code after a handler method has been selected, but before model binding occurs.
- Run code before the handler method executes, after model binding is complete.
- Run code after the handler method executes.
- Can be implemented on a page or globally.
- Cannot be applied to specific page handler methods.
- Can have constructor dependencies populated by Dependency Injection (DI). For more information, see ServiceFilterAttribute and TypeFilterAttribute.

While page constructors and middleware enable executing custom code before a handler method executes, only Razor Page filters enable access to HttpContext and the page. Middleware has access to the `HttpContext`, but not to the "page context". Filters have a FilterContext derived parameter, which provides access to `HttpContext`. Here's a sample for a page filter: Implement a filter attribute that adds a header to the response, something that can't be done with constructors or middleware. Access to the page context, which includes access to the instances of the page and it's model, are only available when executing filters, handlers, or the body of a Razor Page.

View or download sample code (how to download)

Razor Page filters provide the following methods, which can be applied globally or at the page level:

- Synchronous methods:
  - OnPageHandlerSelected : Called after a handler method has been selected, but before model binding occurs.
  - OnPageHandlerExecuting : Called before the handler method executes, after model binding is complete.

    - OnPageHandlerExecuted : Called after the handler method executes, before the action result.

- Asynchronous methods:
    - OnPageHandlerSelectionAsync : Called asynchronously after the handler method has been selected, but before model binding occurs.
    - OnPageHandlerExecutionAsync : Called asynchronously before the handler method is invoked, after model binding is complete.

Implement **either** the synchronous or the async version of a filter interface, **not** both. The framework checks first to see if the filter implements the async interface, and if so, it calls that. If not, it calls the synchronous interface's method(s). If both interfaces are implemented, only the async methods are called. The same rule applies to overrides in pages, implement the synchronous or the async version of the override, not both.

Implement Razor Page filters globally

The following code implements `IAsyncPageFilter`:

C#

```
public class SampleAsyncPageFilter : IAsyncPageFilter
{
    private readonly IConfiguration _config;

    public SampleAsyncPageFilter(IConfiguration config)
    {
        _config = config;
    }

    public Task OnPageHandlerSelectionAsync(PageHandlerSelectedContext
context)
    {
        var key = _config["UserAgentID"];
        context.HttpContext.Request.Headers.TryGetValue("user-agent",
                                                        out StringValues
value);
        ProcessUserAgent.Write(context.ActionDescriptor.DisplayName,

"SampleAsyncPageFilter.OnPageHandlerSelectionAsync",
                               value, key.ToString());

        return Task.CompletedTask;
    }

    public async Task
OnPageHandlerExecutionAsync(PageHandlerExecutingContext context,

PageHandlerExecutionDelegate next)
```

```
    {
        // Do post work.
        await next.Invoke();
    }
}
```

In the preceding code, `ProcessUserAgent.Write` is user supplied code that works with the user agent string.

The following code enables the `SampleAsyncPageFilter` in the `Startup` class:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages()
        .AddMvcOptions(options =>
        {
            options.Filters.Add(new SampleAsyncPageFilter(Configuration));
        });
}
```

The following code calls AddFolderApplicationModelConvention to apply the `SampleAsyncPageFilter` to only pages in */Movies*:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages(options =>
    {
        options.Conventions.AddFolderApplicationModelConvention(
            "/Movies",
            model => model.Filters.Add(new
SampleAsyncPageFilter(Configuration)));
    });
}
```

The following code implements the synchronous `IPageFilter`:

C#

```
public class SamplePageFilter : IPageFilter
{
    private readonly IConfiguration _config;

    public SamplePageFilter(IConfiguration config)
    {
        _config = config;
```

```
    }

    public void OnPageHandlerSelected(PageHandlerSelectedContext context)
    {
        var key = _config["UserAgentID"];
        context.HttpContext.Request.Headers.TryGetValue("user-agent", out
StringValues value);
        ProcessUserAgent.Write(context.ActionDescriptor.DisplayName,
                               "SamplePageFilter.OnPageHandlerSelected",
                               value, key.ToString());
    }

    public void OnPageHandlerExecuting(PageHandlerExecutingContext context)
    {
        Debug.WriteLine("Global sync OnPageHandlerExecuting called.");
    }

    public void OnPageHandlerExecuted(PageHandlerExecutedContext context)
    {
        Debug.WriteLine("Global sync OnPageHandlerExecuted called.");
    }
}
```

The following code enables the `SamplePageFilter`:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages()
        .AddMvcOptions(options =>
        {
            options.Filters.Add(new SamplePageFilter(Configuration));
        });
}
```

Implement Razor Page filters by overriding filter methods

The following code overrides the asynchronous Razor Page filters:

C#

```
public class IndexModel : PageModel
{
    private readonly IConfiguration _config;

    public IndexModel(IConfiguration config)
    {
```

```
        _config = config;
    }

    public override Task
OnPageHandlerSelectionAsync(PageHandlerSelectedContext context)
    {
        Debug.WriteLine("/IndexModel OnPageHandlerSelectionAsync");
        return Task.CompletedTask;
    }

    public async override Task
OnPageHandlerExecutionAsync(PageHandlerExecutingContext context,

PageHandlerExecutionDelegate next)
    {
        var key = _config["UserAgentID"];
        context.HttpContext.Request.Headers.TryGetValue("user-agent", out
StringValues value);
        ProcessUserAgent.Write(context.ActionDescriptor.DisplayName,
                               "/IndexModel-OnPageHandlerExecutionAsync",
                                value, key.ToString());

        await next.Invoke();
    }
}
```

Implement a filter attribute

The built-in attribute-based filter OnResultExecutionAsync filter can be subclassed. The following filter adds a header to the response:

C#

```
using System.Threading.Tasks;
using Microsoft.AspNetCore.Mvc.Filters;

namespace PageFilter.Filters
{
    public class AddHeaderAttribute  : ResultFilterAttribute
    {
        private readonly string _name;
        private readonly string _value;

        public AddHeaderAttribute (string name, string value)
        {
            _name = name;
            _value = value;
        }

        public override void OnResultExecuting(ResultExecutingContext
context)
```

```
        {
            context.HttpContext.Response.Headers.Add(_name, new string[] {
_value });
        }
    }
}
```

The following code applies the `AddHeader` attribute:

C#

```
using Microsoft.AspNetCore.Mvc.RazorPages;
using PageFilter.Filters;

namespace PageFilter.Movies
{
    [AddHeader("Author", "Rick")]
    public class TestModel : PageModel
    {
        public void OnGet()
        {

        }
    }
}
```

Use a tool such as the browser developer tools to examine the headers. Under **Response Headers**, `author: Rick` is displayed.

See Overriding the default order for instructions on overriding the order.

See Cancellation and short circuiting for instructions to short-circuit the filter pipeline from a filter.

Authorize filter attribute

The Authorize attribute can be applied to a `PageModel`:

C#

```
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace PageFilter.Pages
{
    [Authorize]
    public class ModelWithAuthFilterModel : PageModel
```

```
    {
        public IActionResult OnGet() => Page();
    }
}
```

Razor Pages route and app conventions in ASP.NET Core

Article • 04/10/2024

Learn how to use page route and app model provider conventions to control page routing, discovery, and processing in Razor Pages apps.

To specify a page route, add route segments, or add parameters to a route, use the page's `@page` directive. For more information, see Custom routes.

There are reserved words that can't be used as route segments or parameter names. For more information, see Routing: Reserved routing names.

View or download sample code (how to download)

Expand table

Scenario	The sample demonstrates
Model conventions Conventions.Add • IPageRouteModelConvention • IPageApplicationModelConvention • IPageHandlerModelConvention	Add a route template and header to an app's pages.
Page route action conventions • AddFolderRouteModelConvention • AddPageRouteModelConvention • AddPageRoute	Add a route template to pages in a folder and to a single page.
Page model action conventions • AddFolderApplicationModelConvention • AddPageApplicationModelConvention • ConfigureFilter (filter class, lambda expression, or filter factory)	Add a header to pages in a folder, add a header to a single page, and configure a filter factory to add a header to an app's pages.

Razor Pages conventions are configured using an AddRazorPages overload that configures RazorPagesOptions. The following convention examples are explained later in this topic:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages(options =>
    {
        options.Conventions.Add( ... );
        options.Conventions.AddFolderRouteModelConvention(
            "/OtherPages", model => { ... });
        options.Conventions.AddPageRouteModelConvention(
            "/About", model => { ... });
        options.Conventions.AddPageRoute(
            "/Contact", "TheContactPage/{text?}");
        options.Conventions.AddFolderApplicationModelConvention(
            "/OtherPages", model => { ... });
        options.Conventions.AddPageApplicationModelConvention(
            "/About", model => { ... });
        options.Conventions.ConfigureFilter(model => { ... });
        options.Conventions.ConfigureFilter( ... );
    });
}
```

Route order

Routes specify an Order for processing (route matching).

Expand table

Route order	Behavior
-1	The route is processed before other routes are processed.
0	Order isn't specified (default value). Not assigning `Order` (`Order = null`) defaults the route `Order` to 0 (zero) for processing.
1, 2, ... n	Specifies the route processing order.

Route processing is established by convention:

- Routes are processed in sequential order (-1, 0, 1, 2, ... n).
- When routes have the same `Order`, the most specific route is matched first followed by less specific routes.
- When routes with the same `Order` and the same number of parameters match a request URL, routes are processed in the order that they're added to the PageConventionCollection.

If possible, avoid depending on an established route processing order. Generally, routing selects the correct route with URL matching. If you must set route `Order` properties to route requests correctly, the app's routing scheme is probably confusing to clients and fragile to maintain. Seek to simplify the app's routing scheme. The sample app requires an explicit route processing order to demonstrate several routing scenarios using a single app. However, you should attempt to avoid the practice of setting route `Order` in production apps.

Razor Pages routing and MVC controller routing share an implementation. Information on route order in the MVC topics is available at Routing to controller actions: Ordering attribute routes.

Model conventions

Add a delegate for IPageConvention to add model conventions that apply to Razor Pages.

Add a route model convention to all pages

Use Conventions to create and add an IPageRouteModelConvention to the collection of IPageConvention instances that are applied during page route model construction.

The sample app contains the `GlobalTemplatePageRouteModelConvention` class to add a `{globalTemplate?}` route template to all of the pages in the app:

C#

```
using Microsoft.AspNetCore.Mvc.ApplicationModels;
namespace SampleApp.Conventions;

public class GlobalTemplatePageRouteModelConvention :
IPageRouteModelConvention
{
    public void Apply(PageRouteModel model)
    {
        var selectorCount = model.Selectors.Count;
        for (var i = 0; i < selectorCount; i++)
        {
            var selector = model.Selectors[i];
            model.Selectors.Add(new SelectorModel
            {
                AttributeRouteModel = new AttributeRouteModel
                {
                    Order = 1,
```

```
                    Template = AttributeRouteModel.CombineTemplates(
                        selector.AttributeRouteModel!.Template,
                        "{globalTemplate?}"),
                };
            });
        }
    }
}
```

In the preceding code:

- The PageRouteModel is passed to the Apply method.
- The PageRouteModel.Selectors gets the count of selectors.
- A new SelectorModel is added which contains a AttributeRouteModel

Razor Pages options, such as adding Conventions, are added when Razor Pages is added to the service collection. For an example, see the sample app.

C#

```
using Microsoft.AspNetCore.Mvc.ApplicationModels;
using Microsoft.EntityFrameworkCore;
using SampleApp.Conventions;
using SampleApp.Data;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddDbContext<AppDbContext>(options =>

options.UseInMemoryDatabase("InMemoryDb"));

builder.Services.AddRazorPages(options =>
   {
       options.Conventions.Add(new
GlobalTemplatePageRouteModelConvention());

       options.Conventions.AddFolderRouteModelConvention("/OtherPages",
model =>
       {
           var selectorCount = model.Selectors.Count;
           for (var i = 0; i < selectorCount; i++)
           {
               var selector = model.Selectors[i];
               model.Selectors.Add(new SelectorModel
               {
                   AttributeRouteModel = new AttributeRouteModel
                   {
                       Order = 2,
                       Template = AttributeRouteModel.CombineTemplates(
                           selector.AttributeRouteModel!.Template,
                           "{otherPagesTemplate?}"),
                   }
```

```
                });
            }
        });

        options.Conventions.AddPageRouteModelConvention("/About", model =>
        {
            var selectorCount = model.Selectors.Count;
            for (var i = 0; i < selectorCount; i++)
            {
                var selector = model.Selectors[i];
                model.Selectors.Add(new SelectorModel
                {
                    AttributeRouteModel = new AttributeRouteModel
                    {
                        Order = 2,
                        Template = AttributeRouteModel.CombineTemplates(
                            selector.AttributeRouteModel!.Template,
                            "{aboutTemplate?}"),
                    }
                });
            }
        });

    });

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

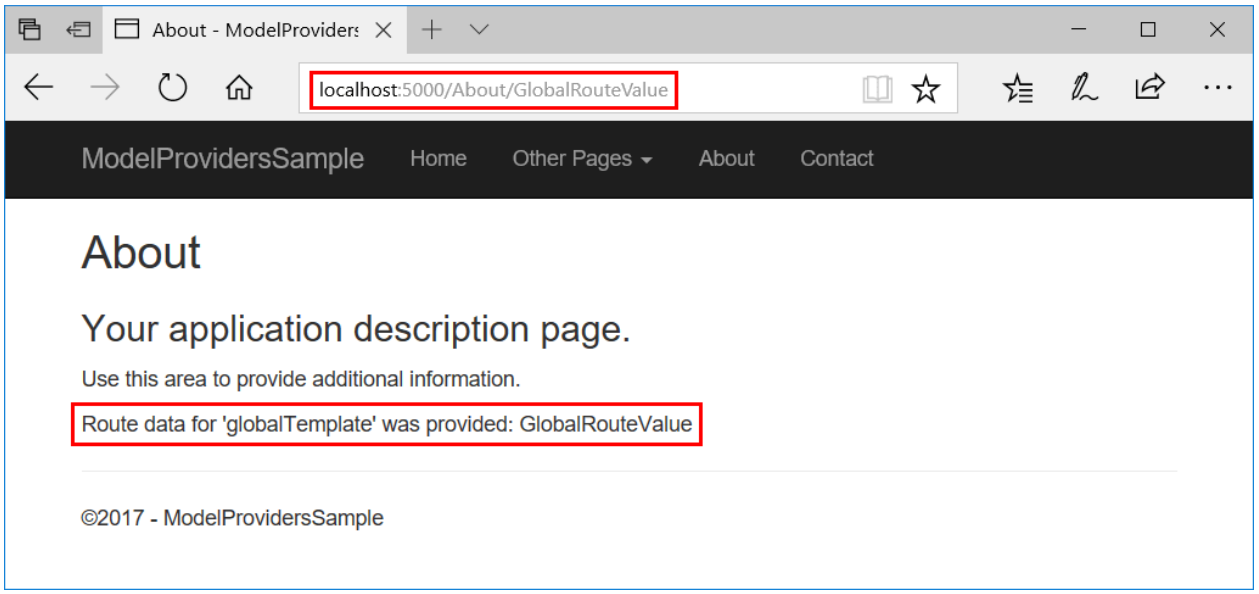
app.UseHttpsRedirection();
app.UseStaticFiles();
app.UseAuthorization();
app.MapRazorPages();
app.Run();
```

Consider the `GlobalTemplatePageRouteModelConvention` class:

C#

```
using Microsoft.AspNetCore.Mvc.ApplicationModels;
namespace SampleApp.Conventions;

public class GlobalTemplatePageRouteModelConvention :
IPageRouteModelConvention
{
    public void Apply(PageRouteModel model)
    {
        var selectorCount = model.Selectors.Count;
        for (var i = 0; i < selectorCount; i++)
```



```
        {
            var selector = model.Selectors[i];
            model.Selectors.Add(new SelectorModel
            {
                AttributeRouteModel = new AttributeRouteModel
                {
                    Order = 1,
                    Template = AttributeRouteModel.CombineTtemplates(
                        selector.AttributeRouteModel!.Template,
                        "{globalTemplate?}"),
                }
            });
        }
    }
}
```

The Order property for the AttributeRouteModel is set to `1`. This ensures the following route matching behavior in the sample app:

- A route template for `TheContactPage/{text?}` is added later in this topic. The `Contact Page` route has a default order of `null` (`Order = 0`), so it matches before the `{globalTemplate?}` route template which has `Order = 1`.
- The `{aboutTemplate?}` route template is show in the preceding code. The `{aboutTemplate?}` template is given an `Order` of `2`. When the About page is requested at `/About/RouteDataValue`, "RouteDataValue" is loaded into `RouteData.Values["globalTemplate"]` (`Order = 1`) and not `RouteData.Values["aboutTemplate"]` (`Order = 2`) due to setting the `Order` property.
- The `{otherPagesTemplate?}` route template is shown in the preceding code. The `{otherPagesTemplate?}` template is given an `Order` of `2`. When any page in the *Pages/OtherPages* folder is requested with a route parameter:
- For example, `/OtherPages/Page1/xyz`
- The route data value `"xyz"` is loaded into `RouteData.Values["globalTemplate"]` (`Order = 1`).
- `RouteData.Values["otherPagesTemplate"]` with (`Order = 2`) is not loaded due to the `Order` property `2` having a higher value.

When possible, don't set the `Order`. When `Order` is not set, it defaults to `Order = 0`. Rely on routing to select the correct route rather than the `Order` property.

Request the sample's `About` page at `localhost:{port}/About/GlobalRouteValue` and inspect the result:

The sample app uses the Rick.Docs.Samples.RouteInfo NuGet package to display routing information in the logging output. Using `localhost:{port}/About/GlobalRouteValue`, the logger displays the request, the `Order`, and the template used:

.NET CLI

```
info: SampleApp.Pages.AboutModel[0]
       /About/GlobalRouteValue   Order = 1 Template =
About/{globalTemplate?}
```

Add an app model convention to all pages

Use Conventions to create and add an IPageApplicationModelConvention to the collection of IPageConvention instances that are applied during page app model construction.

To demonstrate this and other conventions later in the topic, the sample app includes an `AddHeaderAttribute` class. The class constructor accepts a `name` string and a `values` string array. These values are used in its `OnResultExecuting` method to set a response header. The full class is shown in the Page model action conventions section later in the topic.

The sample app uses the `AddHeaderAttribute` class to add a header, `GlobalHeader`, to all of the pages in the app:

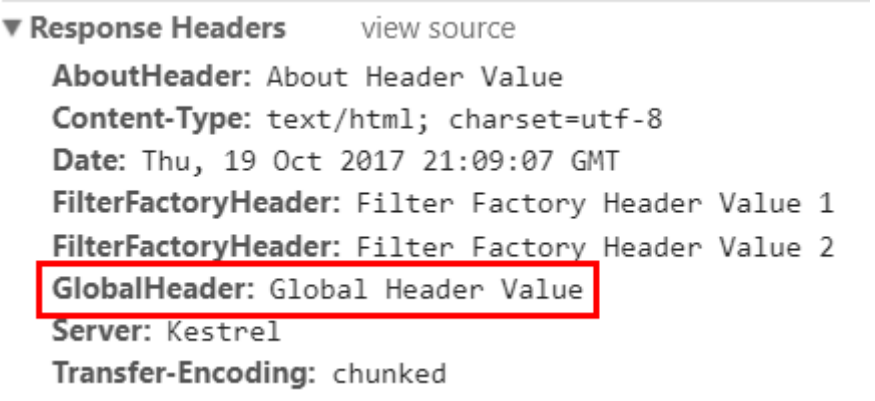
C#

```
public class GlobalHeaderPageApplicationModelConvention
    : IPageApplicationModelConvention
```

```
{
    public void Apply(PageApplicationModel model)
    {
        model.Filters.Add(new AddHeaderAttribute(
            "GlobalHeader", new string[] { "Global Header Value" }));
    }
}
```

`Program.cs`:

C#



```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddDbContext<AppDbContext>(options =>
    options.UseInMemoryDatabase("InMemoryDb"));

builder.Services.AddRazorPages(options =>
   {
       options.Conventions.Add(new
GlobalTemplatePageRouteModelConvention());

       options.Conventions.Add(new
GlobalHeaderPageApplicationModelConvention());
```

Request the sample's About page at `localhost:{port}/About` and inspect the headers to view the result:

Add a handler model convention to all pages

Use Conventions to create and add an IPageHandlerModelConvention to the collection of IPageConvention instances that are applied during page handler model construction.

C#

```
public class GlobalPageHandlerModelConvention
    : IPageHandlerModelConvention
```

```
{
    public void Apply(PageHandlerModel model)
    {
        // Access the PageHandlerModel
    }
}
```

Page route action conventions

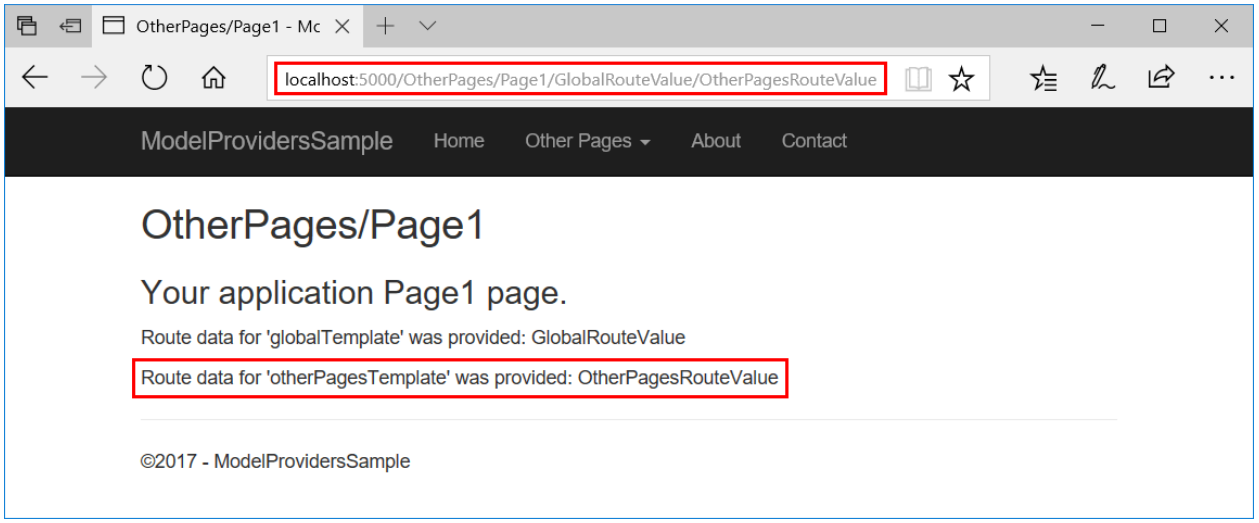
The default route model provider that derives from IPageRouteModelProvider invokes conventions which are designed to provide extensibility points for configuring page routes.

Folder route model convention

Use AddFolderRouteModelConvention to create and add an IPageRouteModelConvention that invokes an action on the PageRouteModel for all of the pages under the specified folder.

The sample app uses AddFolderRouteModelConvention to add an `{otherPagesTemplate?}` route template to the pages in the *OtherPages* folder:

C#



```
options.Conventions.AddFolderRouteModelConvention("/OtherPages", model =>
{
    var selectorCount = model.Selectors.Count;
    for (var i = 0; i < selectorCount; i++)
    {
        var selector = model.Selectors[i];
        model.Selectors.Add(new SelectorModel
        {
            AttributeRouteModel = new AttributeRouteModel
            {
                Order = 2,
                Template = AttributeRouteModel.CombineTemplates(
                    selector.AttributeRouteModel!.Template,
                    "{otherPagesTemplate?}"),
            }
        });
    }
});
```

The Order property for the AttributeRouteModel is set to `2`. This ensures that the template for `{globalTemplate?}` (set earlier in the topic to `1`) is given priority for the first route data value position when a single route value is provided. If a page in the

Pages/OtherPages folder is requested with a route parameter value (for example, `/OtherPages/Page1/RouteDataValue`), "RouteDataValue" is loaded into `RouteData.Values["globalTemplate"]` (`Order = 1`) and not `RouteData.Values["otherPagesTemplate"]` (`Order = 2`) due to setting the `Order` property.

Wherever possible, don't set the `Order`, which results in `Order = 0`. Rely on routing to select the correct route.

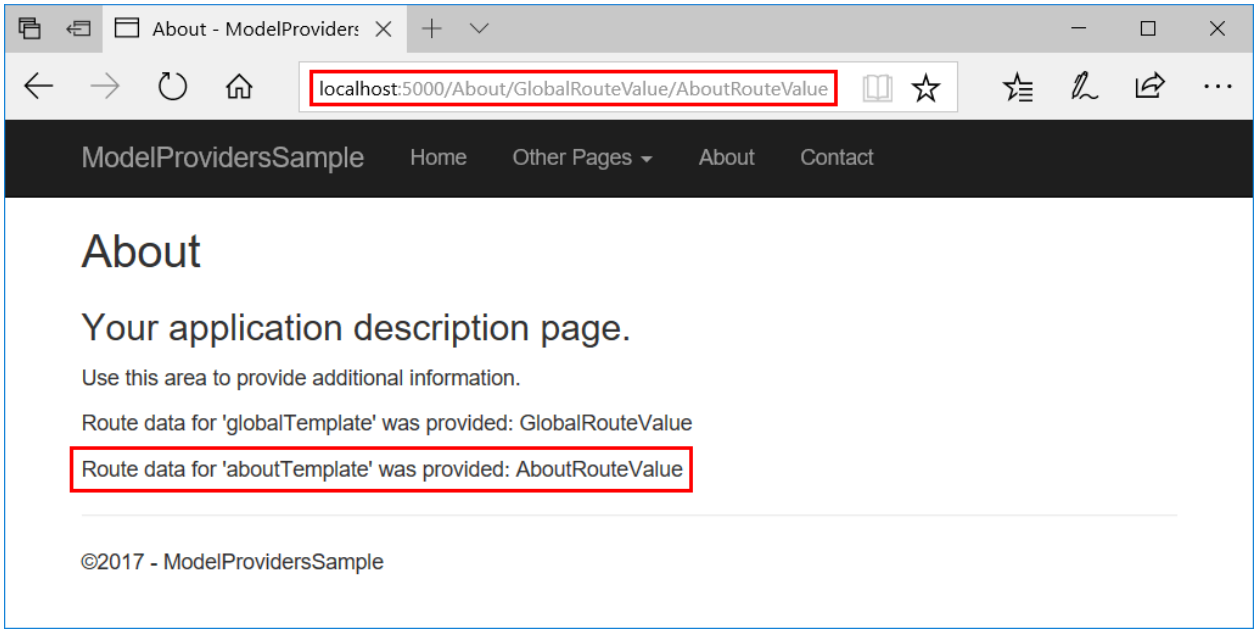
Request the sample's Page1 page at `localhost:5000/OtherPages/Page1/GlobalRouteValue/OtherPagesRouteValue` and inspect the result:

Page route model convention

Use AddPageRouteModelConvention to create and add an IPageRouteModelConvention that invokes an action on the PageRouteModel for the page with the specified name.

The sample app uses `AddPageRouteModelConvention` to add an `{aboutTemplate?}` route template to the About page:

C#



```
options.Conventions.AddPageRouteModelConvention("/About", model =>
{
    var selectorCount = model.Selectors.Count;
    for (var i = 0; i < selectorCount; i++)
    {
        var selector = model.Selectors[i];
        model.Selectors.Add(new SelectorModel
        {
            AttributeRouteModel = new AttributeRouteModel
            {
                Order = 2,
                Template = AttributeRouteModel.CombineTemplates(
```

```
                    selector.AttributeRouteModel!.Template,
                    "{aboutTemplate?}"),
            }
        });
    }
});
```

The Order property for the AttributeRouteModel is set to `2`. This ensures that the template for `{globalTemplate?}` (set earlier in the topic to `1`) is given priority for the first route data value position when a single route value is provided. If the About page is requested with a route parameter value at `/About/RouteDataValue`, "RouteDataValue" is loaded into `RouteData.Values["globalTemplate"]` (`Order = 1`) and not `RouteData.Values["aboutTemplate"]` (`Order = 2`) due to setting the `Order` property.

Wherever possible, don't set the `Order`, which results in `Order = 0`. Rely on routing to select the correct route.

Request the sample's About page at `localhost:{port}/About/GlobalRouteValue/AboutRouteValue` and inspect the result:

The logger output displays:

.NET CLI

```
info: SampleApp.Pages.AboutModel[0]
      /About/GlobalRouteValue/AboutRouteValue   Order = 2 Template =
About/{globalTemplate?}/{aboutTemplate?}
```

Use a parameter transformer to customize page routes

See Parameter transformers.

Configure a page route

Use AddPageRoute to configure a route to a page at the specified page path. Generated links to the page use the specified route. AddPageRoute uses AddPageRouteModelConvention to establish the route.

The sample app creates a route to `/TheContactPage` for the `Contact` Razor Page:

C#

```
options.Conventions.AddPageRoute("/Contact", "TheContactPage/{text?}");
```

The `Contact` page can also be reached at `/`Contact1` via its default route.

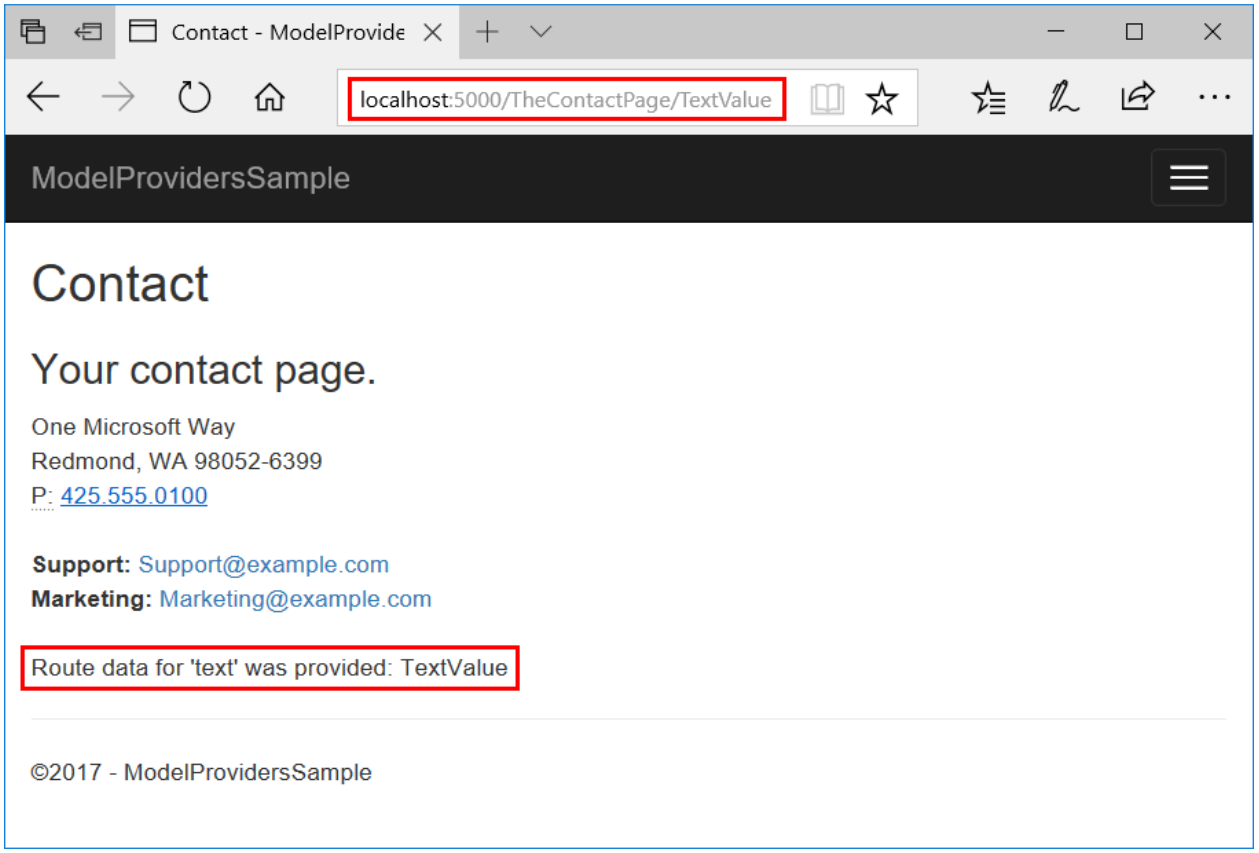
The sample app's custom route to the `Contact` page allows for an optional `text` route segment (`{text?}`). The page also includes this optional segment in its `@page` directive in case the visitor accesses the page at its `/Contact` route:

CSHTML

```
@page "{text?}"
@model ContactModel
@{
    ViewData["Title"] = "Contact";
}

<h1>@ViewData["Title"]</h1>
<h2>@Model.Message</h2>

<address>
    One Microsoft Way<br>
    Redmond, WA 98052-6399<br>
    <abbr title="Phone">P:</abbr>
    425.555.0100
</address>



<address>
    <strong>Support:</strong> <a
href="mailto:Support@example.com">Support@example.com</a><br>
    <strong>Marketing:</strong> <a
href="mailto:Marketing@example.com">Marketing@example.com</a>
</address>
```

```
<p>@Model.RouteDataTextTemplateValue</p>
```

Note that the URL generated for the **Contact** link in the rendered page reflects the updated route:

Visit the `Contact` page at either its ordinary route, `/Contact`, or the custom route, `/TheContactPage`. If you supply an additional `text` route segment, the page shows the HTML-encoded segment that you provide:

Page model action conventions

The default page model provider that implements IPageApplicationModelProvider invokes conventions which are designed to provide extensibility points for configuring

page models. These conventions are useful when building and modifying page discovery and processing scenarios.

For the examples in this section, the sample app uses an `AddHeaderAttribute` class, which is a ResultFilterAttribute, that applies a response header:

C#

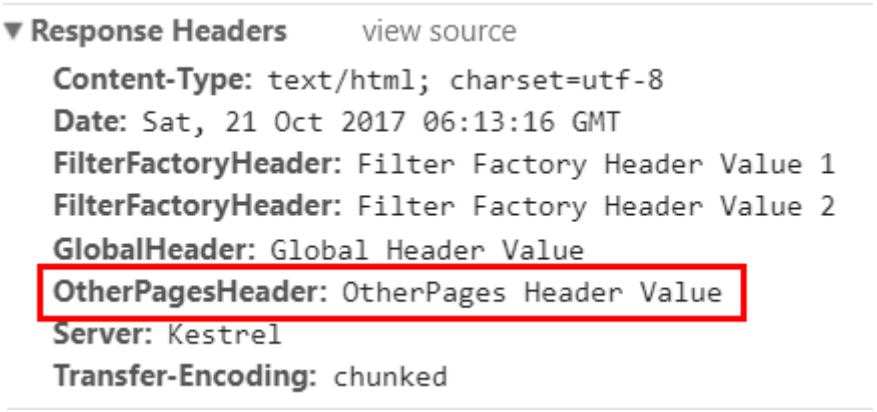
```
public class AddHeaderAttribute : ResultFilterAttribute
{
    private readonly string _name;
    private readonly string[] _values;

    public AddHeaderAttribute(string name, string[] values)
    {
        _name = name;
        _values = values;
    }

    public override void OnResultExecuting(ResultExecutingContext context)
    {
        context.HttpContext.Response.Headers.Add(_name, _values);
        base.OnResultExecuting(context);
    }
}
```

Using conventions, the sample demonstrates how to apply the attribute to all of the pages in a folder and to a single page.

Folder app model convention



Use AddFolderApplicationModelConvention to create and add an IPageApplicationModelConvention that invokes an action on PageApplicationModel instances for all pages under the specified folder.

The sample demonstrates the use of `AddFolderApplicationModelConvention` by adding a header, `OtherPagesHeader`, to the pages inside the *OtherPages* folder of the app:

C#

```
options.Conventions.AddFolderApplicationModelConvention("/OtherPages", model
=>
{
    model.Filters.Add(new AddHeaderAttribute(
        "OtherPagesHeader", new string[] { "OtherPages Header Value" }));
});
```

Request the sample's Page1 page at `localhost:5000/OtherPages/Page1` and inspect the headers to view the result:

Page app model convention

Use AddPageApplicationModelConvention to create and add an IPageApplicationModelConvention that invokes an action on the PageApplicationModel for the page with the specified name.

The sample demonstrates the use of `AddPageApplicationModelConvention` by adding a header, `AboutHeader`, to the About page:

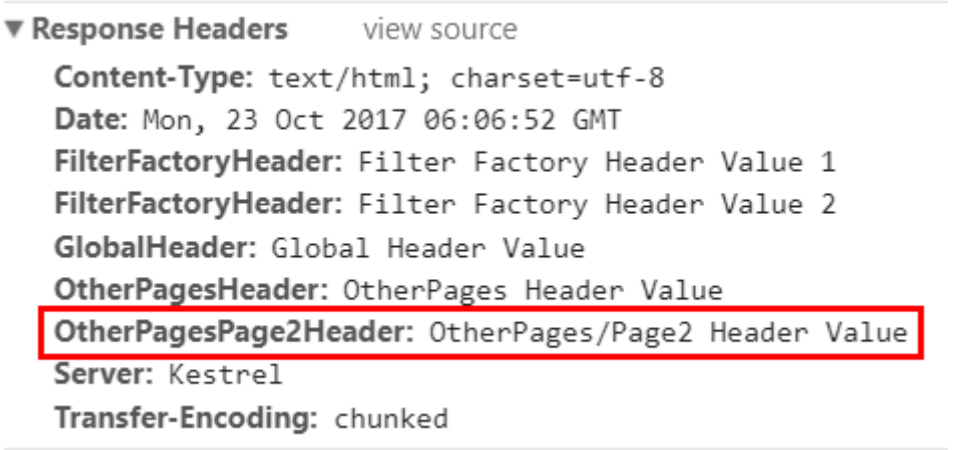
C#

```
options.Conventions.AddPageApplicationModelConvention("/About", model =>
{
    model.Filters.Add(new AddHeaderAttribute(
        "AboutHeader", new string[] { "About Header Value" }));
});
```

Request the sample's About page at `localhost:5000/About` and inspect the headers to view the result:

Configure a filter

ConfigureFilter configures the specified filter to apply. You can implement a filter class, but the sample app shows how to implement a filter in a lambda expression, which is implemented behind-the-scenes as a factory that returns a filter:



```
C#

options.Conventions.ConfigureFilter(model =>
{
    if (model.RelativePath.Contains("OtherPages/Page2"))
    {
        return new AddHeaderAttribute(
            "OtherPagesPage2Header",
            new string[] { "OtherPages/Page2 Header Value" });
    }
    return new EmptyFilter();
});
```

The page app model is used to check the relative path for segments that lead to the Page2 page in the *OtherPages* folder. If the condition passes, a header is added. If not, the `EmptyFilter` is applied.

`EmptyFilter` is an Action filter. Since Action filters are ignored by Razor Pages, the `EmptyFilter` has no effect as intended if the path doesn't contain `OtherPages/Page2`.

Request the sample's Page2 page at `localhost:5000/OtherPages/Page2` and inspect the headers to view the result:

Configure a filter factory

ConfigureFilter configures the specified factory to apply filters to all Razor Pages.

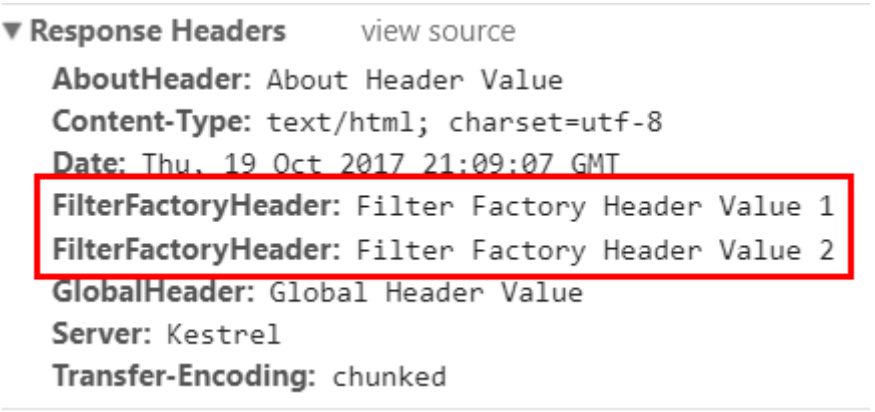
The sample app provides an example of using a filter factory by adding a header, `FilterFactoryHeader`, with two values to the app's pages:

```
C#
```

```
options.Conventions.ConfigureFilter(new AddHeaderWithFactory());
```

`AddHeaderWithFactory.cs`:

C#



```
public class AddHeaderWithFactory : IFilterFactory
{
    // Implement IFilterFactory
    public IFilterMetadata CreateInstance(IServiceProvider serviceProvider)
    {
        return new AddHeaderFilter();
    }

    private class AddHeaderFilter : IResultFilter
    {
        public void OnResultExecuting(ResultExecutingContext context)
        {
            context.HttpContext.Response.Headers.Add(
                "FilterFactoryHeader",
                new string[]
                {
                    "Filter Factory Header Value 1",
                    "Filter Factory Header Value 2"
                });
        }

        public void OnResultExecuted(ResultExecutedContext context)
        {
        }
    }

    public bool IsReusable
    {
        get
        {
            return false;
        }
    }
}
```

Request the sample's About page at `localhost:5000/About` and inspect the headers to view the result:

MVC Filters and the Page filter (IPageFilter)

MVC Action filters are ignored by Razor Pages, since Razor Pages use handler methods. Other types of MVC filters are available for you to use: Authorization, Exception, Resource, and Result. For more information, see the Filters topic.

The Page filter (IPageFilter) is a filter that applies to Razor Pages. For more information, see Filter methods for Razor Pages.

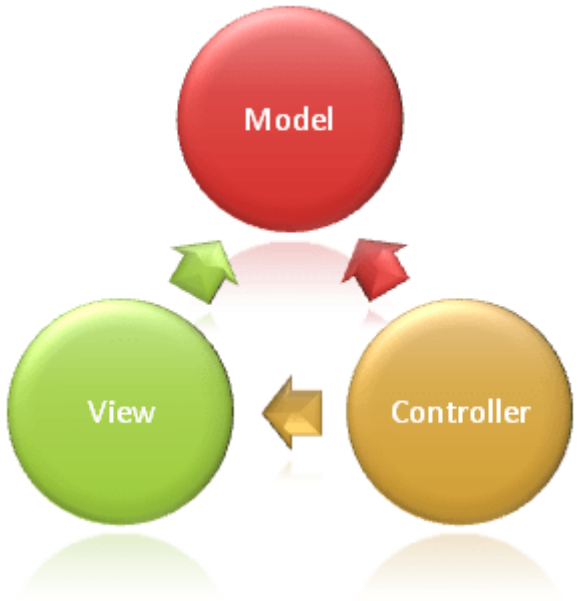
Overview of ASP.NET Core MVC

Article • 06/17/2024



By Steve Smith

ASP.NET Core MVC is a rich framework for building web apps and APIs using the Model-View-Controller design pattern.

MVC pattern

The Model-View-Controller (MVC) architectural pattern separates an application into three main groups of components: Models, Views, and Controllers. This pattern helps to achieve separation of concerns. Using this pattern, user requests are routed to a Controller which is responsible for working with the Model to perform user actions and/or retrieve results of queries. The Controller chooses the View to display to the user, and provides it with any Model data it requires.

The following diagram shows the three main components and which ones reference the others:

This delineation of responsibilities helps you scale the application in terms of complexity because it's easier to code, debug, and test something (model, view, or controller) that has a single job. It's more difficult to update, test, and debug code that has dependencies spread across two or more of these three areas. For example, user interface logic tends to change more frequently than business logic. If presentation code and business logic are combined in a single object, an object containing business logic

must be modified every time the user interface is changed. This often introduces errors and requires the retesting of business logic after every minimal user interface change.

> **Note**
>
> Both the view and the controller depend on the model. However, the model depends on neither the view nor the controller. This is one of the key benefits of the separation. This separation allows the model to be built and tested independent of the visual presentation.

Model Responsibilities

The Model in an MVC application represents the state of the application and any business logic or operations that should be performed by it. Business logic should be encapsulated in the model, along with any implementation logic for persisting the state of the application. Strongly-typed views typically use ViewModel types designed to contain the data to display on that view. The controller creates and populates these ViewModel instances from the model.

View Responsibilities

Views are responsible for presenting content through the user interface. They use the Razor view engine to embed .NET code in HTML markup. There should be minimal logic within views, and any logic in them should relate to presenting content. If you find the need to perform a great deal of logic in view files in order to display data from a complex model, consider using a View Component, ViewModel, or view template to simplify the view.

Controller Responsibilities

Controllers are the components that handle user interaction, work with the model, and ultimately select a view to render. In an MVC application, the view only displays information; the controller handles and responds to user input and interaction. In the MVC pattern, the controller is the initial entry point, and is responsible for selecting which model types to work with and which view to render (hence its name - it controls how the app responds to a given request).

> **Note**

Controllers shouldn't be overly complicated by too many responsibilities. To keep controller logic from becoming overly complex, push business logic out of the controller and into the domain model.

> **Tip**
>
> If you find that your controller actions frequently perform the same kinds of actions, move these common actions into **filters**.

ASP.NET Core MVC

The ASP.NET Core MVC framework is a lightweight, open source, highly testable presentation framework optimized for use with ASP.NET Core.

ASP.NET Core MVC provides a patterns-based way to build dynamic websites that enables a clean separation of concerns. It gives you full control over markup, supports TDD-friendly development and uses the latest web standards.

Routing

ASP.NET Core MVC is built on top of ASP.NET Core's routing, a powerful URL-mapping component that lets you build applications that have comprehensible and searchable URLs. This enables you to define your application's URL naming patterns that work well for search engine optimization (SEO) and for link generation, without regard for how the files on your web server are organized. You can define your routes using a convenient route template syntax that supports route value constraints, defaults and optional values.

Convention-based routing enables you to globally define the URL formats that your application accepts and how each of those formats maps to a specific action method on a given controller. When an incoming request is received, the routing engine parses the URL and matches it to one of the defined URL formats, and then calls the associated controller's action method.

C#

```
routes.MapRoute(name: "Default", template: "
{controller=Home}/{action=Index}/{id?}");
```

Attribute routing enables you to specify routing information by decorating your controllers and actions with attributes that define your application's routes. This means that your route definitions are placed next to the controller and action with which they're associated.

C#

```
[Route("api/[controller]")]
public class ProductsController : Controller
{
    [HttpGet("{id}")]
    public IActionResult GetProduct(int id)
    {
      ...
    }
}
```

Model binding

ASP.NET Core MVC model binding converts client request data (form values, route data, query string parameters, HTTP headers) into objects that the controller can handle. As a result, your controller logic doesn't have to do the work of figuring out the incoming request data; it simply has the data as parameters to its action methods.

C#

```
public async Task<IActionResult> Login(LoginViewModel model, string
returnUrl = null) { ... }
```

Model validation

ASP.NET Core MVC supports validation by decorating your model object with data annotation validation attributes. The validation attributes are checked on the client side before values are posted to the server, as well as on the server before the controller action is called.

C#

```
using System.ComponentModel.DataAnnotations;
public class LoginViewModel
{
    [Required]
    [EmailAddress]
    public string Email { get; set; }
```

```
    [Required]
    [DataType(DataType.Password)]
    public string Password { get; set; }

    [Display(Name = "Remember me?")]
    public bool RememberMe { get; set; }
}
```

A controller action:

C#

```
public async Task<IActionResult> Login(LoginViewModel model, string
returnUrl = null)
{
    if (ModelState.IsValid)
    {
      // work with the model
    }
    // At this point, something failed, redisplay form
    return View(model);
}
```

The framework handles validating request data both on the client and on the server. Validation logic specified on model types is added to the rendered views as unobtrusive annotations and is enforced in the browser with jQuery Validation.

Dependency injection

ASP.NET Core has built-in support for dependency injection (DI). In ASP.NET Core MVC, controllers can request needed services through their constructors, allowing them to follow the Explicit Dependencies Principle.

Your app can also use dependency injection in view files, using the `@inject` directive:

CSHTML

```
@inject SomeService ServiceName

<!DOCTYPE html>
<html lang="en">
<head>
    <title>@ServiceName.GetTitle</title>
</head>
<body>
    <h1>@ServiceName.GetTitle</h1>
```

```
</body>
</html>
```

Filters

Filters help developers encapsulate cross-cutting concerns, like exception handling or authorization. Filters enable running custom pre- and post-processing logic for action methods, and can be configured to run at certain points within the execution pipeline for a given request. Filters can be applied to controllers or actions as attributes (or can be run globally). Several filters (such as `Authorize`) are included in the framework. `[Authorize]` is the attribute that is used to create MVC authorization filters.

C#

```
[Authorize]
public class AccountController : Controller
```

Areas

Areas provide a way to partition a large ASP.NET Core MVC Web app into smaller functional groupings. An area is an MVC structure inside an application. In an MVC project, logical components like Model, Controller, and View are kept in different folders, and MVC uses naming conventions to create the relationship between these components. For a large app, it may be advantageous to partition the app into separate high level areas of functionality. For instance, an e-commerce app with multiple business units, such as checkout, billing, and search etc. Each of these units have their own logical component views, controllers, and models.

Web APIs

In addition to being a great platform for building web sites, ASP.NET Core MVC has great support for building Web APIs. You can build services that reach a broad range of clients including browsers and mobile devices.

The framework includes support for HTTP content-negotiation with built-in support to format data as JSON or XML. Write custom formatters to add support for your own formats.

Use link generation to enable support for hypermedia. Easily enable support for Cross-Origin Resource Sharing (CORS) so that your Web APIs can be shared across multiple

Web applications.

Testability

The framework's use of interfaces and dependency injection make it well-suited to unit testing, and the framework includes features (like a TestHost and InMemory provider for Entity Framework) that make integration tests quick and easy as well. Learn more about how to test controller logic.

Razor view engine

ASP.NET Core MVC views use the Razor view engine to render views. Razor is a compact, expressive and fluid template markup language for defining views using embedded C# code. Razor is used to dynamically generate web content on the server. You can cleanly mix server code with client side content and code.

CSHTML

```
<ul>
    @for (int i = 0; i < 5; i++) {
        <li>List item @i</li>
    }
</ul>
```

Using the Razor view engine you can define layouts, partial views and replaceable sections.

Strongly typed views

Razor views in MVC can be strongly typed based on your model. Controllers can pass a strongly typed model to views enabling your views to have type checking and IntelliSense support.

For example, the following view renders a model of type `IEnumerable<Product>`:

CSHTML

```
@model IEnumerable<Product>
<ul>
    @foreach (Product p in Model)
    {
        <li>@p.Name</li>
```

```
    }
</ul>
```

Tag Helpers

Tag Helpers enable server side code to participate in creating and rendering HTML elements in Razor files. You can use tag helpers to define custom tags (for example, `<environment>`) or to modify the behavior of existing tags (for example, `<label>`). Tag Helpers bind to specific elements based on the element name and its attributes. They provide the benefits of server-side rendering while still preserving an HTML editing experience.

There are many built-in Tag Helpers for common tasks - such as creating forms, links, loading assets and more - and even more available in public GitHub repositories and as NuGet packages. Tag Helpers are authored in C#, and they target HTML elements based on element name, attribute name, or parent tag. For example, the built-in LinkTagHelper can be used to create a link to the `Login` action of the `AccountsController`:

CSHTML

```
<p>
    Thank you for confirming your email.
    Please <a asp-controller="Account" asp-action="Login">Click here to Log
in</a>.
</p>
```

The `EnvironmentTagHelper` can be used to include different scripts in your views (for example, raw or minified) based on the runtime environment, such as Development, Staging, or Production:

CSHTML

```
<environment names="Development">
    <script src="~/lib/jquery/dist/jquery.js"></script>
</environment>
<environment names="Staging,Production">
    <script src="https://ajax.aspnetcdn.com/ajax/jquery/jquery-2.1.4.js"
            asp-fallback-src="~/lib/jquery/dist/jquery.js"
            asp-fallback-test="window.jQuery">
    </script>
</environment>
```

Tag Helpers provide an HTML-friendly development experience and a rich IntelliSense environment for creating HTML and Razor markup. Most of the built-in Tag Helpers

target existing HTML elements and provide server-side attributes for the element.

View Components

View Components allow you to package rendering logic and reuse it throughout the application. They're similar to partial views, but with associated logic.

Compatibility version

The SetCompatibilityVersion method allows an app to opt-in or opt-out of potentially breaking behavior changes introduced in ASP.NET Core MVC 2.1 or later.

For more information, see Compatibility version for ASP.NET Core MVC.

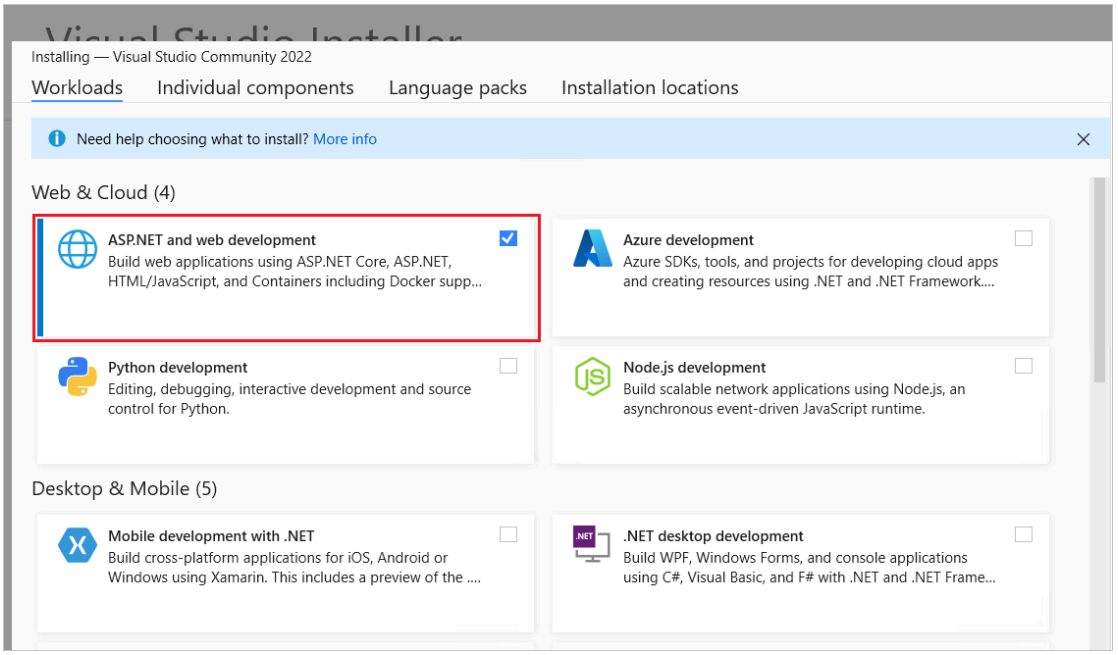
By Rick Anderson

This tutorial teaches ASP.NET Core MVC web development with controllers and views. If you're new to ASP.NET Core web development, consider the Razor Pages version of this tutorial, which provides an easier starting point. See Choose an ASP.NET Core UI, which compares Razor Pages, MVC, and Blazor for UI development.

This is the first tutorial of a series that teaches ASP.NET Core MVC web development with controllers and views.

At the end of the series, you'll have an app that manages, validates, and displays movie data. You learn how to:

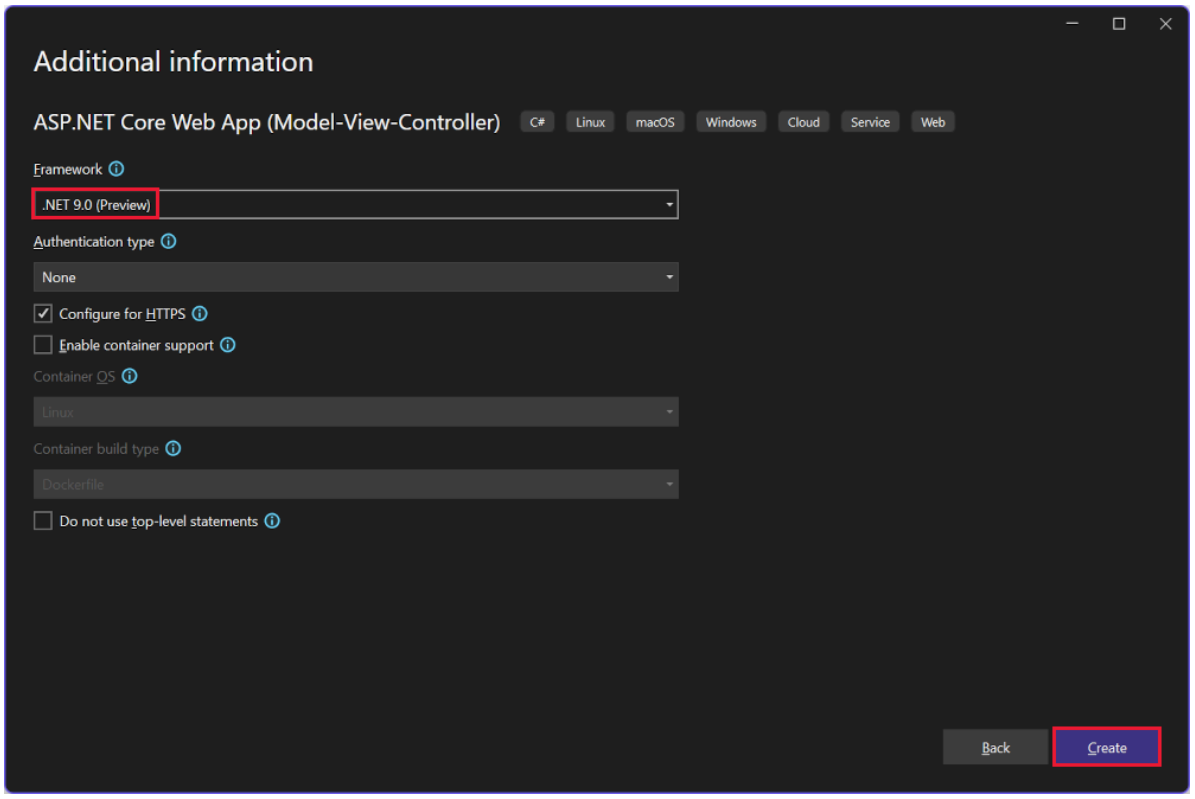


- ✓ Create a web app.
- ✓ Add and scaffold a model.
- ✓ Work with a database.
- ✓ Add search and validation.

View or download sample code (how to download).

Prerequisites

Visual Studio



- Visual Studio 2022 Preview with the **ASP.NET and web development** workload.

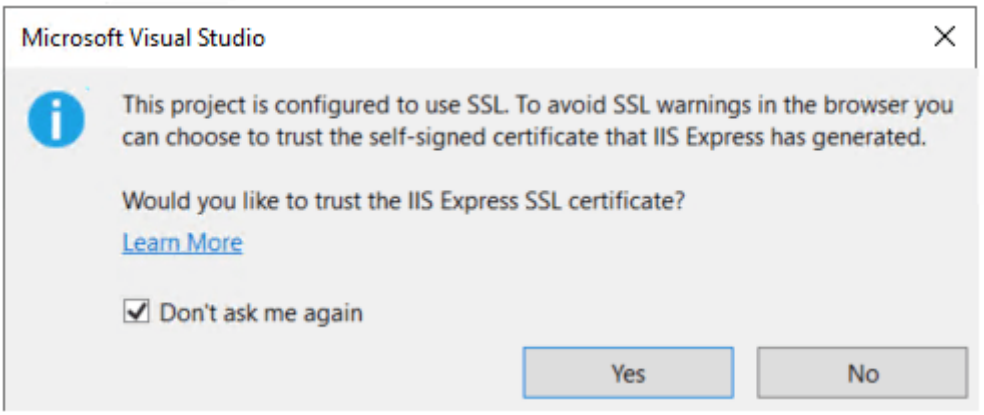
Create a web app

Visual Studio

- Start Visual Studio and select **Create a new project**.
- In the **Create a new project** dialog, select **ASP.NET Core Web App (Model-View-Controller)** > **Next**.
- In the **Configure your new project** dialog:
  - Enter `MvcMovie` for **Project name**. It's important to name the project *MvcMovie*. Capitalization needs to match each `namespace` when code is copied.
  - The **Location** for the project can be set to anywhere.
- Select **Next**.
- In the **Additional information** dialog:
  - Select **.NET 9.0 (Preview)**.
  - Verify that **Do not use top-level statements** is unchecked.
- Select **Create**.

For more information, including alternative approaches to create the project, see Create a new project in Visual Studio.

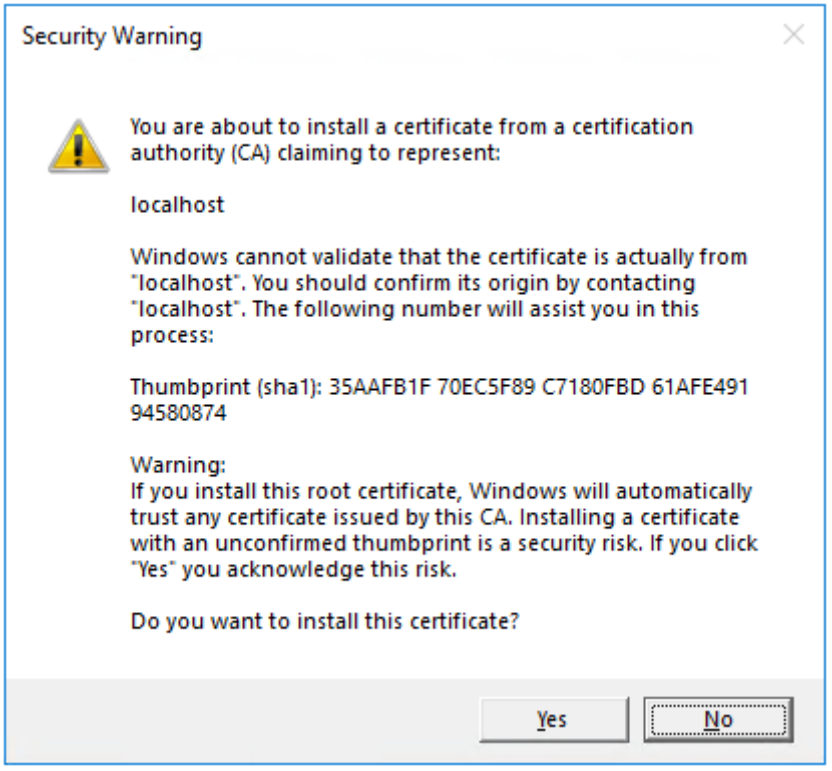
Visual Studio uses the default project template for the created MVC project. The created project:



- Is a working app.
- Is a basic starter project.

Run the app

Visual Studio



- Press `Ctrl`+`F5` to run the app without the debugger.

  Visual Studio displays the following dialog when a project is not yet configured to use SSL:

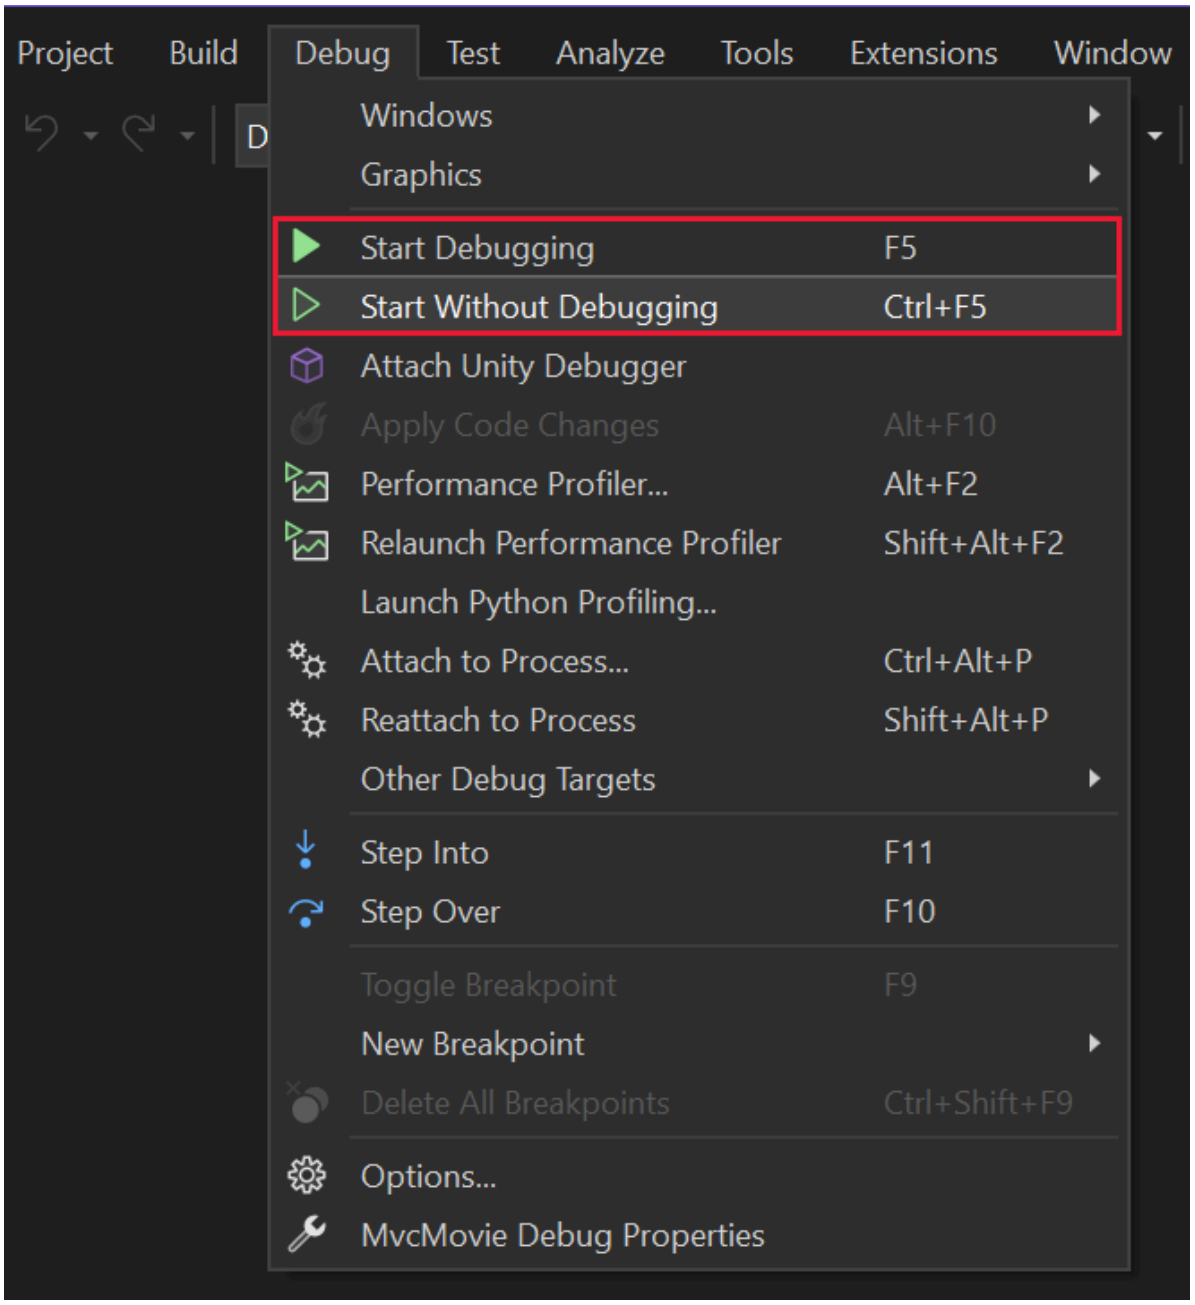
Select **Yes** if you trust the IIS Express SSL certificate.

The following dialog is displayed:

Select **Yes** if you agree to trust the development certificate.

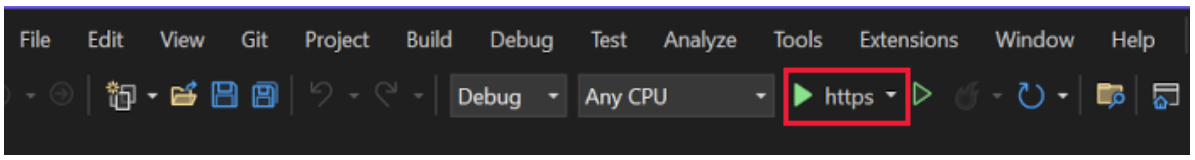
For information on trusting the Firefox browser, see Firefox SEC_ERROR_INADEQUATE_KEY_USAGE certificate error.

Visual Studio runs the app and opens the default browser.



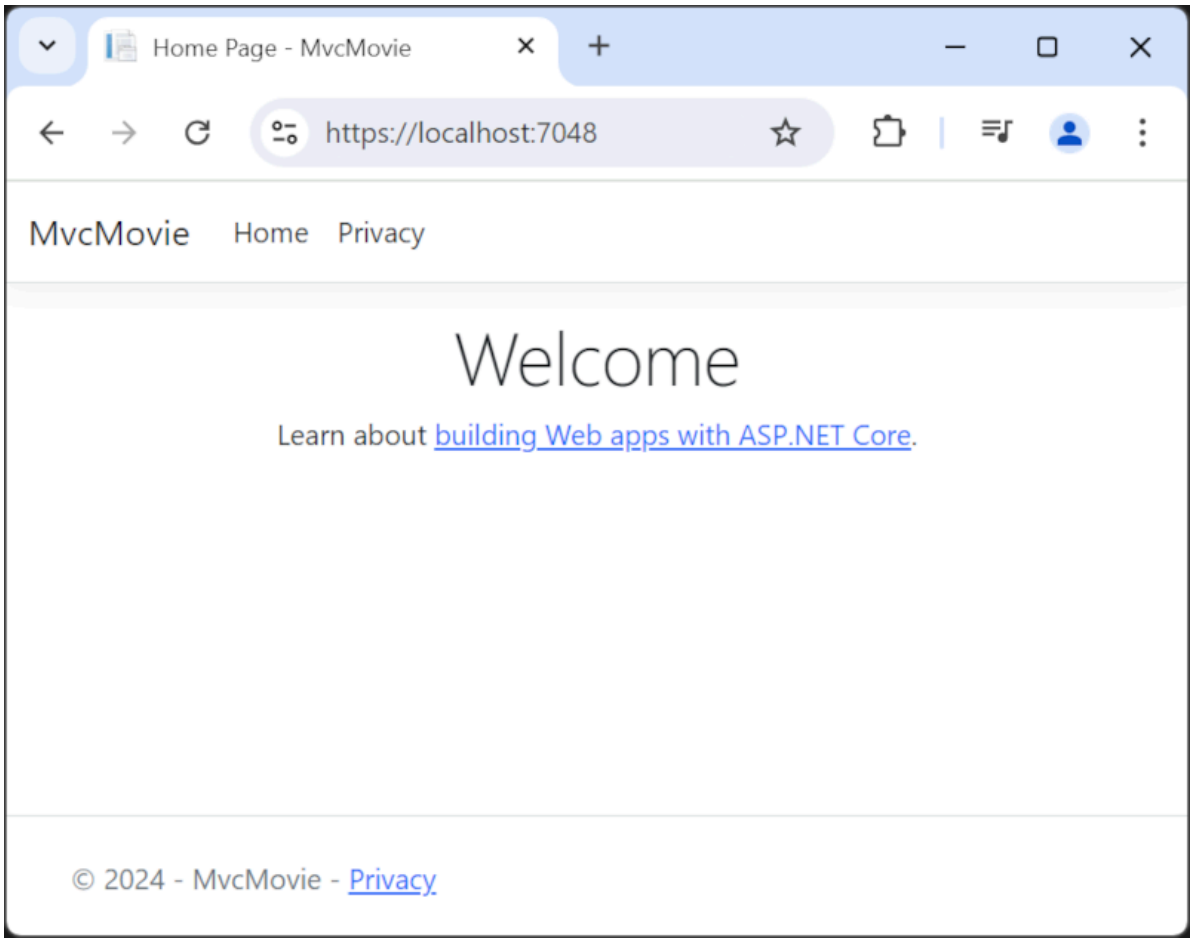
The address bar shows `localhost:<port#>` and not something like `example.com`. The standard hostname for your local computer is `localhost`. When Visual Studio creates a web project, a random port is used for the web server.

Launching the app without debugging by pressing `Ctrl`+`F5` allows you to:



- Make code changes.

- Save the file.
- Quickly refresh the browser and see the code changes.



You can launch the app in debug or non-debug mode from the **Debug** menu:

You can debug the app by selecting the **https** button in the toolbar:

The following image shows the app:

- Close the browser window. Visual Studio will stop the application.

Visual Studio

Visual Studio help

- Learn to debug C# code using Visual Studio
- Introduction to the Visual Studio IDE

In the next tutorial in this series, you learn about MVC and start writing some code.

Next: Add a controller

By Rick Anderson

The Model-View-Controller (MVC) architectural pattern separates an app into three main components: **M**odel, **V**iew, and **C**ontroller. The MVC pattern helps you create apps that are more testable and easier to update than traditional monolithic apps.

MVC-based apps contain:

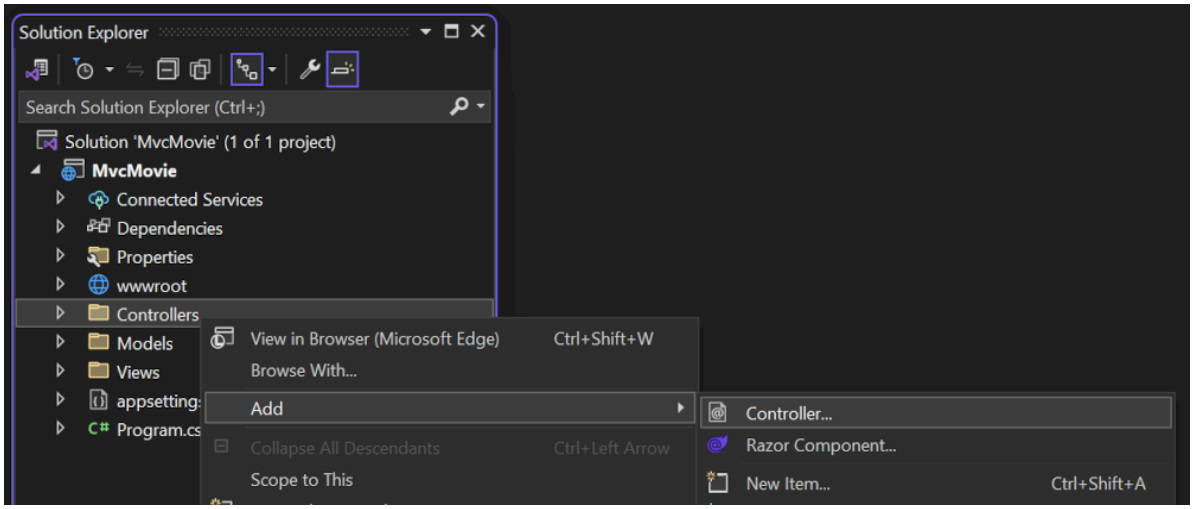
- **M**odels: Classes that represent the data of the app. The model classes use validation logic to enforce business rules for that data. Typically, model objects retrieve and store model state in a database. In this tutorial, a `Movie` model retrieves movie data from a database, provides it to the view or updates it. Updated data is written to a database.
- **V**iews: Views are the components that display the app's user interface (UI). Generally, this UI displays the model data.
- **C**ontrollers: Classes that:
  - Handle browser requests.
  - Retrieve model data.
  - Call view templates that return a response.

In an MVC app, the view only displays information. The controller handles and responds to user input and interaction. For example, the controller handles URL segments and query-string values, and passes these values to the model. The model might use these values to query the database. For example:

- `https://localhost:5001/Home/Privacy`: specifies the `Home` controller and the `Privacy` action.

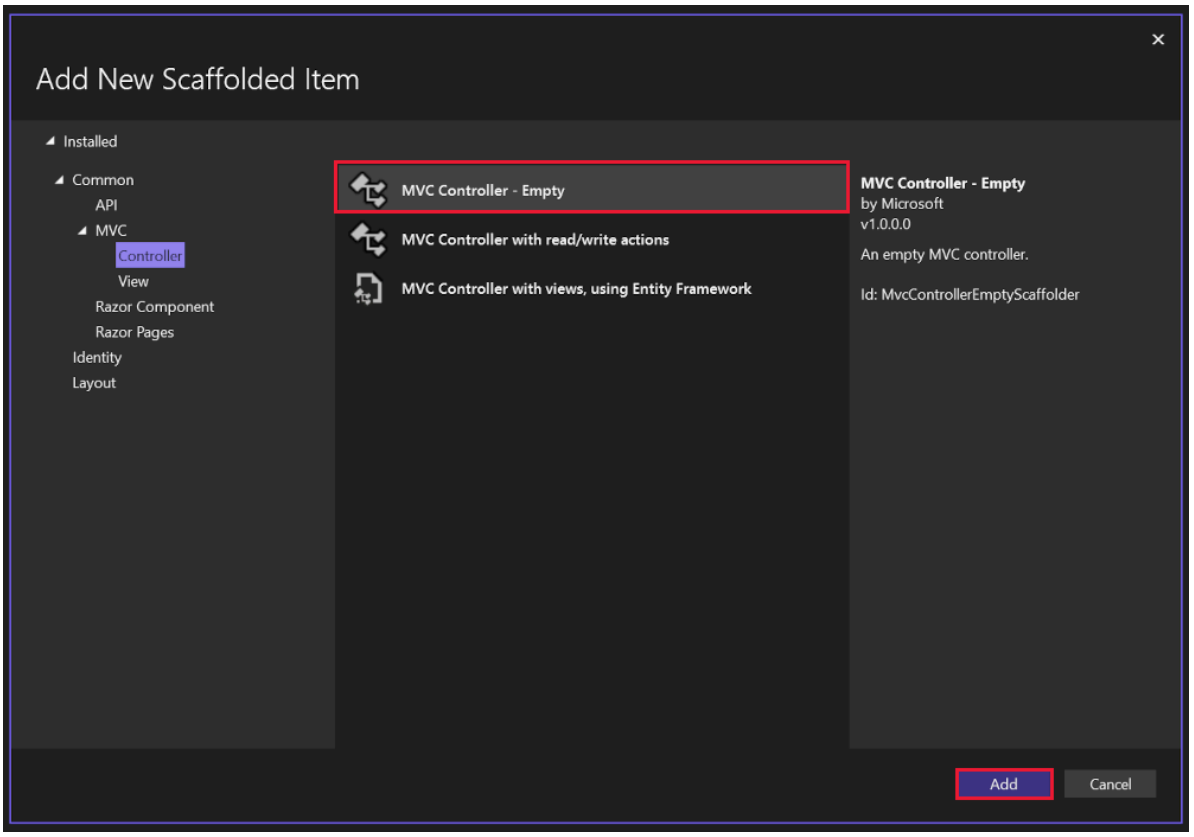
- `https://localhost:5001/Movies/Edit/5`: is a request to edit the movie with ID=5 using the `Movies` controller and the `Edit` action, which are detailed later in the tutorial.

Route data is explained later in the tutorial.



The MVC architectural pattern separates an app into three main groups of components: Models, Views, and Controllers. This pattern helps to achieve separation of concerns: The UI logic belongs in the view. Input logic belongs in the controller. Business logic belongs in the model. This separation helps manage complexity when building an app, because it enables work on one aspect of the implementation at a time without impacting the code of another. For example, you can work on the view code without depending on the business logic code.

These concepts are introduced and demonstrated in this tutorial series while building a movie app. The MVC project contains folders for the *Controllers* and *Views*.



Add a controller

Visual Studio

In **Solution Explorer**, right-click **Controllers** > **Add** > **Controller**.

In the **Add New Scaffolded Item** dialog box, select **MVC Controller - Empty** > **Add**.

In the **Add New Item - MvcMovie** dialog, enter `HelloWorldController.cs` and select **Add**.

Replace the contents of `Controllers/HelloWorldController.cs` with the following code:

C#

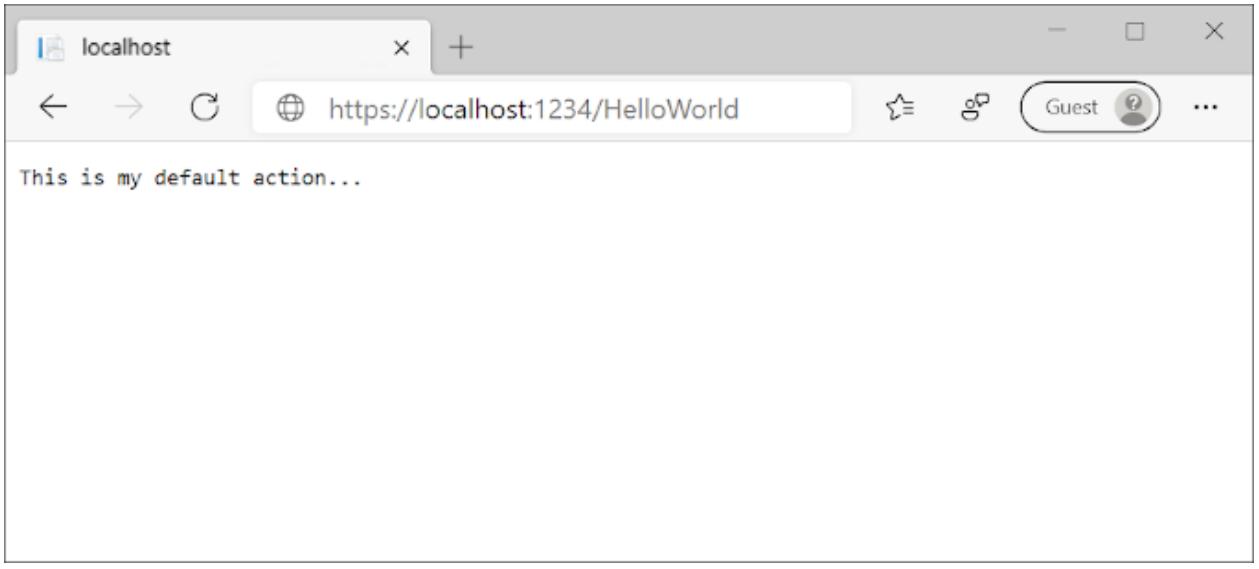
```
using Microsoft.AspNetCore.Mvc;
using System.Text.Encodings.Web;

namespace MvcMovie.Controllers;

public class HelloWorldController : Controller
{
    //
    // GET: /HelloWorld/
    public string Index()
    {
        return "This is my default action...";
    }
    //
    // GET: /HelloWorld/Welcome/
    public string Welcome()
    {
        return "This is the Welcome action method...";
    }
}
```

Every `public` method in a controller is callable as an HTTP endpoint. In the sample above, both methods return a string. Note the comments preceding each method.

An HTTP endpoint:



- Is a targetable URL in the web application, such as `https://localhost:5001/HelloWorld`.
- Combines:
  - The protocol used: `HTTPS`.
  - The network location of the web server, including the TCP port: `localhost:5001`.
  - The target URI: `HelloWorld`.

The first comment states this is an HTTP GET method that's invoked by appending `/HelloWorld/` to the base URL.

The second comment specifies an HTTP GET method that's invoked by appending `/HelloWorld/Welcome/` to the URL. Later on in the tutorial, the scaffolding engine is used to generate `HTTP POST` methods, which update data.

Run the app without the debugger by pressing `Ctrl`+`F5` (Windows) or `⌘`+`F5` (macOS).

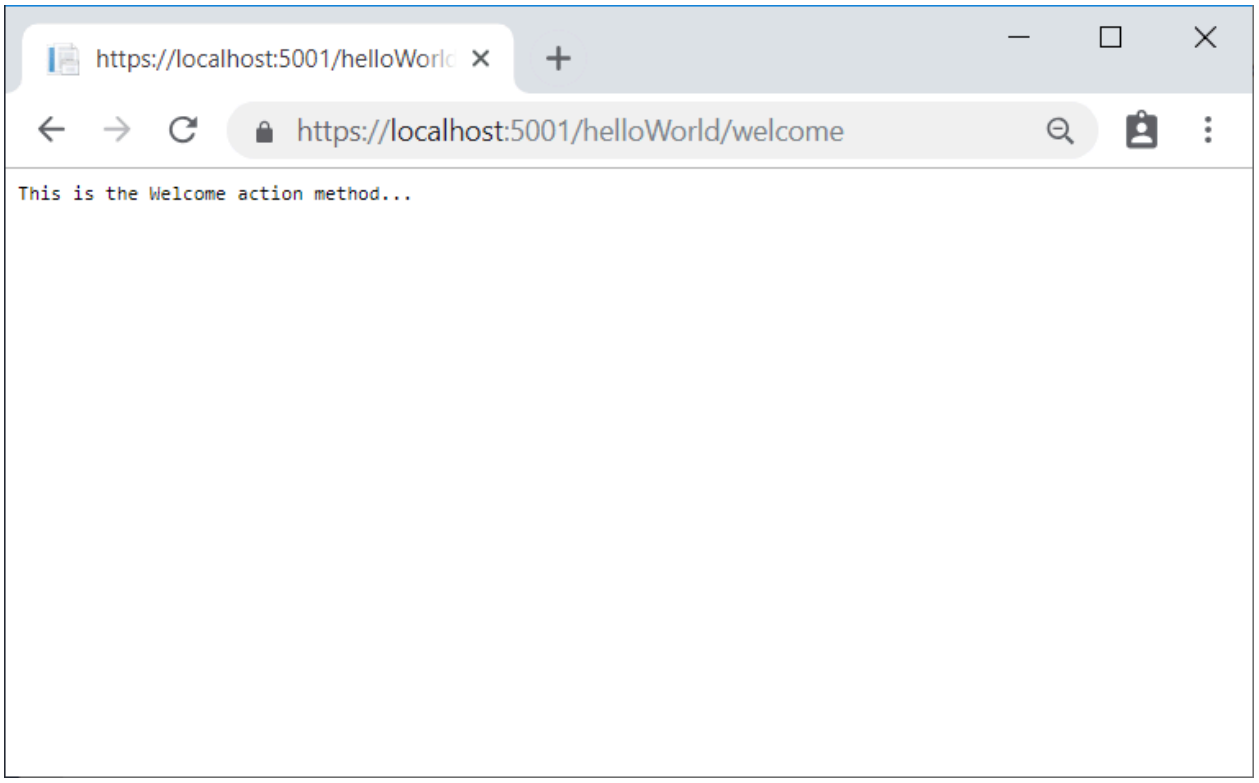
Append `/HelloWorld` to the path in the address bar. The `Index` method returns a string.

MVC invokes controller classes, and the action methods within them, depending on the incoming URL. The default URL routing logic used by MVC, uses a format like this to determine what code to invoke:

`/[Controller]/[ActionName]/[Parameters]`

The routing format is set in the `Program.cs` file.

C#



```
app.MapControllerRoute(
    name: "default",
    pattern: "{controller=Home}/{action=Index}/{id?}");
```

When you browse to the app and don't supply any URL segments, it defaults to the "Home" controller and the "Index" method specified in the template line highlighted above. In the preceding URL segments:

- The first URL segment determines the controller class to run. So `localhost:5001/HelloWorld` maps to the **HelloWorld** Controller class.
- The second part of the URL segment determines the action method on the class. So `localhost:5001/HelloWorld/Index` causes the `Index` method of the `HelloWorldController` class to run. Notice that you only had to browse to `localhost:5001/HelloWorld` and the `Index` method was called by default. `Index` is the default method that will be called on a controller if a method name isn't explicitly specified.
- The third part of the URL segment (`id`) is for route data. Route data is explained later in the tutorial.

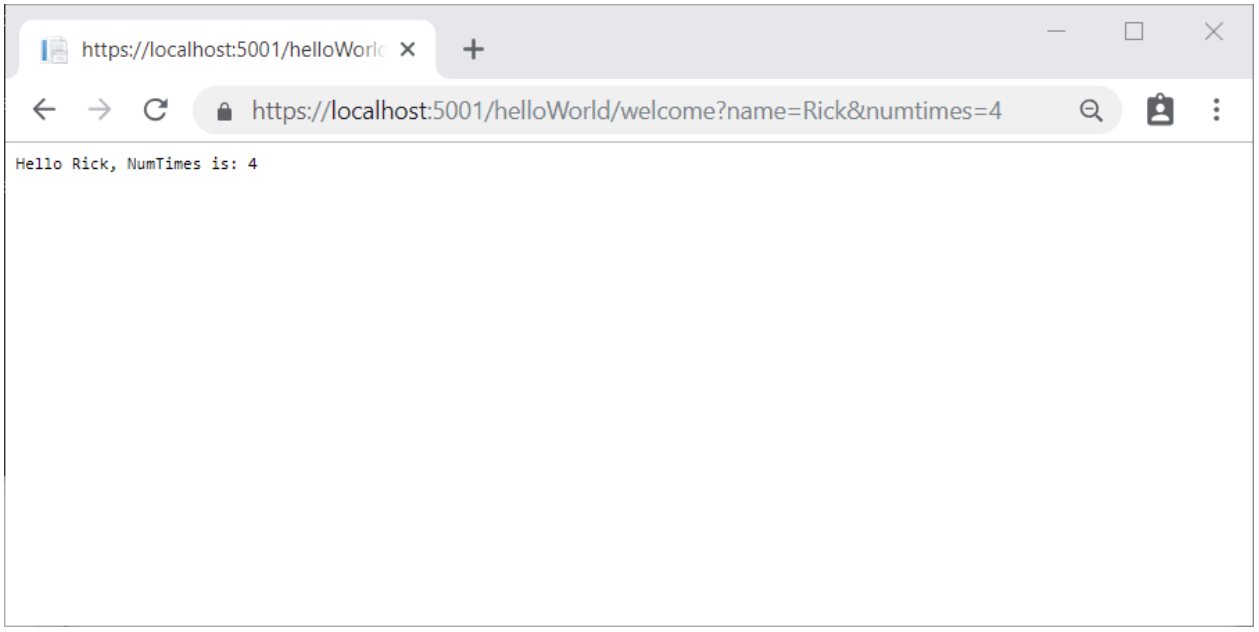
Browse to: `https://localhost:{PORT}/HelloWorld/Welcome`. Replace `{PORT}` with your port number.

The `Welcome` method runs and returns the string `This is the Welcome action method...`. For this URL, the controller is `HelloWorld` and `Welcome` is the action method. You haven't used the `[Parameters]` part of the URL yet.

Modify the code to pass some parameter information from the URL to the controller. For example, `/HelloWorld/Welcome?name=Rick&numtimes=4`.

Change the `Welcome` method to include two parameters as shown in the following code.

C#



```
// GET: /HelloWorld/Welcome/
// Requires using System.Text.Encodings.Web;
public string Welcome(string name, int numTimes = 1)
{
    return HtmlEncoder.Default.Encode($"Hello {name}, NumTimes is:
{numTimes}");
}
```

The preceding code:

- Uses the C# optional-parameter feature to indicate that the `numTimes` parameter defaults to 1 if no value is passed for that parameter.
- Uses `HtmlEncoder.Default.Encode` to protect the app from malicious input, such as through JavaScript.
- Uses Interpolated Strings in `$"Hello {name}, NumTimes is: {numTimes}"`.

Run the app and browse to: `https://localhost:{PORT}/HelloWorld/Welcome?name=Rick&numtimes=4`. Replace `{PORT}` with your port number.

Try different values for `name` and `numtimes` in the URL. The MVC model binding system automatically maps the named parameters from the query string to parameters in the method. See Model Binding for more information.

In the previous image:

- The URL segment `Parameters` isn't used.
- The `name` and `numTimes` parameters are passed in the query string.
- The `?` (question mark) in the above URL is a separator, and the query string follows.
- The `&` character separates field-value pairs.

Replace the `Welcome` method with the following code:

C#

```
public string Welcome(string name, int ID = 1)
{
    return HtmlEncoder.Default.Encode($"Hello {name}, ID: {ID}");
}
```

Run the app and enter the following URL: `https://localhost:{PORT}/HelloWorld/Welcome/3?name=Rick`

In the preceding URL:

- The third URL segment matched the route parameter `id`.
- The `Welcome` method contains a parameter `id` that matched the URL template in the `MapControllerRoute` method.
- The trailing `?` starts the query string.

C#

```
app.MapControllerRoute(
    name: "default",
    pattern: "{controller=Home}/{action=Index}/{id?}");
```

In the preceding example:

- The third URL segment matched the route parameter `id`.
- The `Welcome` method contains a parameter `id` that matched the URL template in the `MapControllerRoute` method.
- The trailing `?` (in `id?`) indicates the `id` parameter is optional.

Part 3, add a view to an ASP.NET Core MVC app

Article • 07/26/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Rick Anderson

In this section, you modify the `HelloWorldController` class to use Razor view files. This cleanly encapsulates the process of generating HTML responses to a client.

View templates are created using Razor. Razor-based view templates:

- Have a `.cshtml` file extension.
- Provide an elegant way to create HTML output with C#.

Currently the `Index` method returns a string with a message in the controller class. In the `HelloWorldController` class, replace the `Index` method with the following code:

C#

```
public IActionResult Index()
{
    return View();
}
```

The preceding code:

- Calls the controller's View method.
- Uses a view template to generate an HTML response.

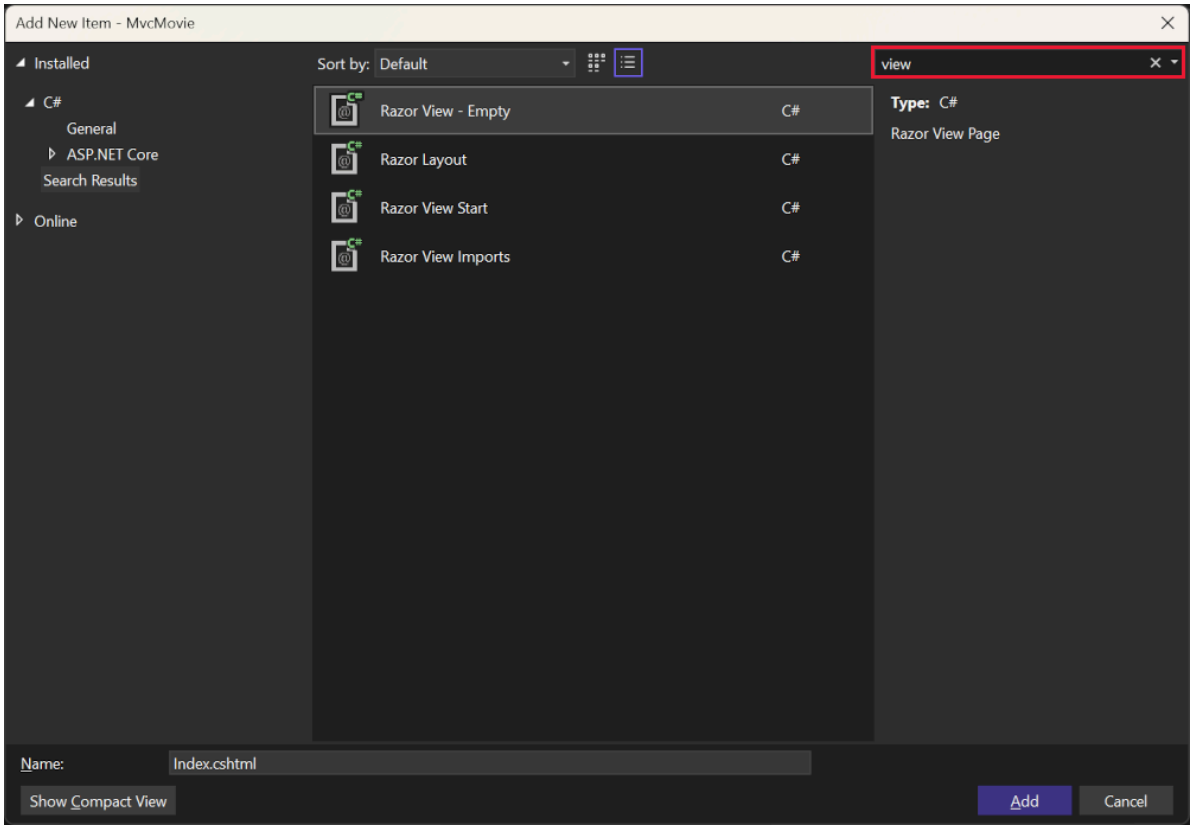
Controller methods:

- Are referred to as *action methods*. For example, the `Index` action method in the preceding code.

- Generally return an IActionResult or a class derived from ActionResult, not a type like `string`.

Add a view

Visual Studio



Right-click on the *Views* folder, and then **Add** > **New Folder** and name the folder *HelloWorld*.

Right-click on the *Views/HelloWorld* folder, and then **Add** > **New Item**.

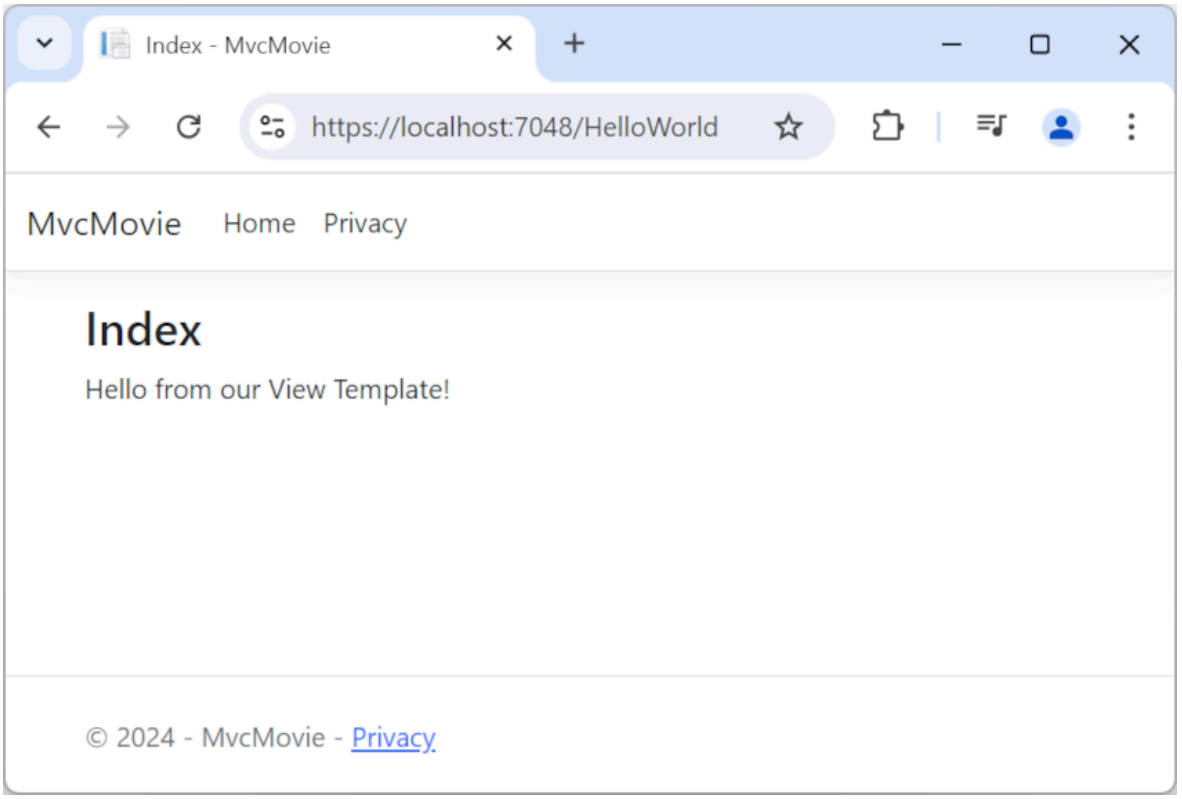
In the **Add New Item** dialog select **Show All Templates**.

In the **Add New Item - MvcMovie** dialog:

- In the search box in the upper-right, enter *view*
- Select **Razor View - Empty**
- Keep the **Name** box value, `Index.cshtml`.
- Select **Add**

Replace the contents of the `Views/HelloWorld/Index.cshtml` Razor view file with the following:

CSHTML



```
@{
    ViewData["Title"] = "Index";
}

<h2>Index</h2>

<p>Hello from our View Template!</p>
```

Navigate to `https://localhost:{PORT}/HelloWorld`:

- The `Index` method in the `HelloWorldController` ran the statement `return View();`, which specified that the method should use a view template file to render a response to the browser.
- A view template file name wasn't specified, so MVC defaulted to using the default view file. When the view file name isn't specified, the default view is returned. The default view has the same name as the action method, `Index` in this example. The view template `/Views/HelloWorld/Index.cshtml` is used.
- The following image shows the string "Hello from our View Template!" hard-coded in the view:

Change views and layout pages

Select the menu links **MvcMovie**, **Home**, and **Privacy**. Each page shows the same menu layout. The menu layout is implemented in the `Views/Shared/_Layout.cshtml` file.

Open the `Views/Shared/_Layout.cshtml` file.

Layout templates allow:

- Specifying the HTML container layout of a site in one place.
- Applying the HTML container layout across multiple pages in the site.

Find the `@RenderBody()` line. `RenderBody` is a placeholder where all the view-specific pages you create show up, *wrapped* in the layout page. For example, if you select the **Privacy** link, the `Views/Home/Privacy.cshtml` view is rendered inside the `RenderBody` method.

Change the title, footer, and menu link in the layout file

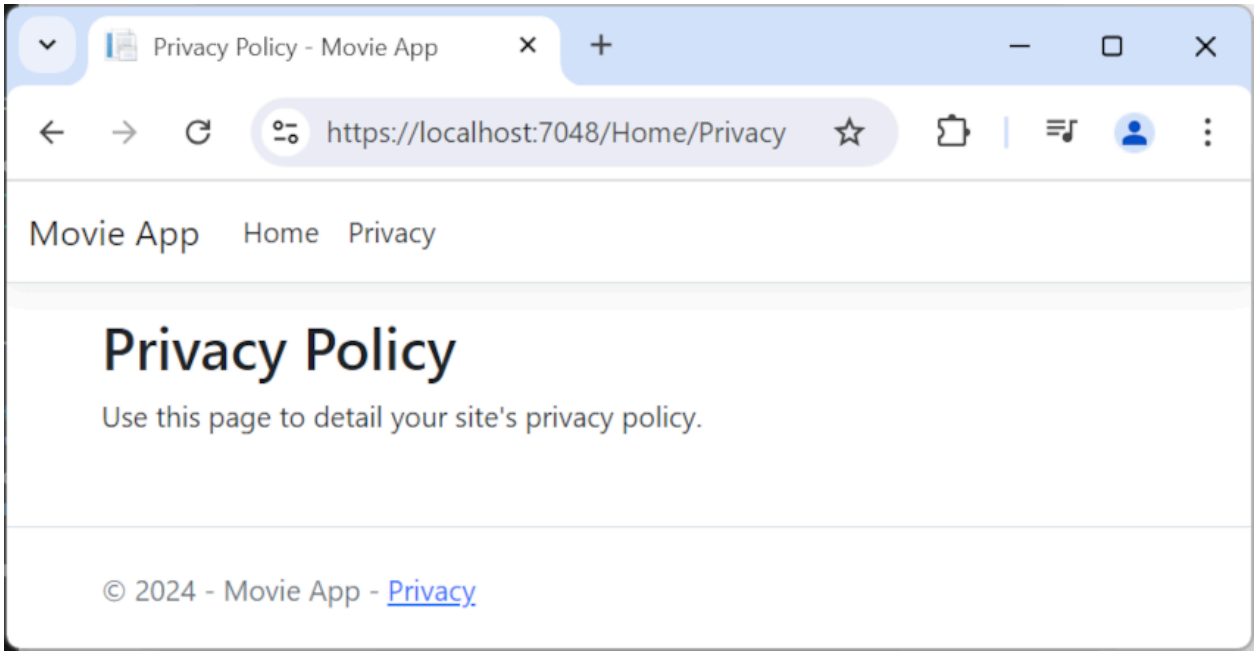
Replace the content of the `Views/Shared/_Layout.cshtml` file with the following markup. The changes are highlighted:

CSHTML

```
<!DOCTYPE html>
<html lang="en">
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - Movie App</title>
    <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.css" />
    <link rel="stylesheet" href="~/css/site.css" asp-append-version="true"
/>
    <link rel="stylesheet" href="~/MvcMovie.styles.css" asp-append-
version="true" />
</head>
<body>
    <header>
        <nav class="navbar navbar-expand-sm navbar-toggleable-sm navbar-
light bg-white border-bottom box-shadow mb-3">
            <div class="container-fluid">
                <a class="navbar-brand" asp-area="" asp-controller="Movies"
asp-action="Index">Movie App</a>
                <button class="navbar-toggler" type="button" data-bs-
toggle="collapse" data-bs-target=".navbar-collapse" aria-
controls="navbarSupportedContent"
                        aria-expanded="false" aria-label="Toggle
navigation">
                    <span class="navbar-toggler-icon"></span>
```

```
                </button>
                <div class="navbar-collapse collapse d-sm-inline-flex
justify-content-between">
                    <ul class="navbar-nav flex-grow-1">
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
controller="Home" asp-action="Index">Home</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
controller="Home" asp-action="Privacy">Privacy</a>
                        </li>
                    </ul>
                </div>
            </div>
        </nav>
    </header>
    <div class="container">
        <main role="main" class="pb-3">
            @RenderBody()
        </main>
    </div>

    <footer class="border-top footer text-muted">
        <div class="container">
            &copy; 2024 - Movie App - <a asp-area="" asp-controller="Home"
asp-action="Privacy">Privacy</a>
        </div>
    </footer>
    <script src="~/lib/jquery/dist/jquery.js"></script>
    <script src="~/lib/bootstrap/dist/js/bootstrap.js"></script>
    <script src="~/js/site.js" asp-append-version="true"></script>
    @await RenderSectionAsync("Scripts", required: false)
</body>
</html>
```



The preceding markup made the following changes:

- Three occurrences of `MvcMovie` to `Movie App`.
- The anchor element `<a class="navbar-brand" asp-area="" asp-controller="Home" asp-action="Index">MvcMovie</a>` to `<a class="navbar-brand" asp-controller="Movies" asp-action="Index">Movie App</a>`.

In the preceding markup, the `asp-area=""` anchor Tag Helper attribute and attribute value was omitted because this app isn't using Areas.

Note: The `Movies` controller hasn't been implemented. At this point, the `Movie App` link isn't functional.

Save the changes and select the **Privacy** link. Notice how the title on the browser tab displays **Privacy Policy - Movie App** instead of **Privacy Policy - MvcMovie**

Select the **Home** link.

Notice that the title and anchor text display **Movie App**. The changes were made once in the layout template and all pages on the site reflect the new link text and new title.

Examine the `Views/_ViewStart.cshtml` file:

CSHTML

```
@{
    Layout = "_Layout";
}
```

The `Views/_ViewStart.cshtml` file brings in the `Views/Shared/_Layout.cshtml` file to each view. The `Layout` property can be used to set a different layout view, or set it to `null` so no layout file will be used.

Open the `Views/HelloWorld/Index.cshtml` view file.

Change the title and `<h2>` element as highlighted in the following:

CSHTML

```
@{
    ViewData["Title"] = "Movie List";
}

<h2>My Movie List</h2>
```

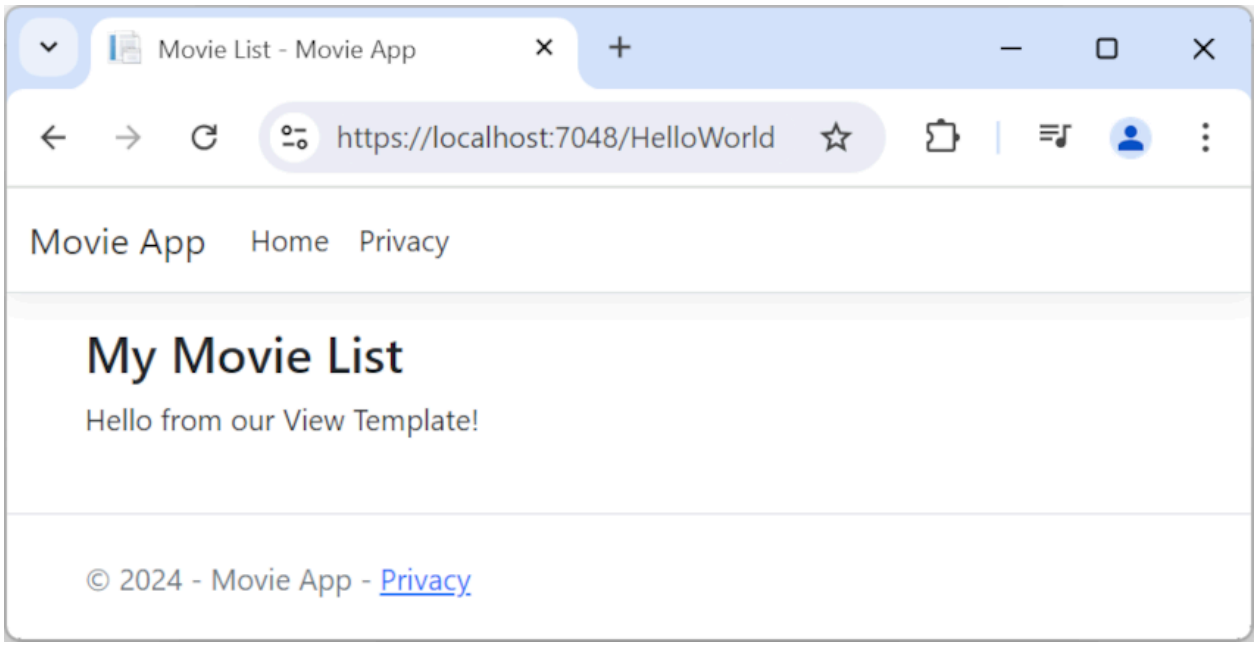
```
<p>Hello from our View Template!</p>
```

The title and `<h2>` element are slightly different so it's clear which part of the code changes the display.

`ViewData["Title"] = "Movie List";` in the code above sets the `Title` property of the `ViewData` dictionary to "Movie List". The `Title` property is used in the `<title>` HTML element in the layout page:

CSHTML

```
<title>@ViewData["Title"] - Movie App</title>
```



Save the change and navigate to `https://localhost:{PORT}/HelloWorld`.

Notice that the following have changed:

- Browser title.
- Primary heading.
- Secondary headings.

If there are no changes in the browser, it could be cached content that is being viewed. Press Ctrl+F5 in the browser to force the response from the server to be loaded. The browser title is created with `ViewData["Title"]` we set in the `Index.cshtml` view template and the additional "- Movie App" added in the layout file.

The content in the `Index.cshtml` view template is merged with the `Views/Shared/_Layout.cshtml` view template. A single HTML response is sent to the browser. Layout templates make it easy to make changes that apply across all of the pages in an app. To learn more, see Layout.

The small bit of "data", the "Hello from our View Template!" message, is hard-coded however. The MVC application has a "V" (view), a "C" (controller), but no "M" (model) yet.

Passing Data from the Controller to the View

Controller actions are invoked in response to an incoming URL request. A controller class is where the code is written that handles the incoming browser requests. The controller retrieves data from a data source and decides what type of response to send back to the browser. View templates can be used from a controller to generate and format an HTML response to the browser.

Controllers are responsible for providing the data required in order for a view template to render a response.

View templates should **not**:

- Do business logic
- Interact with a database directly.

A view template should work only with the data that's provided to it by the controller. Maintaining this "separation of concerns" helps keep the code:

- Clean.
- Testable.
- Maintainable.

Currently, the `Welcome` method in the `HelloWorldController` class takes a `name` and an `ID` parameter and then outputs the values directly to the browser.

Rather than have the controller render this response as a string, change the controller to use a view template instead. The view template generates a dynamic response, which means that appropriate data must be passed from the controller to the view to generate the response. Do this by having the controller put the dynamic data (parameters) that the view template needs in a `ViewData` dictionary. The view template can then access the dynamic data.

In `HelloWorldController.cs`, change the `Welcome` method to add a `Message` and `NumTimes` value to the `ViewData` dictionary.

The `ViewData` dictionary is a dynamic object, which means any type can be used. The `ViewData` object has no defined properties until something is added. The MVC model binding system automatically maps the named parameters `name` and `numTimes` from the query string to parameters in the method. The complete `HelloWorldController`:

C#

```
using Microsoft.AspNetCore.Mvc;
using System.Text.Encodings.Web;

namespace MvcMovie.Controllers;

public class HelloWorldController : Controller
{
    public IActionResult Index()
    {
        return View();
    }
    public IActionResult Welcome(string name, int numTimes = 1)
    {
        ViewData["Message"] = "Hello " + name;
        ViewData["NumTimes"] = numTimes;
        return View();
    }
}
```

The `ViewData` dictionary object contains data that will be passed to the view.

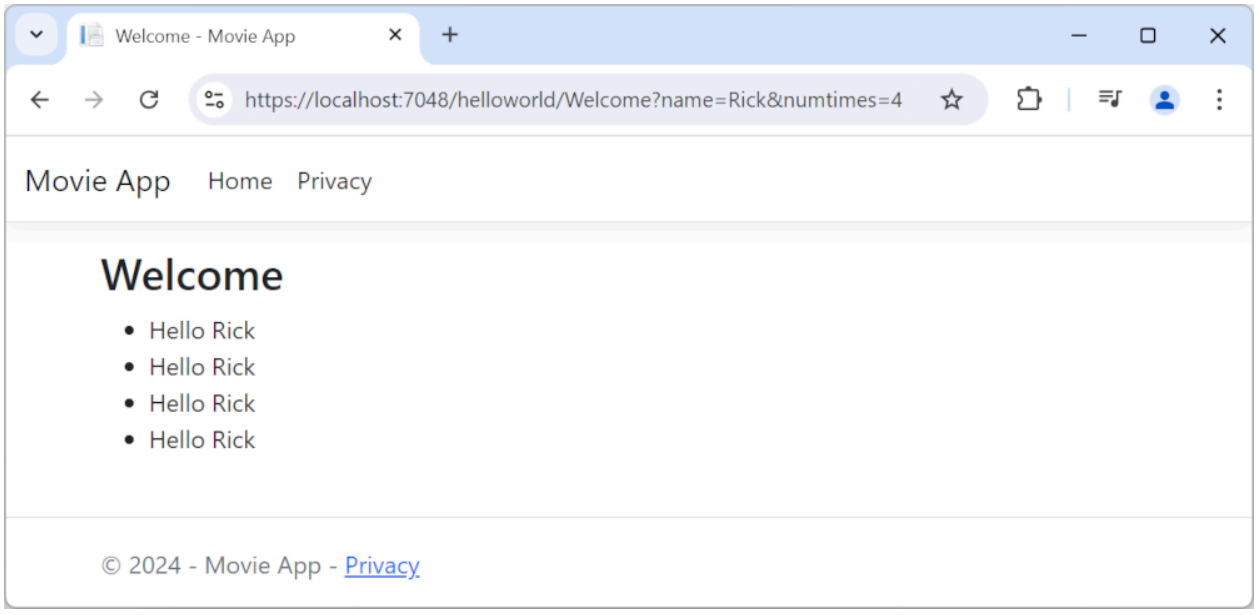
Create a Welcome view template named `Views/HelloWorld/Welcome.cshtml`.

You'll create a loop in the `Welcome.cshtml` view template that displays "Hello" `NumTimes`. Replace the contents of `Views/HelloWorld/Welcome.cshtml` with the following:

CSHTML

```
@{
    ViewData["Title"] = "Welcome";
```

```
}



<h2>Welcome</h2>

<ul>
    @for (int i = 0; i < (int)ViewData["NumTimes"]!; i++)
    {
        <li>@ViewData["Message"]</li>
    }
</ul>
```

Save your changes and browse to the following URL:

`https://localhost:{PORT}/HelloWorld/Welcome?name=Rick&numtimes=4`

Data is taken from the URL and passed to the controller using the MVC model binder. The controller packages the data into a `ViewData` dictionary and passes that object to the view. The view then renders the data as HTML to the browser.

In the preceding sample, the `ViewData` dictionary was used to pass data from the controller to a view. Later in the tutorial, a view model is used to pass data from a controller to a view. The view model approach to passing data is preferred over the `ViewData` dictionary approach.

In the next tutorial, a database of movies is created.

Part 4, add a model to an ASP.NET Core MVC app

Article • 07/26/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Rick Anderson and Jon P Smith.

In this tutorial, classes are added for managing movies in a database. These classes are the "**M**odel" part of the **M**VC app.

These model classes are used with Entity Framework Core (EF Core) to work with a database. EF Core is an object-relational mapping (ORM) framework that simplifies the data access code that you have to write.

The model classes created are known as ***POCO*** classes, from **P**lain **O**ld **C**LR **O**bjects. POCO classes don't have any dependency on EF Core. They only define the properties of the data to be stored in the database.

In this tutorial, model classes are created first, and EF Core creates the database.

Add a data model class

Visual Studio

Right-click the *Models* folder > **Add** > **Class**. Name the file `Movie.cs`.

Update the `Models/Movie.cs` file with the following code:

C#

```
using System.ComponentModel.DataAnnotations;

namespace MvcMovie.Models;
```

```
public class Movie
{
    public int Id { get; set; }
    public string? Title { get; set; }
    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }
    public string? Genre { get; set; }
    public decimal Price { get; set; }
}
```

The `Movie` class contains an `Id` field, which is required by the database for the primary key.

The DataType attribute on `ReleaseDate` specifies the type of the data (`Date`). With this attribute:

- The user isn't required to enter time information in the date field.
- Only the date is displayed, not time information.

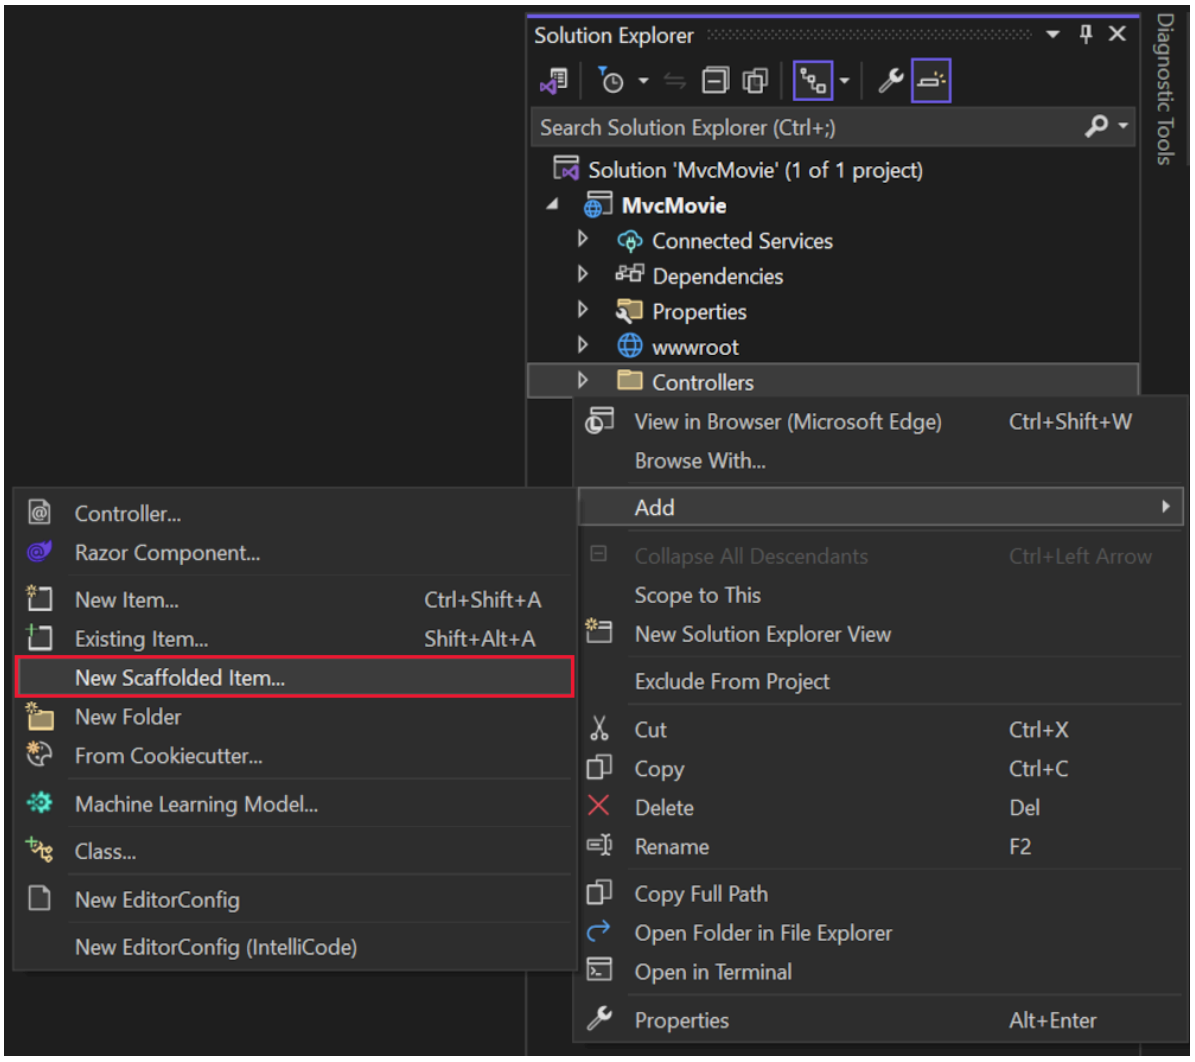
DataAnnotations are covered in a later tutorial.

The question mark after `string` indicates that the property is nullable. For more information, see Nullable reference types.

Add NuGet packages

Visual Studio

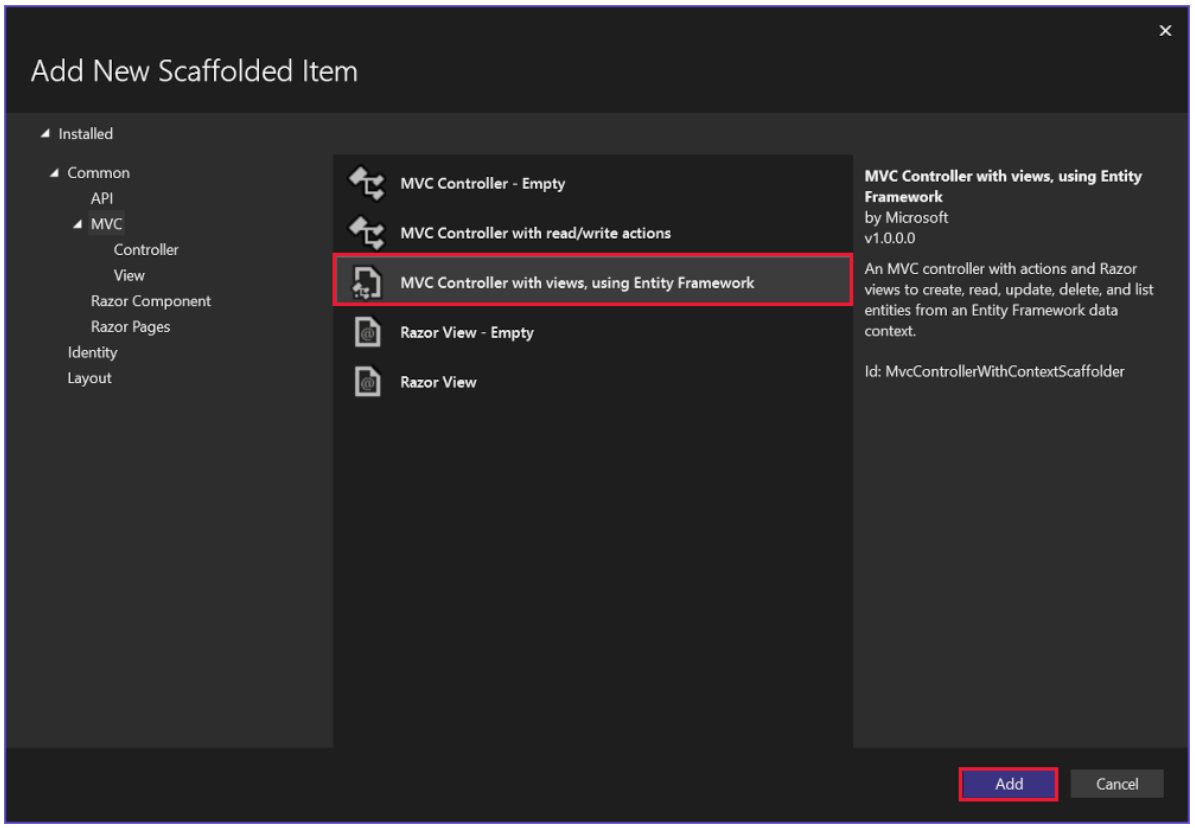
Visual Studio automatically installs the required packages.



Build the project as a check for compiler errors.

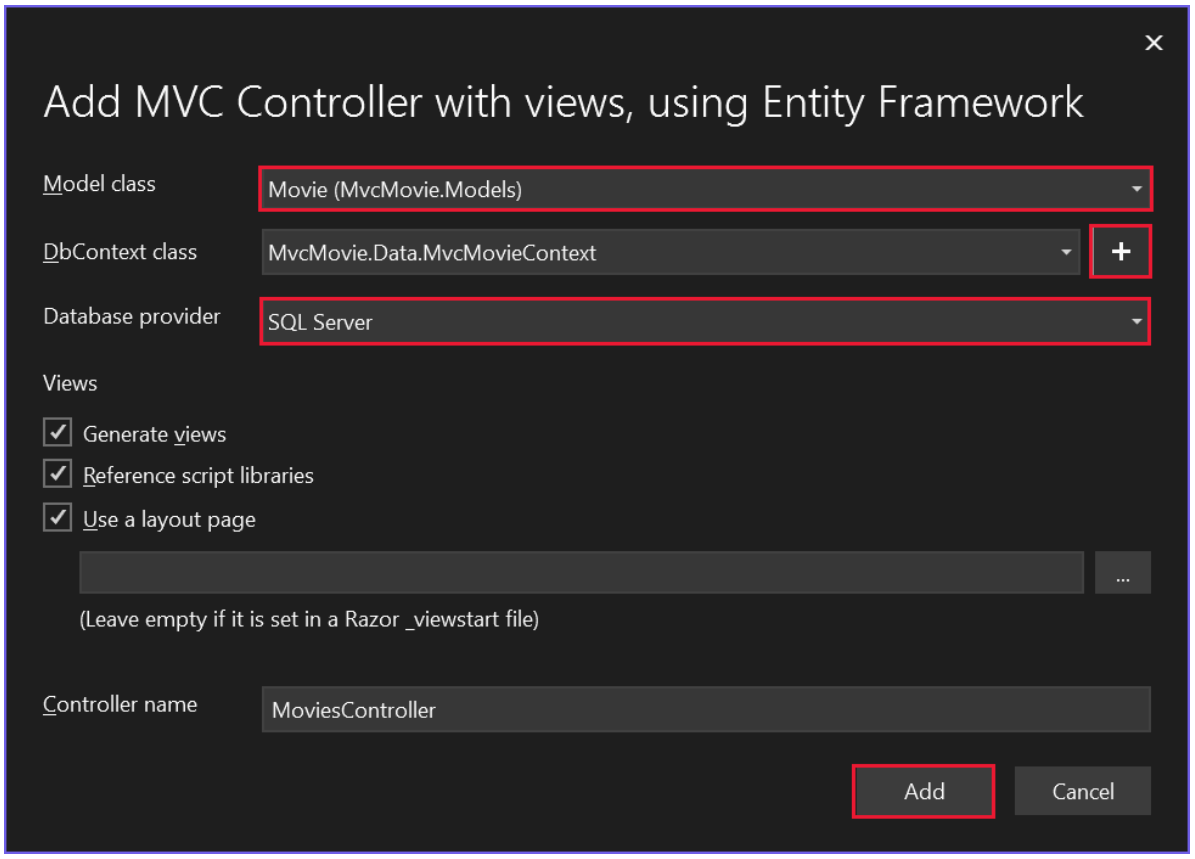
Scaffold movie pages

Use the scaffolding tool to produce `Create`, `Read`, `Update`, and `Delete` (CRUD) pages for the movie model.



Visual Studio

In **Solution Explorer**, right-click the *Controllers* folder and select **Add** > **New Scaffolded Item**.



In the **Add New Scaffolded Item** dialog:

- In the left pane, select **Installed** > **Common** > **MVC**.
- Select **MVC Controller with views, using Entity Framework**.
- Select **Add**.

Complete the **Add MVC Controller with views, using Entity Framework** dialog:

- In the **Model class** drop down, select **Movie (MvcMovie.Models)**.
- In the **Data context class** row, select the + (plus) sign.
  - In the **Add Data Context** dialog, the class name *MvcMovie.Data.MvcMovieContext* is generated.
  - Select **Add**.
- In the **Database provider** drop down, select **SQL Server**.
- **Views** and **Controller name**: Keep the default.
- Select **Add**.

If you get an error message, select **Add** a second time to try it again.

Scaffolding adds the following packages:

- `Microsoft.EntityFrameworkCore.SqlServer`
- `Microsoft.EntityFrameworkCore.Tools`
- `Microsoft.VisualStudio.Web.CodeGeneration.Design`

Scaffolding creates the following:

- A movies controller: `Controllers/MoviesController.cs`
- Razor view files for **Create**, **Delete**, **Details**, **Edit**, and **Index** pages: `Views/Movies/*.cshtml`
- A database context class: `Data/MvcMovieContext.cs`

Scaffolding updates the following:

- Inserts required package references in the `MvcMovie.csproj` project file.
- Registers the database context in the `Program.cs` file.
- Adds a database connection string to the `appsettings.json` file.

The automatic creation of these files and file updates is known as *scaffolding*.

The scaffolded pages can't be used yet because the database doesn't exist. Running the app and selecting the **Movie App** link results in a *Cannot open database* or *no*

such table: Movie error message.

Build the app to verify that there are no errors.

Initial migration

Use the EF Core Migrations feature to create the database. *Migrations* is a set of tools that create and update a database to match the data model.

Visual Studio

From the **Tools** menu, select **NuGet Package Manager** > **Package Manager Console** .

In the Package Manager Console (PMC), enter the following command:

```
PowerShell

Add-Migration InitialCreate
```

- `Add-Migration InitialCreate`: Generates a `Migrations/{timestamp}_InitialCreate.cs` migration file. The `InitialCreate` argument is the migration name. Any name can be used, but by convention, a name is selected that describes the migration. Because this is the first migration, the generated class contains code to create the database schema. The database schema is based on the model specified in the `MvcMovieContext` class.

The following warning is displayed, which is addressed in a later step:

> No store type was specified for the decimal property 'Price' on entity type 'Movie'. This will cause values to be silently truncated if they do not fit in the default precision and scale. Explicitly specify the SQL server column type that can accommodate all the values in 'OnModelCreating' using 'HasColumnType', specify precision and scale using 'HasPrecision', or configure a value converter using 'HasConversion'.

In the PMC, enter the following command:

```
PowerShell
```

```
Update-Database
```

- `Update-Database`: Updates the database to the latest migration, which the previous command created. This command runs the `Up` method in the `Migrations/{time-stamp}_InitialCreate.cs` file, which creates the database.

For more information on the PMC tools for EF Core, see EF Core tools reference - PMC in Visual Studio.

Test the app

Visual Studio

Run the app and select the **Movie App** link.

If you get an exception similar to the following, you may have missed the `Update-Database` command in the migrations step:

Console

```
SqlException: Cannot open database "MvcMovieContext-1" requested by the
login. The login failed.
```

Note

You may not be able to enter decimal commas in the `Price` field. To support jQuery validation for non-English locales that use a comma (",") for a decimal point and for non US-English date formats, the app must be globalized. For globalization instructions, see this GitHub issue.

Examine the generated database context class and registration

With EF Core, data access is performed using a model. A model is made up of entity classes and a context object that represents a session with the database. The context object allows querying and saving data. The database context is derived from

Microsoft.EntityFrameworkCore.DbContext and specifies the entities to include in the data model.

Scaffolding creates the `Data/MvcMovieContext.cs` database context class:

C#

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.EntityFrameworkCore;
using MvcMovie.Models;

namespace MvcMovie.Data
{
    public class MvcMovieContext : DbContext
    {
        public MvcMovieContext (DbContextOptions<MvcMovieContext> options)
            : base(options)
        {
        }

        public DbSet<MvcMovie.Models.Movie> Movie { get; set; } = default!;
    }
}
```

The preceding code creates a DbSet<Movie> property that represents the movies in the database.

Dependency injection

ASP.NET Core is built with dependency injection (DI). Services, such as the database context, are registered with DI in `Program.cs`. These services are provided to components that require them via constructor parameters.

In the `Controllers/MoviesController.cs` file, the constructor uses Dependency Injection to inject the `MvcMovieContext` database context into the controller. The database context is used in each of the CRUD methods in the controller.

Scaffolding generated the following highlighted code in `Program.cs`:

Visual Studio

C#

```
var builder = WebApplication.CreateBuilder(args);
builder.Services.AddDbContext<MvcMovieContext>(options =>

options.UseSqlServer(builder.Configuration.GetConnectionString("MvcMovie
Context") ?? throw new InvalidOperationException("Connection string
'MvcMovieContext' not found.")));
```

The ASP.NET Core configuration system reads the "MvcMovieContext" database connection string.

Examine the generated database connection string

Scaffolding added a connection string to the `appsettings.json` file:

Visual Studio

JSON

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft.AspNetCore": "Warning"
    }
  },
  "AllowedHosts": "*",
  "ConnectionStrings": {
    "MvcMovieContext": "Server=
(localdb)\\mssqllocaldb;Database=MvcMovieContext-4ebefa10-de29-4dea-
b2ad-8a8dc6bcf374;Trusted_Connection=True;MultipleActiveResultSets=true"
  }
}
```

For local development, the ASP.NET Core configuration system reads the `ConnectionString` key from the `appsettings.json` file.

The `InitialCreate` class

Examine the `Migrations/{timestamp}_InitialCreate.cs` migration file:

C#

```
using System;
using Microsoft.EntityFrameworkCore.Migrations;
```

```
#nullable disable

namespace MvcMovie.Migrations
{
    /// <inheritdoc />
    public partial class InitialCreate : Migration
    {
        /// <inheritdoc />
        protected override void Up(MigrationBuilder migrationBuilder)
        {
            migrationBuilder.CreateTable(
                name: "Movie",
                columns: table => new
                {
                    Id = table.Column<int>(type: "int", nullable: false)
                        .Annotation("SqlServer:Identity", "1, 1"),
                    Title = table.Column<string>(type: "nvarchar(max)",
nullable: true),
                    ReleaseDate = table.Column<DateTime>(type: "datetime2",
nullable: false),
                    Genre = table.Column<string>(type: "nvarchar(max)",
nullable: true),
                    Price = table.Column<decimal>(type: "decimal(18,2)",
nullable: false)
                },
                constraints: table =>
                {
                    table.PrimaryKey("PK_Movie", x => x.Id);
                });
        }

        /// <inheritdoc />
        protected override void Down(MigrationBuilder migrationBuilder)
        {
            migrationBuilder.DropTable(
                name: "Movie");
        }
    }
}
```

In the preceding code:

- `InitialCreate.Up` creates the Movie table and configures `Id` as the primary key.
- `InitialCreate.Down` reverts the schema changes made by the `Up` migration.

Dependency injection in the controller

Open the `Controllers/MoviesController.cs` file and examine the constructor:

```
C#
```

```
public class MoviesController : Controller
{
    private readonly MvcMovieContext _context;

    public MoviesController(MvcMovieContext context)
    {
        _context = context;
    }
```

The constructor uses Dependency Injection to inject the database context (`MvcMovieContext`) into the controller. The database context is used in each of the CRUD methods in the controller.

Test the **Create** page. Enter and submit data.

Test the **Edit**, **Details**, and **Delete** pages.

Strongly typed models and the `@model` directive

Earlier in this tutorial, you saw how a controller can pass data or objects to a view using the `ViewData` dictionary. The `ViewData` dictionary is a dynamic object that provides a convenient late-bound way to pass information to a view.

MVC provides the ability to pass strongly typed model objects to a view. This strongly typed approach enables compile time code checking. The scaffolding mechanism passed a strongly typed model in the `MoviesController` class and views.

Examine the generated `Details` method in the `Controllers/MoviesController.cs` file:

C#

```
// GET: Movies/Details/5
public async Task<IActionResult> Details(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var movie = await _context.Movie
        .FirstOrDefaultAsync(m => m.Id == id);
    if (movie == null)
    {
        return NotFound();
    }
```

```
    return View(movie);
}
```

The `id` parameter is generally passed as route data. For example, `https://localhost:5001/movies/details/1` sets:

- The controller to the `movies` controller, the first URL segment.
- The action to `details`, the second URL segment.
- The `id` to 1, the last URL segment.

The `id` can be passed in with a query string, as in the following example:

`https://localhost:5001/movies/details?id=1`

The `id` parameter is defined as a nullable type (`int?`) in cases when the `id` value isn't provided.

A lambda expression is passed in to the FirstOrDefaultAsync method to select movie entities that match the route data or query string value.

C#

```
var movie = await _context.Movie
    .FirstOrDefaultAsync(m => m.Id == id);
```

If a movie is found, an instance of the `Movie` model is passed to the `Details` view:

C#

```
return View(movie);
```

Examine the contents of the `Views/Movies/Details.cshtml` file:

CSHTML

```
@model MvcMovie.Models.Movie

@{
    ViewData["Title"] = "Details";
}

<h1>Details</h1>

<div>
    <h4>Movie</h4>
    <hr />
```

```
    <dl class="row">
        <dt class = "col-sm-2">
            @Html.DisplayNameFor(model => model.Title)
        </dt>
        <dd class = "col-sm-10">
            @Html.DisplayFor(model => model.Title)
        </dd>
        <dt class = "col-sm-2">
            @Html.DisplayNameFor(model => model.ReleaseDate)
        </dt>
        <dd class = "col-sm-10">
            @Html.DisplayFor(model => model.ReleaseDate)
        </dd>
        <dt class = "col-sm-2">
            @Html.DisplayNameFor(model => model.Genre)
        </dt>
        <dd class = "col-sm-10">
            @Html.DisplayFor(model => model.Genre)
        </dd>
        <dt class = "col-sm-2">
            @Html.DisplayNameFor(model => model.Price)
        </dt>
        <dd class = "col-sm-10">
            @Html.DisplayFor(model => model.Price)
        </dd>
    </dl>
</div>
<div>
    <a asp-action="Edit" asp-route-id="@Model.Id">Edit</a> |
    <a asp-action="Index">Back to List</a>
</div>
```

The `@model` statement at the top of the view file specifies the type of object that the view expects. When the movie controller was created, the following `@model` statement was included:

CSHTML

```
@model MvcMovie.Models.Movie
```

This `@model` directive allows access to the movie that the controller passed to the view. The `Model` object is strongly typed. For example, in the `Details.cshtml` view, the code passes each movie field to the `DisplayNameFor` and `DisplayFor` HTML Helpers with the strongly typed `Model` object. The `Create` and `Edit` methods and views also pass a `Movie` model object.

Examine the `Index.cshtml` view and the `Index` method in the Movies controller. Notice how the code creates a `List` object when it calls the `View` method. The code passes this

`Movies` list from the `Index` action method to the view:

C#

```
// GET: Movies
public async Task<IActionResult> Index()
{
    return View(await _context.Movie.ToListAsync());
}
```

The code returns problem details if the `Movie` property of the data context is null.

When the movies controller was created, scaffolding included the following `@model` statement at the top of the `Index.cshtml` file:

CSHTML

```
@model IEnumerable<MvcMovie.Models.Movie>
```

The `@model` directive allows access to the list of movies that the controller passed to the view by using a `Model` object that's strongly typed. For example, in the `Index.cshtml` view, the code loops through the movies with a `foreach` statement over the strongly typed `Model` object:

CSHTML

```
@model IEnumerable<MvcMovie.Models.Movie>

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-action="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.ReleaseDate)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Genre)
```

```
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Price)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
@foreach (var item in Model) {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.Title)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.ReleaseDate)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Genre)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Price)
            </td>
            <td>
                <a asp-action="Edit" asp-route-id="@item.Id">Edit</a> |
                <a asp-action="Details" asp-route-id="@item.Id">Details</a>
|
                <a asp-action="Delete" asp-route-id="@item.Id">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

Because the `Model` object is strongly typed as an `IEnumerable<Movie>` object, each item in the loop is typed as `Movie`. Among other benefits, the compiler validates the types used in the code.

> For the current release, see the .NET 8 version of this article.

By Rick Anderson and Jon P Smith.

The `MvcMovieContext` object handles the task of connecting to the database and mapping `Movie` objects to database records. The database context is registered with the Dependency Injection container in the `Program.cs` file:

Visual Studio

C#

```
var builder = WebApplication.CreateBuilder(args);
builder.Services.AddDbContext<MvcMovieContext>(options =>

options.UseSqlServer(builder.Configuration.GetConnectionString("MvcMovie
Context") ?? throw new InvalidOperationException("Connection string
'MvcMovieContext' not found.")));
```

The ASP.NET Core Configuration system reads the `ConnectionString` key. For local development, it gets the connection string from the `appsettings.json` file:

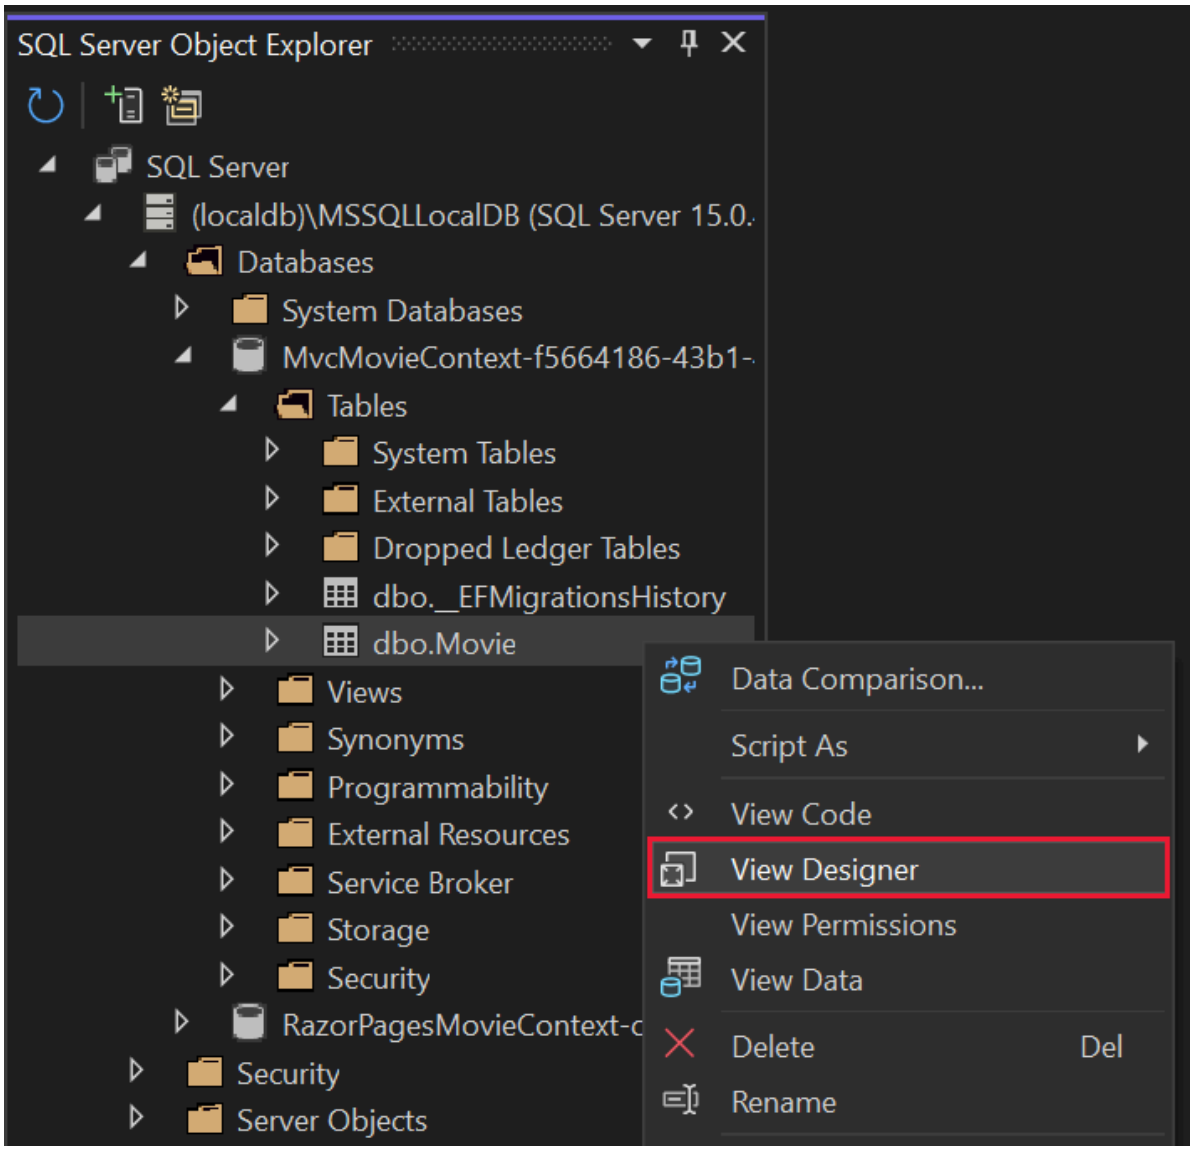
JSON

```
"ConnectionStrings": {
  "MvcMovieContext": "Server=
(localdb)\\mssqllocaldb;Database=MvcMovieContext-4ebefa10-de29-4dea-
b2ad-8a8dc6bcf374;Trusted_Connection=True;MultipleActiveResultSets=true"
}
```

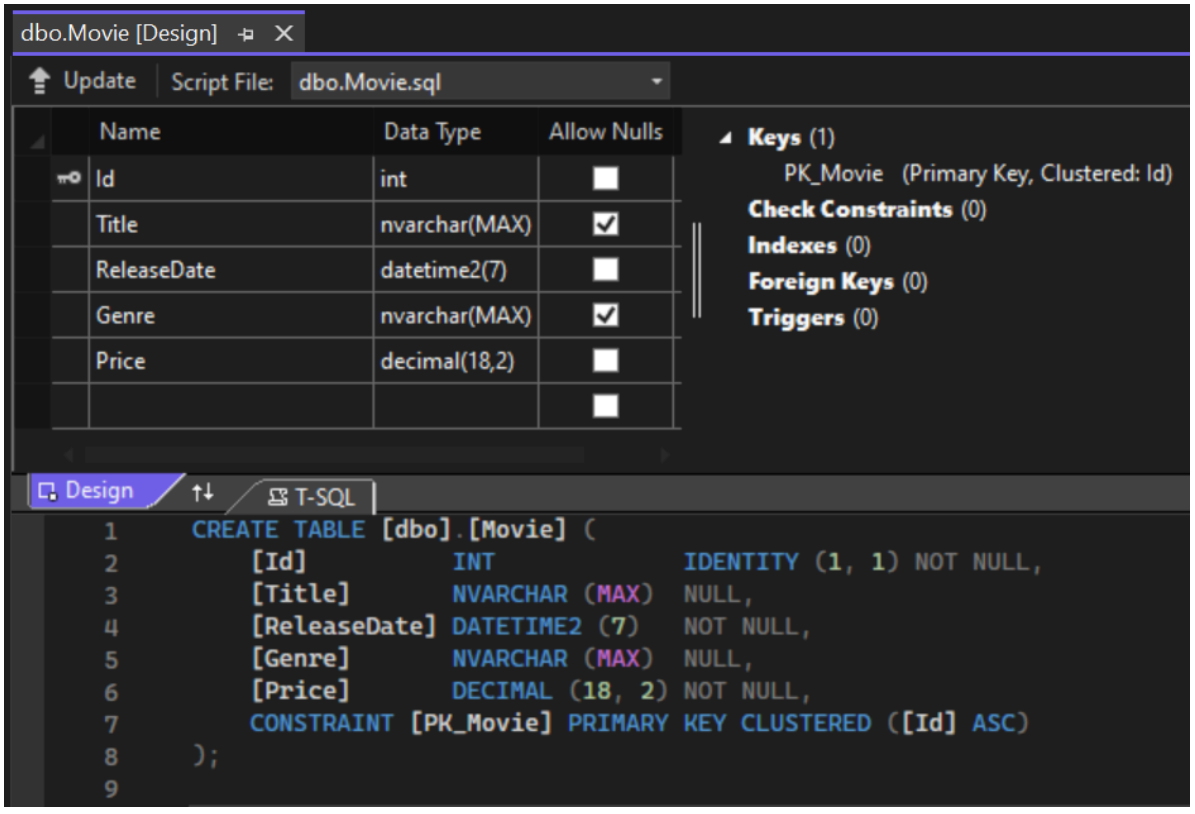
> **Note**
>
> This article uses a local database that doesn't require the user to be authenticated. Production apps should use the most secure authentication flow available. For more information on authentication for deployed test and production apps, see Secure authentication flows.

Visual Studio

SQL Server Express LocalDB



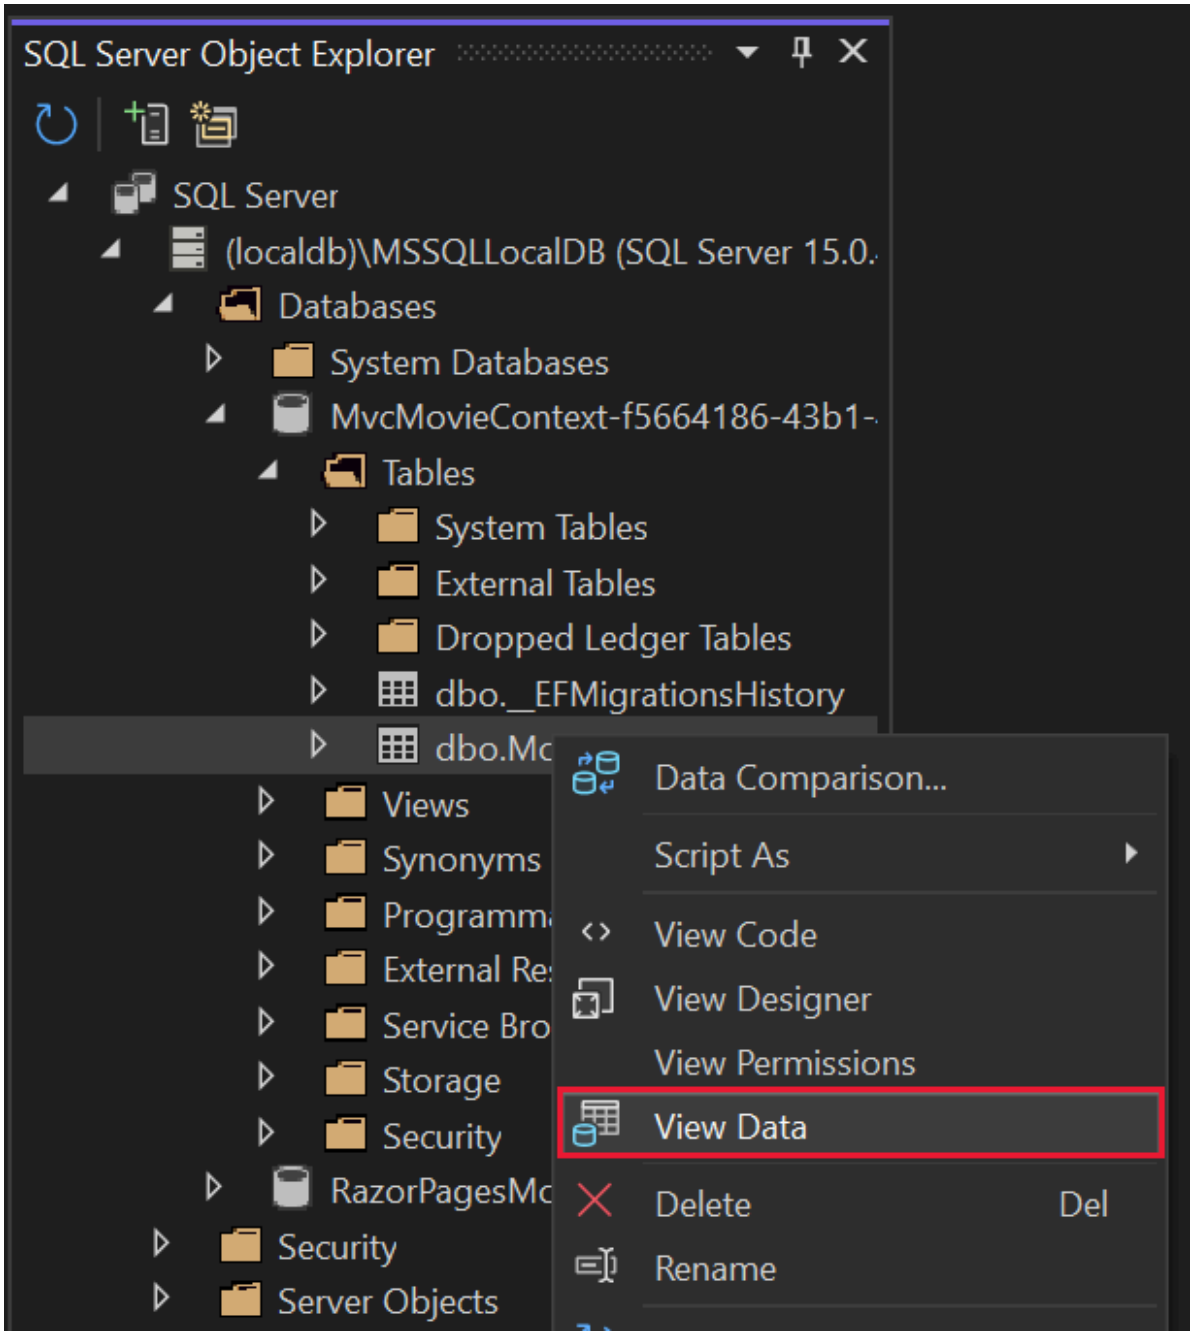
LocalDB:



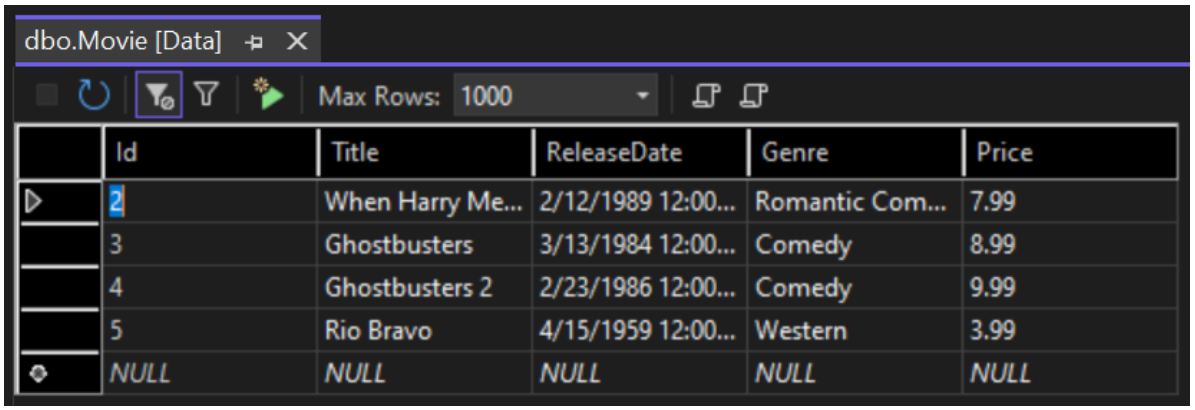
- Is a lightweight version of the SQL Server Express Database Engine, installed by default with Visual Studio.
- Starts on demand by using a connection string.
- Is targeted for program development. It runs in user mode, so there's no complex configuration.
- By default creates *.mdf* files in the *C:/Users/{user}* directory.

Examine the database

From the **View** menu, open **SQL Server Object Explorer** (SSOX).



Right-click on the `Movie` table (`dbo.Movie`) > **View Designer**



SQL Server Object Explorer
SQL Server
(localdb)\MSSQLLocalDB (SQL Server 15.0.

T-SQL
CREATE TABLE [dbo].[Movie] (
[Id] INT IDENTITY (1, 1) NOT NULL,
[Title] NVARCHAR (MAX) NULL,
[ReleaseDate] DATETIME2 (7) NOT NULL,
[Genre] NVARCHAR (MAX) NULL,
[Price] DECIMAL (18, 2) NOT NULL,
CONSTRAINT [PK_Movie] PRIMARY KEY CLUSTERED ([Id] ASC)
);

Note the key icon next to `ID`. By default, EF makes a property named `ID` the primary key.

Right-click on the `Movie` table > **View Data**

Seed the database

Create a new class named `SeedData` in the *Models* folder. Replace the generated code with the following:

C#

```
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;
using MvcMovie.Data;
using System;
using System.Linq;

namespace MvcMovie.Models;

public static class SeedData
{
    public static void Initialize(IServiceProvider serviceProvider)
    {
        using (var context = new MvcMovieContext(
            serviceProvider.GetRequiredService<
                DbContextOptions<MvcMovieContext>>()))
        {
            // Look for any movies.
            if (context.Movie.Any())
            {
                return;   // DB has been seeded
            }
            context.Movie.AddRange(
                new Movie
                {
                    Title = "When Harry Met Sally",
                    ReleaseDate = DateTime.Parse("1989-2-12"),
                    Genre = "Romantic Comedy",
                    Price = 7.99M
                },
                new Movie
                {
                    Title = "Ghostbusters ",
```

```
                    ReleaseDate = DateTime.Parse("1984-3-13"),
                    Genre = "Comedy",
                    Price = 8.99M
                },
                new Movie
                {
                    Title = "Ghostbusters 2",
                    ReleaseDate = DateTime.Parse("1986-2-23"),
                    Genre = "Comedy",
                    Price = 9.99M
                },
                new Movie
                {
                    Title = "Rio Bravo",
                    ReleaseDate = DateTime.Parse("1959-4-15"),
                    Genre = "Western",
                    Price = 3.99M
                }
            );
            context.SaveChanges();
        }
    }
}
```

If there are any movies in the database, the seed initializer returns and no movies are added.

C#

```
if (context.Movie.Any())
{
    return;  // DB has been seeded.
}
```

Add the seed initializer

Visual Studio

Replace the contents of `Program.cs` with the following code. The new code is highlighted.

C#

```
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;
using MvcMovie.Data;
using MvcMovie.Models;
var builder = WebApplication.CreateBuilder(args);
```

```
builder.Services.AddDbContext<MvcMovieContext>(options =>

options.UseSqlServer(builder.Configuration.GetConnectionString("MvcMovie
Context") ?? throw new InvalidOperationException("Connection string
'MvcMovieContext' not found.")));

// Add services to the container.
builder.Services.AddControllersWithViews();

var app = builder.Build();

using (var scope = app.Services.CreateScope())
{
    var services = scope.ServiceProvider;

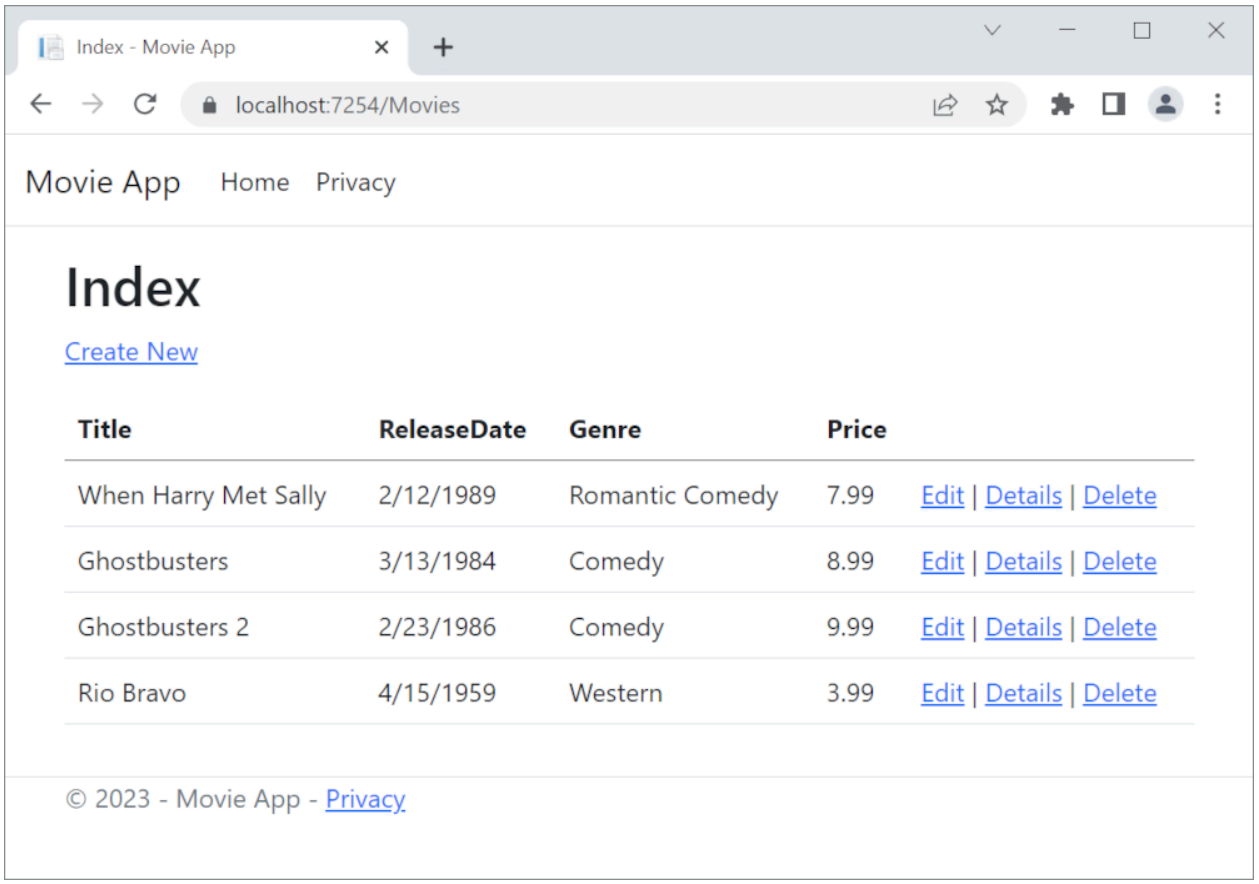
    SeedData.Initialize(services);
}
// Configure the HTTP request pipeline.
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Home/Error");
    // The default HSTS value is 30 days. You may want to change this
for production scenarios, see https://aka.ms/aspnetcore-hsts.
    app.UseHsts();
}

app.UseHttpsRedirection();

app.UseRouting();

app.UseAuthorization();

app.MapStaticAssets();



app.MapControllerRoute(
    name: "default",
    pattern: "{controller=Home}/{action=Index}/{id?}");

app.Run();
```

Delete all the records in the database. You can do this with the delete links in the browser or from SSOX.

Test the app. Force the app to initialize, calling the code in the `Program.cs` file, so the seed method runs. To force initialization, close the command prompt window that Visual Studio opened, and restart by pressing Ctrl+F5.

The app shows the seeded data.

By Rick Anderson

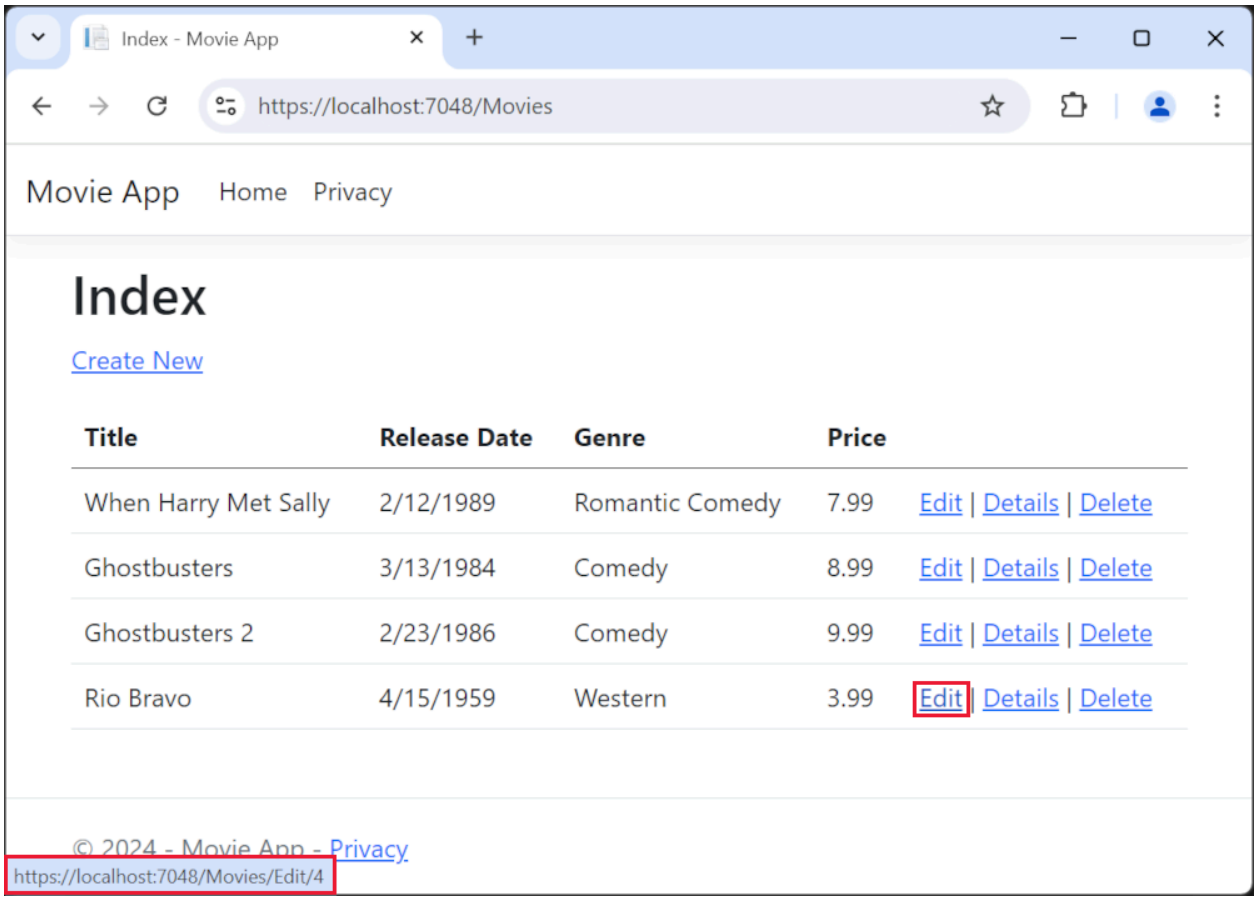
We have a good start to the movie app, but the presentation isn't ideal, for example, **ReleaseDate** should be two words.

Open the `Models/Movie.cs` file and add the highlighted lines shown below:

```
C#
```

```
using System;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace MvcMovie.Models;



public class Movie
{
    public int Id { get; set; }
    public string? Title { get; set; }

    [Display(Name = "Release Date")]
    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }
    public string? Genre { get; set; }
    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }
}
```

`DataAnnotations` are explained in the next tutorial. The Display attribute specifies what to display for the name of a field (in this case "Release Date" instead of "ReleaseDate"). The DataType attribute specifies the type of the data (Date), so the time information stored in the field isn't displayed.

The `[Column(TypeName = "decimal(18, 2)")]` data annotation is required so Entity Framework Core can correctly map `Price` to currency in the database. For more information, see Data Types.

Browse to the `Movies` controller and hold the mouse pointer over an **Edit** link to see the target URL.

The **Edit**, **Details**, and **Delete** links are generated by the Core MVC Anchor Tag Helper in the `Views/Movies/Index.cshtml` file.

CSHTML

```
            <a asp-action="Edit" asp-route-id="@item.Id">Edit</a> |
            <a asp-action="Details" asp-route-id="@item.Id">Details</a> |
            <a asp-action="Delete" asp-route-id="@item.Id">Delete</a>
        </td>
    </tr>
```

Tag Helpers enable server-side code to participate in creating and rendering HTML elements in Razor files. In the code above, the `AnchorTagHelper` dynamically generates the HTML `href` attribute value from the controller action method and route id. You use **View Source** from your favorite browser or use the developer tools to examine the generated markup. A portion of the generated HTML is shown below:

HTML

```
 <td>
    <a href="/Movies/Edit/4"> Edit </a> |
    <a href="/Movies/Details/4"> Details </a> |
    <a href="/Movies/Delete/4"> Delete </a>
</td>
```

Recall the format for routing set in the `Program.cs` file:

C#

```
app.MapControllerRoute(
    name: "default",
    pattern: "{controller=Home}/{action=Index}/{id?}");
```

ASP.NET Core translates `https://localhost:5001/Movies/Edit/4` into a request to the `Edit` action method of the `Movies` controller with the parameter `Id` of 4. (Controller methods are also known as action methods.)

Tag Helpers are one of the most popular new features in ASP.NET Core. For more information, see Additional resources.

Open the `Movies` controller and examine the two `Edit` action methods. The following code shows the `HTTP GET Edit` method, which fetches the movie and populates the edit form generated by the `Edit.cshtml` Razor file.

C#

```
// GET: Movies/Edit/5
public async Task<IActionResult> Edit(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var movie = await _context.Movie.FindAsync(id);
    if (movie == null)
    {
        return NotFound();
    }
    return View(movie);
}
```

The following code shows the `HTTP POST Edit` method, which processes the posted movie values:

C#

```
// POST: Movies/Edit/5
// To protect from overposting attacks, enable the specific properties you
want to bind to.
// For more details, see http://go.microsoft.com/fwlink/?LinkId=317598.
[HttpPost]
[ValidateAntiForgeryToken]
```

```
public async Task<IActionResult> Edit(int id,
[Bind("Id,Title,ReleaseDate,Genre,Price,Rating")] Movie movie)
{
    if (id != movie.Id)
    {
        return NotFound();
    }

    if (ModelState.IsValid)
    {
        try
        {
            _context.Update(movie);
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateConcurrencyException)
        {
            if (!MovieExists(movie.Id))
            {
                return NotFound();
            }
            else
            {
                throw;
            }
        }
        return RedirectToAction(nameof(Index));
    }
    return View(movie);
}
```

The `[Bind]` attribute is one way to protect against over-posting. You should only include properties in the `[Bind]` attribute that you want to change. For more information, see Protect your controller from over-posting. ViewModels provide an alternative approach to prevent over-posting.

Notice the second `Edit` action method is preceded by the `[HttpPost]` attribute.

C#

```
// POST: Movies/Edit/5
// To protect from overposting attacks, enable the specific properties you
want to bind to.
// For more details, see http://go.microsoft.com/fwlink/?LinkId=317598.
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Edit(int id,
[Bind("Id,Title,ReleaseDate,Genre,Price,Rating")] Movie movie)
{
    if (id != movie.Id)
    {
        return NotFound();
```

```
    }

    if (ModelState.IsValid)
    {
        try
        {
            _context.Update(movie);
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateConcurrencyException)
        {
            if (!MovieExists(movie.Id))
            {
                return NotFound();
            }
            else
            {
                throw;
            }
        }
        return RedirectToAction(nameof(Index));
    }
    return View(movie);
}
```

The `HttpPost` attribute specifies that this `Edit` method can be invoked *only* for `POST` requests. You could apply the `[HttpGet]` attribute to the first edit method, but that's not necessary because `[HttpGet]` is the default.

The `ValidateAntiForgeryToken` attribute is used to prevent forgery of a request and is paired up with an antiforgery token generated in the edit view file (`Views/Movies/Edit.cshtml`). The edit view file generates the antiforgery token with the Form Tag Helper.

CSHTML

```
<form asp-action="Edit">
```

The Form Tag Helper generates a hidden antiforgery token that must match the `[ValidateAntiForgeryToken]` generated antiforgery token in the `Edit` method of the Movies controller. For more information, see Prevent Cross-Site Request Forgery (XSRF/CSRF) attacks in ASP.NET Core.

The `HttpGet Edit` method takes the movie `ID` parameter, looks up the movie using the Entity Framework `FindAsync` method, and returns the selected movie to the Edit view. If a movie cannot be found, `NotFound` (HTTP 404) is returned.

C#

```
// GET: Movies/Edit/5
public async Task<IActionResult> Edit(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var movie = await _context.Movie.FindAsync(id);
    if (movie == null)
    {
        return NotFound();
    }
    return View(movie);
}
```

When the scaffolding system created the Edit view, it examined the `Movie` class and created code to render `<label>` and `<input>` elements for each property of the class. The following example shows the Edit view that was generated by the Visual Studio scaffolding system:

CSHTML

```
@model MvcMovie.Models.Movie

@{
    ViewData["Title"] = "Edit";
}

<h1>Edit</h1>

<h4>Movie</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form asp-action="Edit">
            <div asp-validation-summary="ModelOnly" class="text-danger">
</div>
            <input type="hidden" asp-for="Id" />
            <div class="form-group">
                <label asp-for="Title" class="control-label"></label>
                <input asp-for="Title" class="form-control" />
                <span asp-validation-for="Title" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="ReleaseDate" class="control-label"></label>
                <input asp-for="ReleaseDate" class="form-control" />
                <span asp-validation-for="ReleaseDate" class="text-danger">
</span>
            </div>
```

```
            <div class="form-group">
                <label asp-for="Genre" class="control-label"></label>
                <input asp-for="Genre" class="form-control" />
                <span asp-validation-for="Genre" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Price" class="control-label"></label>
                <input asp-for="Price" class="form-control" />
                <span asp-validation-for="Price" class="text-danger"></span>
            </div>
            <div class="form-group">
                <input type="submit" value="Save" class="btn btn-primary" />
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-action="Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

Notice how the view template has a `@model MvcMovie.Models.Movie` statement at the top of the file. `@model MvcMovie.Models.Movie` specifies that the view expects the model for the view template to be of type `Movie`.

The scaffolded code uses several Tag Helper methods to streamline the HTML markup. The Label Tag Helper displays the name of the field ("Title", "ReleaseDate", "Genre", or "Price"). The Input Tag Helper renders an HTML `<input>` element. The Validation Tag Helper displays any validation messages associated with that property.

Run the application and navigate to the `/Movies` URL. Click an **Edit** link. In the browser, view the source for the page. The generated HTML for the `<form>` element is shown below.

HTML

```
<form action="/Movies/Edit/7" method="post">
    <div class="form-horizontal">
        <h4>Movie</h4>
        <hr />
        <div class="text-danger" />
        <input type="hidden" data-val="true" data-val-required="The ID field
is required." id="ID" name="ID" value="7" />
        <div class="form-group">
            <label class="control-label col-md-2" for="Genre" />
            <div class="col-md-10">
```

```
                <input class="form-control" type="text" id="Genre"
name="Genre" value="Western" />
                <span class="text-danger field-validation-valid" data-
valmsg-for="Genre" data-valmsg-replace="true"></span>
            </div>
        </div>
        <div class="form-group">
            <label class="control-label col-md-2" for="Price" />
            <div class="col-md-10">
                <input class="form-control" type="text" data-val="true"
data-val-number="The field Price must be a number." data-val-required="The
Price field is required." id="Price" name="Price" value="3.99" />
                <span class="text-danger field-validation-valid" data-
valmsg-for="Price" data-valmsg-replace="true"></span>
            </div>
        </div>
        <!-- Markup removed for brevity -->
        <div class="form-group">
            <div class="col-md-offset-2 col-md-10">
                <input type="submit" value="Save" class="btn btn-default" />
            </div>
        </div>
    </div>
    <input name="__RequestVerificationToken" type="hidden"
value="CfDJ8Inyxgp63fRFqUePGvuI5jGZsloJu1L7X9le1gy7NCIlSduCRx9jDQClrV9pOTTmq
UyXnJBXhmrjcUVDJyDUMm7-
MF_9rK8aAZdRdlOri7FmKVkRe_2v5LIHGKFcTjPrWPYnc9AdSbomkiOSaTEg7RU" />
</form>
```

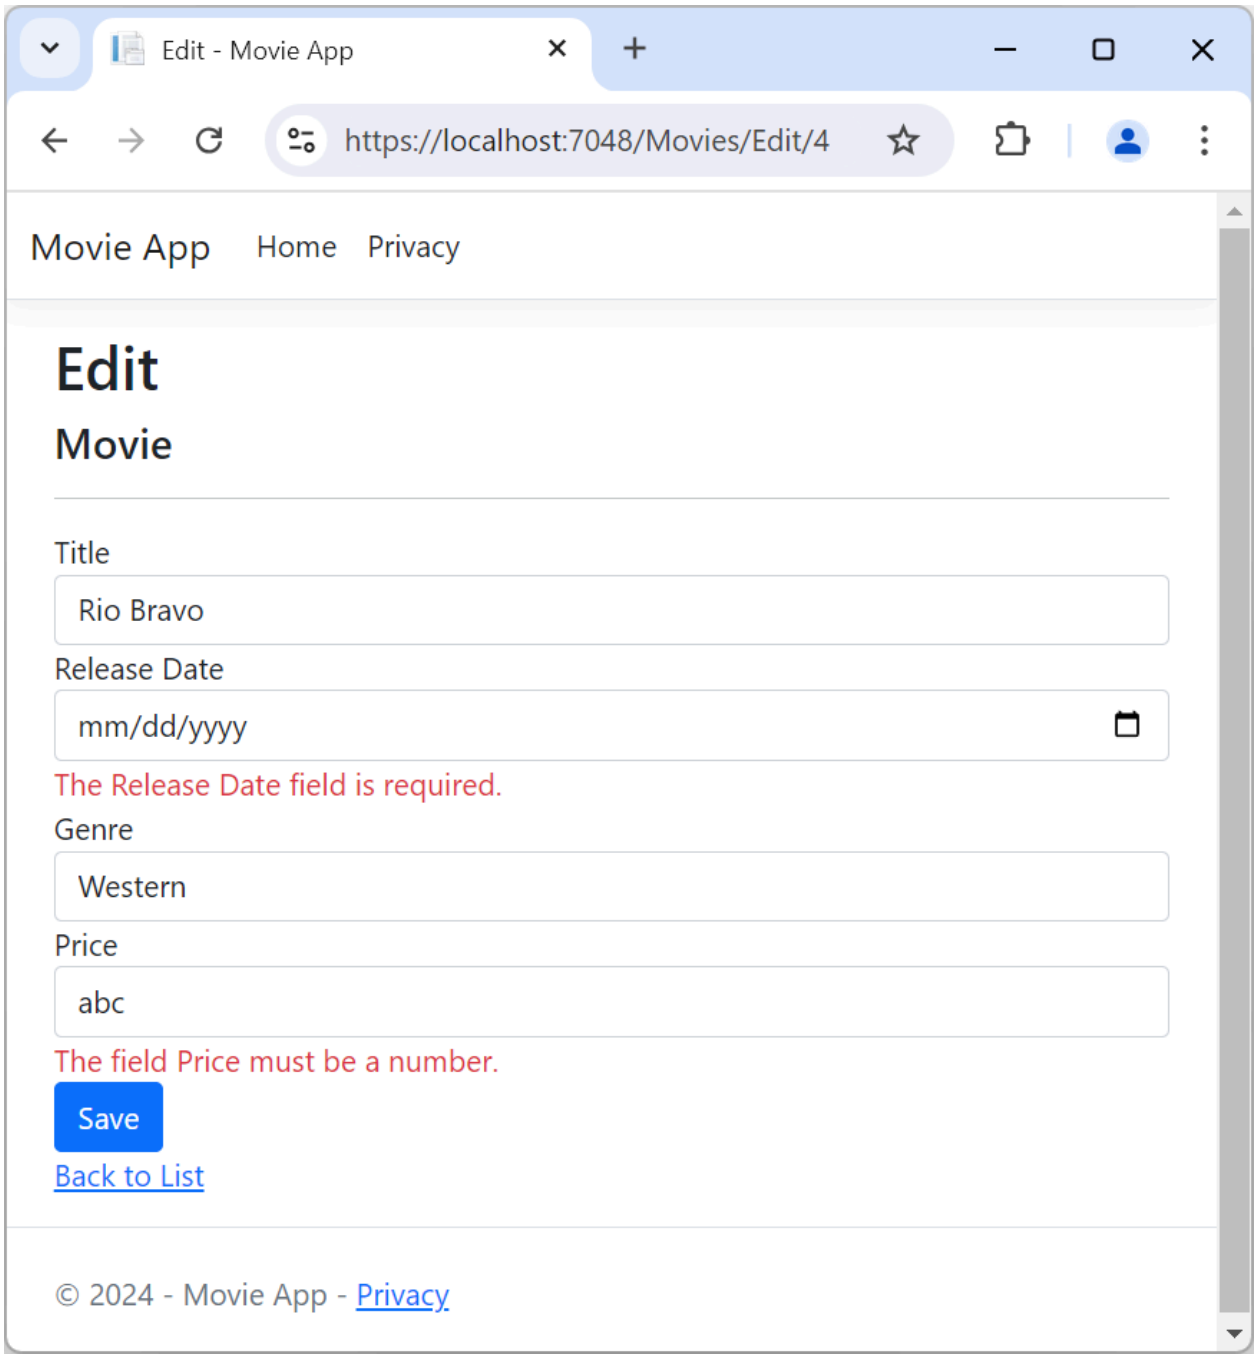
The `<input>` elements are in an `HTML <form>` element whose `action` attribute is set to post to the `/Movies/Edit/id` URL. The form data will be posted to the server when the `Save` button is clicked. The last line before the closing `</form>` element shows the hidden XSRF token generated by the Form Tag Helper.

Processing the POST Request

The following listing shows the `[HttpPost]` version of the `Edit` action method.

C#

```
// POST: Movies/Edit/5
// To protect from overposting attacks, enable the specific properties you
want to bind to.
// For more details, see http://go.microsoft.com/fwlink/?LinkId=317598.
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Edit(int id,
[Bind("Id,Title,ReleaseDate,Genre,Price,Rating")] Movie movie)
{
    if (id != movie.Id)
```



```
    {
        return NotFound();
    }

    if (ModelState.IsValid)
    {
        try
        {
            _context.Update(movie);
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateConcurrencyException)
        {
            if (!MovieExists(movie.Id))
            {
                return NotFound();
            }
            else
            {
                throw;
            }
        }
        return RedirectToAction(nameof(Index));
    }
    return View(movie);
}
```

The `[ValidateAntiForgeryToken]` attribute validates the hidden XSRF token generated by the antiforgery token generator in the Form Tag Helper

The model binding system takes the posted form values and creates a `Movie` object that's passed as the `movie` parameter. The `ModelState.IsValid` property verifies that the data submitted in the form can be used to modify (edit or update) a `Movie` object. If the data is valid, it's saved. The updated (edited) movie data is saved to the database by calling the `SaveChangesAsync` method of database context. After saving the data, the code redirects the user to the `Index` action method of the `MoviesController` class, which displays the movie collection, including the changes just made.

Before the form is posted to the server, client-side validation checks any validation rules on the fields. If there are any validation errors, an error message is displayed and the form isn't posted. If JavaScript is disabled, you won't have client-side validation but the server will detect the posted values that are not valid, and the form values will be redisplayed with error messages. Later in the tutorial we examine Model Validation in more detail. The Validation Tag Helper in the `Views/Movies/Edit.cshtml` view template takes care of displaying appropriate error messages.

All the `HttpGet` methods in the movie controller follow a similar pattern. They get a movie object (or list of objects, in the case of `Index`), and pass the object (model) to the view. The `Create` method passes an empty movie object to the `Create` view. All the methods that create, edit, delete, or otherwise modify data do so in the `[HttpPost]` overload of the method. Modifying data in an `HTTP GET` method is a security risk. Modifying data in an `HTTP GET` method also violates HTTP best practices and the architectural REST pattern, which specifies that GET requests shouldn't change the state of your application. In other words, performing a GET operation should be a safe operation that has no side effects and doesn't modify your persisted data.

By Rick Anderson

In this section, you add search capability to the `Index` action method that lets you search movies by *genre* or *name*.

Update the `Index` method found inside `Controllers/MoviesController.cs` with the following code:

C#

```
public async Task<IActionResult> Index(string searchString)
{
    if (_context.Movie == null)
    {
        return Problem("Entity set 'MvcMovieContext.Movie'  is null.");
    }

    var movies = from m in _context.Movie
                 select m;

    if (!String.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s =>
s.Title!.ToUpper().Contains(searchString.ToUpper()));
    }

    return View(await movies.ToListAsync());
}
```

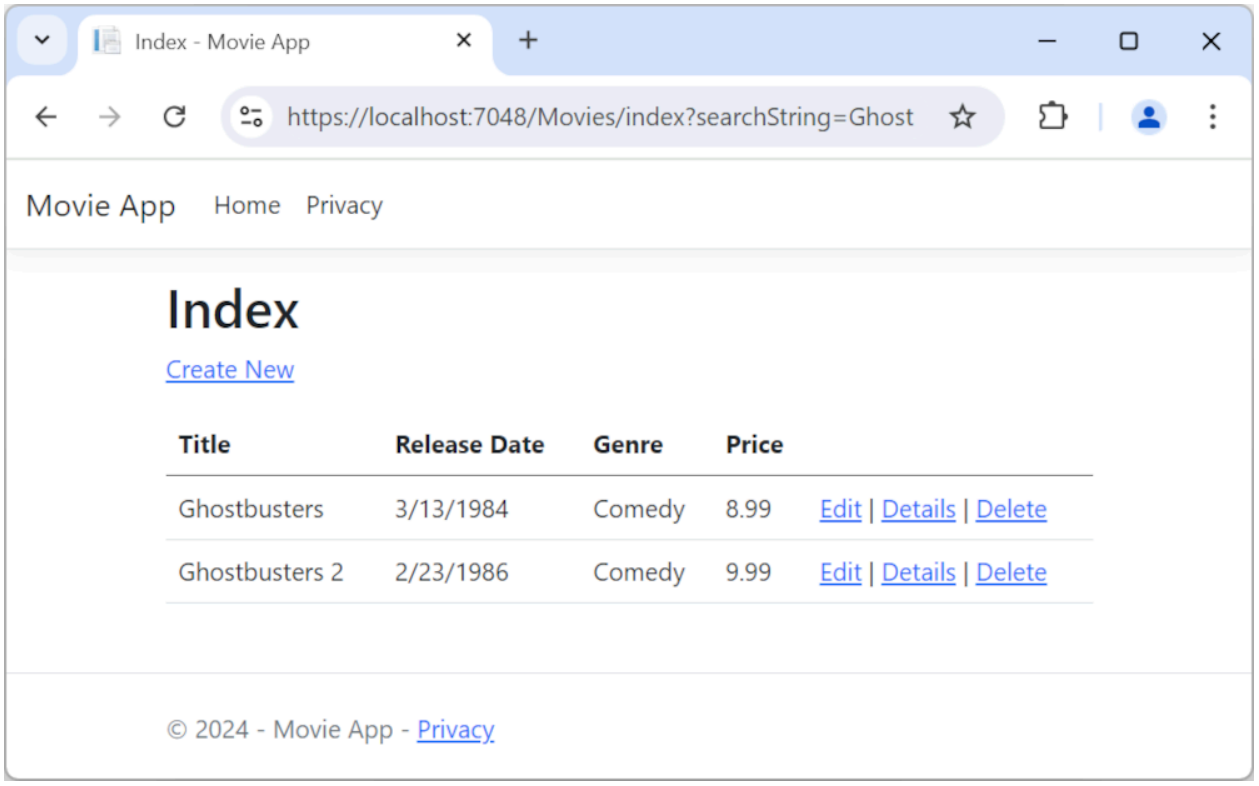
The following line in the `Index` action method creates a LINQ query to select the movies:

C#

```
var movies = from m in _context.Movie
             select m;
```

The query is *only defined* at this point, it has **not** been run against the database.

If the `searchString` parameter contains a string, the movies query is modified to filter on the value of the search string:



C#

```
if (!String.IsNullOrEmpty(searchString))
{
    movies = movies.Where(s =>
s.Title!.ToUpper().Contains(searchString.ToUpper()));
}
```

The `s => s.Title!.ToUpper().Contains(searchString.ToUpper())` code above is a Lambda Expression. Lambdas are used in method-based LINQ queries as arguments to standard query operator methods such as the Where method or `Contains` (used in the code above). LINQ queries are not executed when they're defined or when they're modified by calling a method such as `Where`, `Contains`, or `OrderBy`. Rather, query execution is deferred. That means that the evaluation of an expression is delayed until its realized value is actually iterated over or the `ToListAsync` method is called. For more information about deferred query execution, see Query Execution.

> ⓘ Note
>
> The Contains method is run on the database, not in the C# code. The case sensitivity on the query depends on the database and the collation. On SQL Server, `Contains` maps to SQL LIKE, which is case insensitive. SQLite with the default collation is a mixture of case sensitive and case ***IN***sensitive, depending on the query. For information on making case insensitive SQLite queries, see the following:
>
> - How to use case-insensitive query with Sqlite provider? (dotnet/efcore #11414)
> - How to make a SQLite column case insensitive (dotnet/AspNetCore.Docs #22314)
> - Collations and Case Sensitivity

Navigate to `/Movies/Index`. Append a query string such as `?searchString=Ghost` to the URL. The filtered movies are displayed.

If you change the signature of the `Index` method to have a parameter named `id`, the `id` parameter will match the optional `{id}` placeholder for the default routes set in `Program.cs`.

C#

```
app.MapControllerRoute(
    name: "default",
    pattern: "{controller=Home}/{action=Index}/{id?}");
```

Change the parameter to `id` and change all occurrences of `searchString` to `id`.

The previous `Index` method:

C#

```
public async Task<IActionResult> Index(string searchString)
{
    if (_context.Movie == null)
    {
        return Problem("Entity set 'MvcMovieContext.Movie'  is null.");
    }

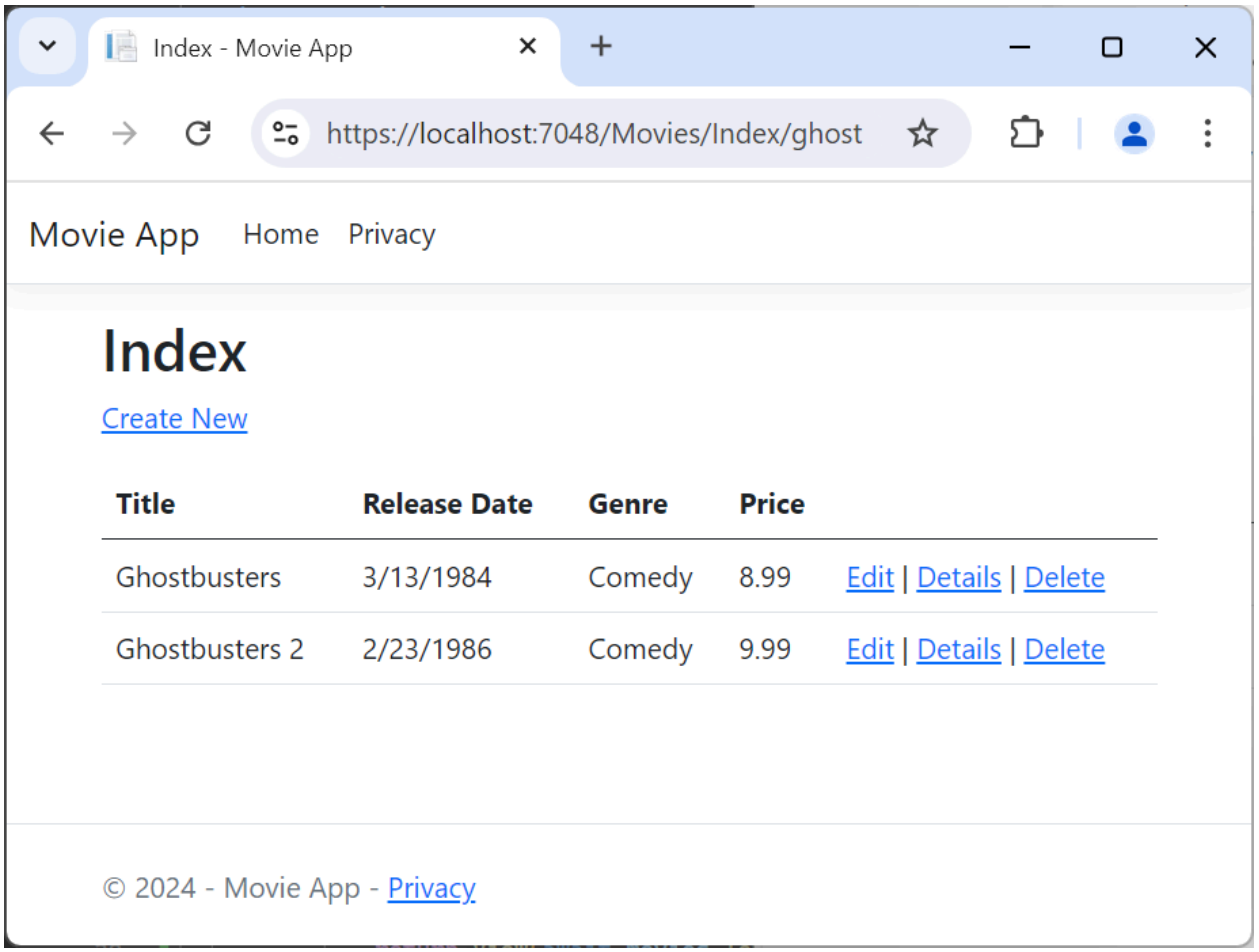
    var movies = from m in _context.Movie
                 select m;
```

```
    if (!String.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s =>
s.Title!.ToUpper().Contains(searchString.ToUpper()));
    }

    return View(await movies.ToListAsync());
}
```

The updated `Index` method with `id` parameter:

C#



```
public async Task<IActionResult> Index(string id)
{
    if (_context.Movie == null)
    {
        return Problem("Entity set 'MvcMovieContext.Movie'  is null.");
    }

    var movies = from m in _context.Movie
                 select m;

    if (!String.IsNullOrEmpty(id))
    {
        movies = movies.Where(s =>
s.Title!.ToUpper().Contains(id.ToUpper()));
    }

    return View(await movies.ToListAsync());
}
```

You can now pass the search title as route data (a URL segment) instead of as a query string value.

However, you can't expect users to modify the URL every time they want to search for a movie. So now you'll add UI elements to help them filter movies. If you changed the signature of the `Index` method to test how to pass the route-bound `ID` parameter, change it back so that it takes a parameter named `searchString`:

C#

```
public async Task<IActionResult> Index(string searchString)
{
    if (_context.Movie == null)
    {
        return Problem("Entity set 'MvcMovieContext.Movie'  is null.");
    }

    var movies = from m in _context.Movie
                 select m;

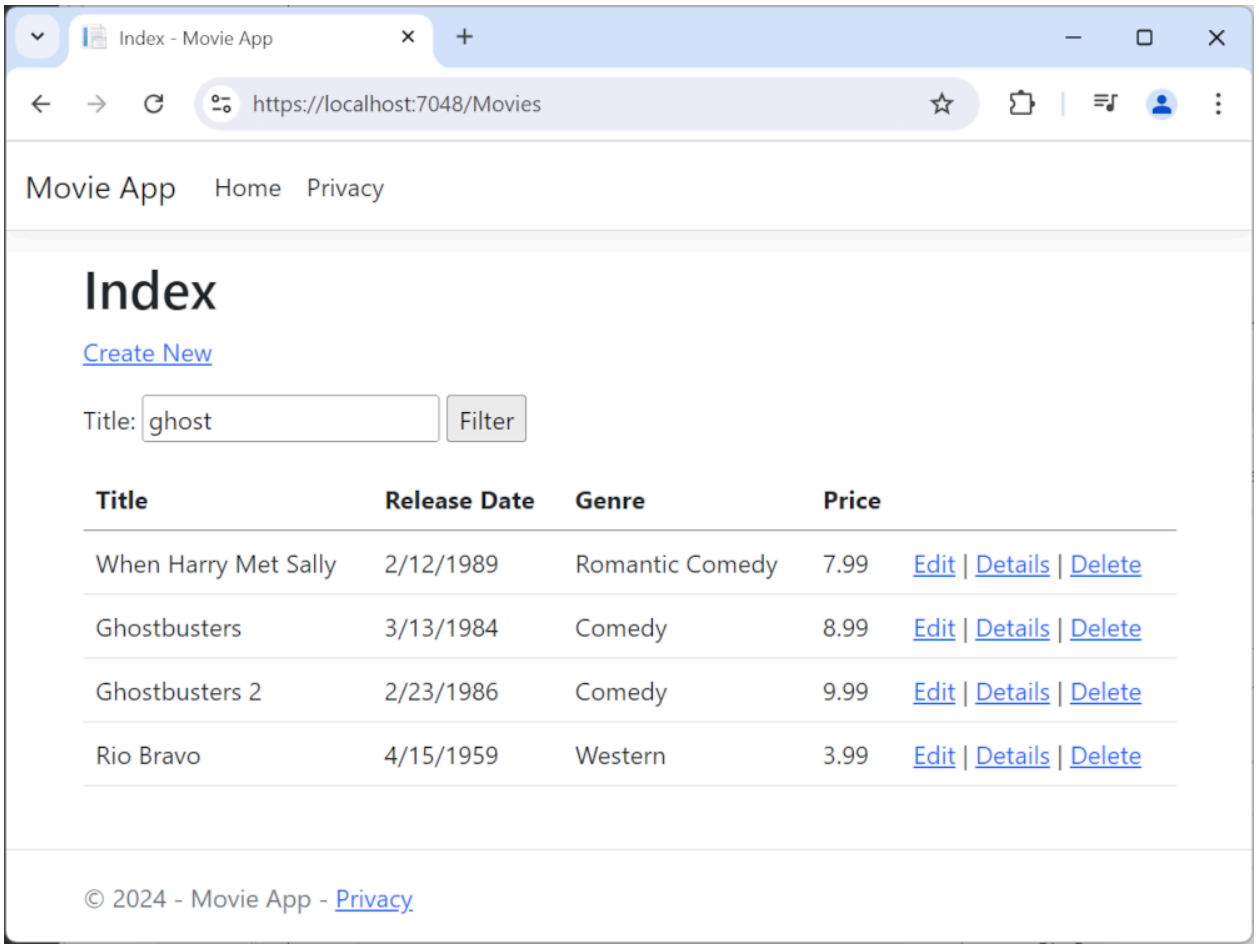
    if (!String.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s =>
s.Title!.ToUpper().Contains(searchString.ToUpper()));
    }

    return View(await movies.ToListAsync());
}
```

Open the `Views/Movies/Index.cshtml` file, and add the `<form>` markup highlighted below:

CSHTML

```
@model IEnumerable<MvcMovie.Models.Movie>



@{
    ViewData["Title"] = "Index";
}

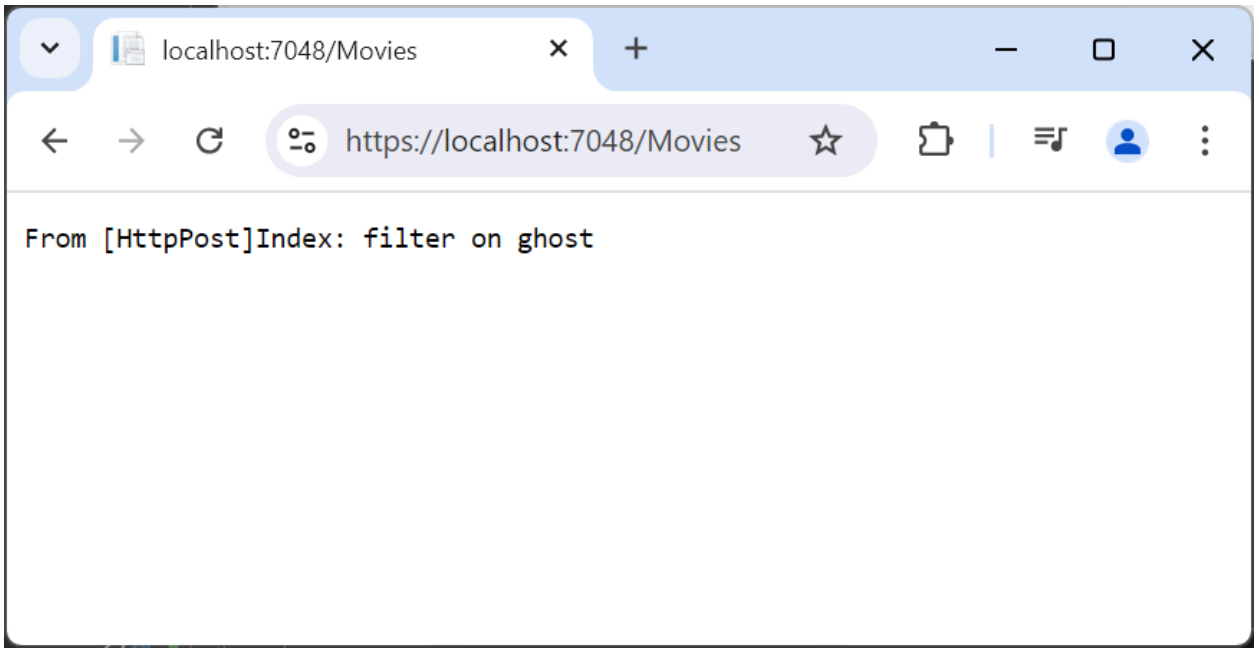
<h1>Index</h1>

<p>
    <a asp-action="Create">Create New</a>
</p>

<form asp-controller="Movies" asp-action="Index">
    <p>
        <label>Title: <input type="text" name="SearchString" /></label>
        <input type="submit" value="Filter" />
    </p>
</form>
<table class="table">
```

The HTML `<form>` tag uses the Form Tag Helper, so when you submit the form, the filter string is posted to the `Index` action of the movies controller. Save your changes and then test the filter.

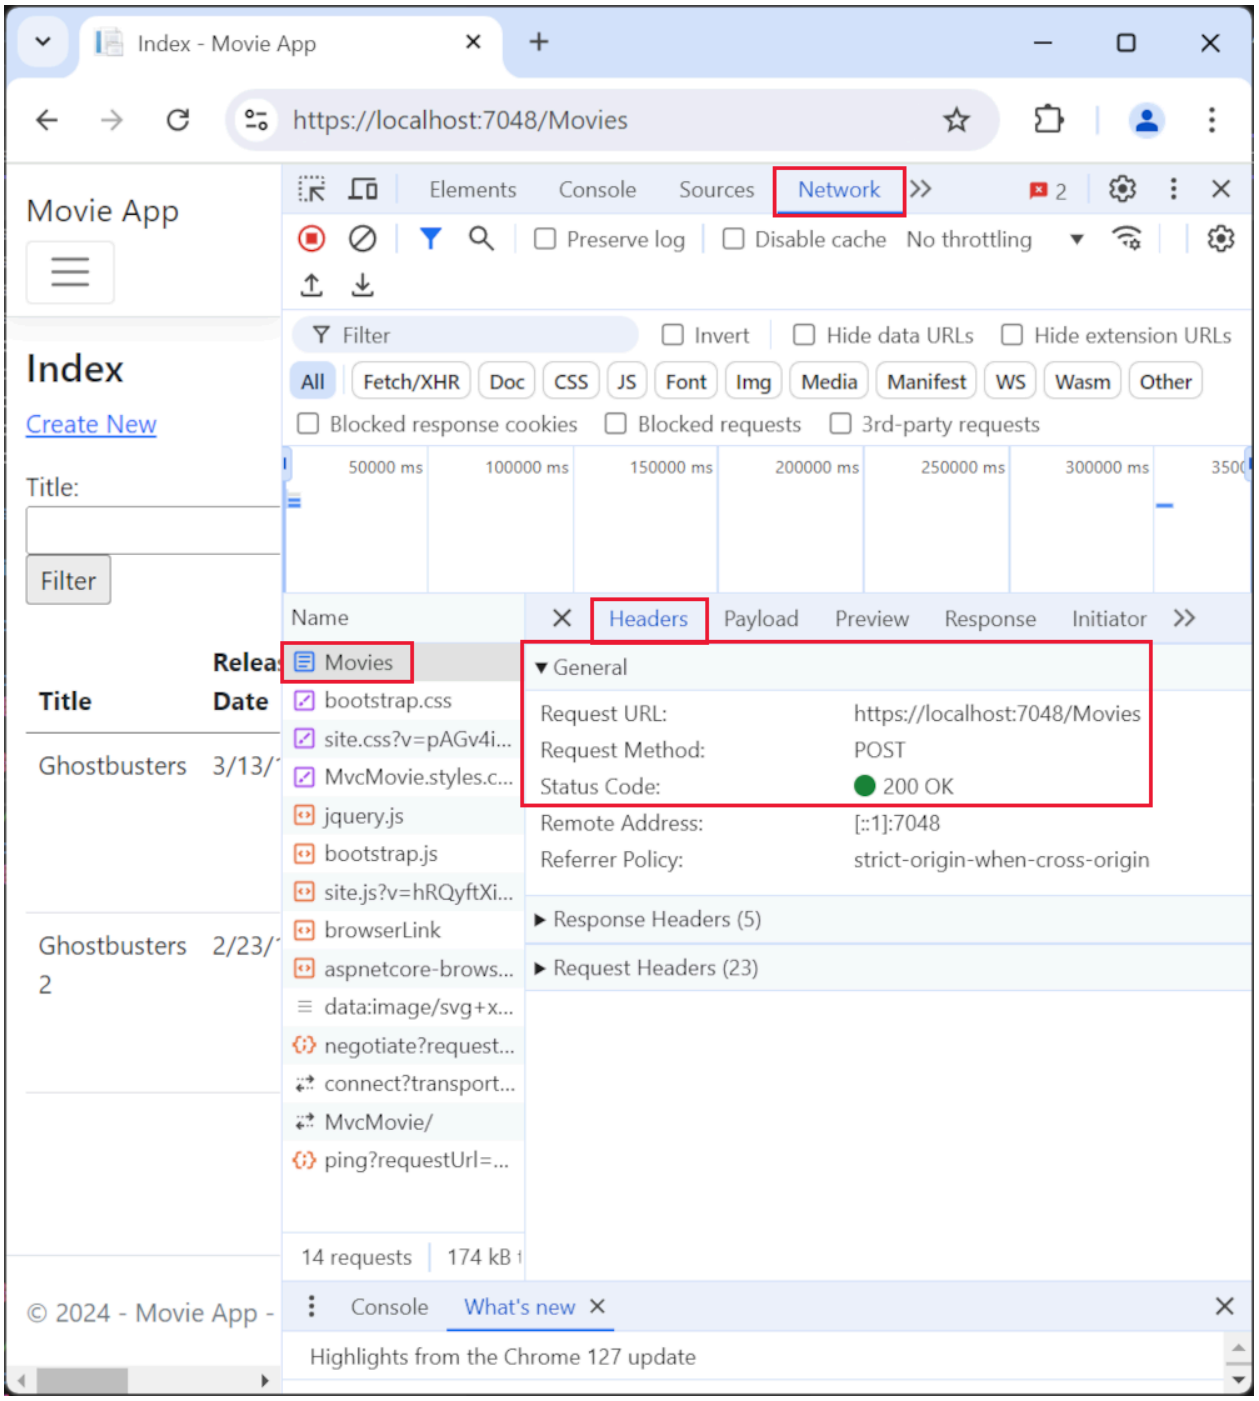
There's no `[HttpPost]` overload of the `Index` method as you might expect. You don't need it, because the method isn't changing the state of the app, just filtering data.



You could add the following `[HttpPost] Index` method.

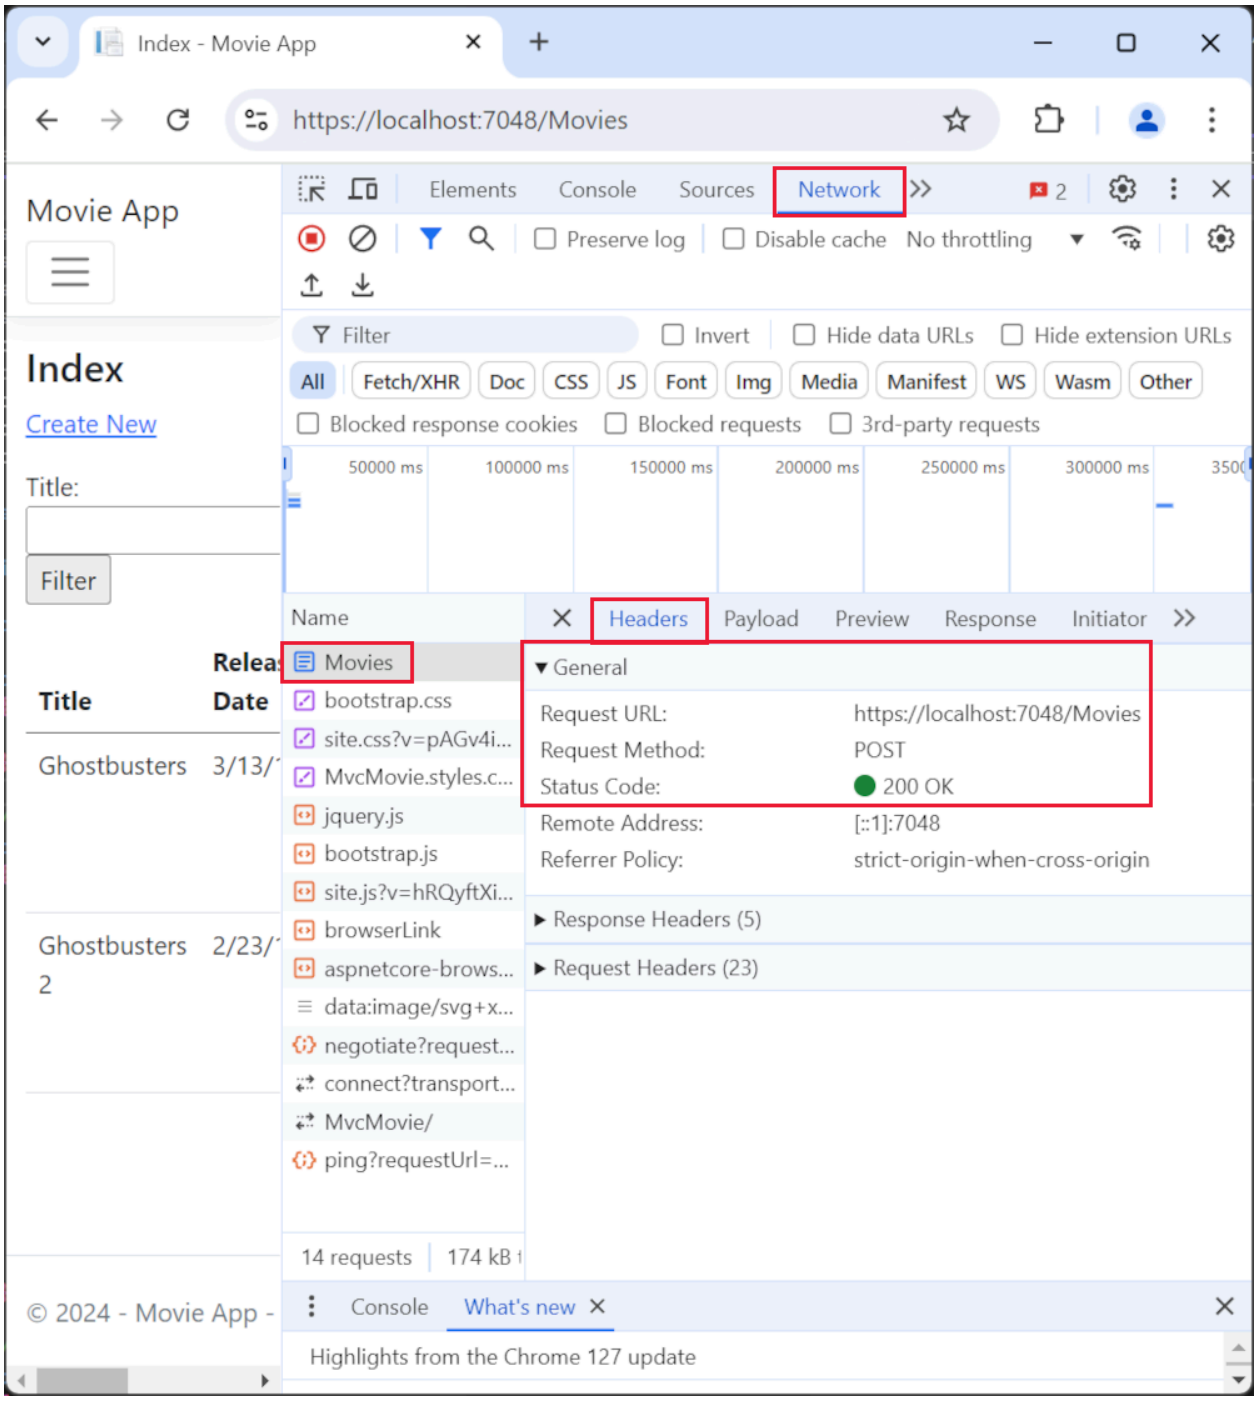
C#

```
[HttpPost]
public string Index(string searchString, bool notUsed)
{
    return "From [HttpPost]Index: filter on " + searchString;
}
```



The `notUsed` parameter is used to create an overload for the `Index` method. We'll talk about that later in the tutorial.

If you add this method, the action invoker would match the `[HttpPost] Index` method, and the `[HttpPost] Index` method would run as shown in the image below.



However, even if you add this `[HttpPost]` version of the `Index` method, there's a limitation in how this has all been implemented. Imagine that you want to bookmark a particular search or you want to send a link to friends that they can click in order to see the same filtered list of movies. Notice that the URL for the HTTP POST request is the same as the URL for the GET request (localhost:{PORT}/Movies/Index) -- there's no search information in the URL. The search string information is sent to the server as a form field value. You can verify that with the browser Developer tools or the excellent Fiddler tool.

The following image shows the Chrome browser Developer tools with the **Network** and **Headers** tabs selected:

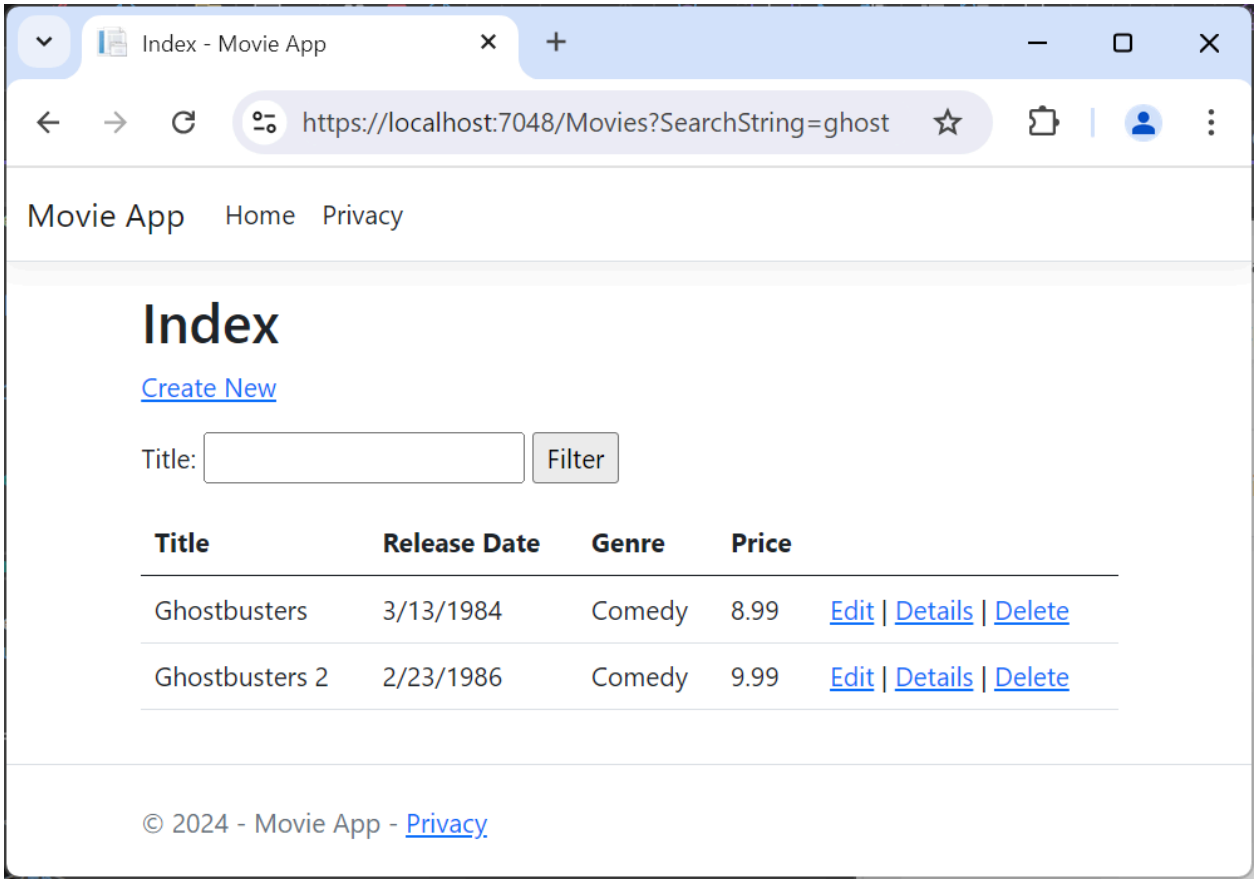
The **Network** and **Payload** tabs are selected to view form data:

You can see the search parameter and XSRF token in the request body. Note, as mentioned in the previous tutorial, the Form Tag Helper generates an XSRF antiforgery token. We're not modifying data, so we don't need to validate the token in the controller method.

Because the search parameter is in the request body and not the URL, you can't capture that search information to bookmark or share with others. Fix this by specifying the request should be `HTTP GET` in the `form` tag found in the `Views/Movies/Index.cshtml` file.

CSHTML

```
@model IEnumerable<MvcMovie.Models.Movie>
```



```
@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-action="Create">Create New</a>
</p>

<form asp-controller="Movies" asp-action="Index" method="get">
    <p>
        <label>Title: <input type="text" name="SearchString" /></label>
        <input type="submit" value="Filter" />
    </p>
</form>
<table class="table">
```

Now when you submit a search, the URL contains the search query string. Searching will also go to the `HttpGet Index` action method, even if you have a `HttpPost Index` method.

Add Search by genre

Add the following `MovieGenreViewModel` class to the *Models* folder:

C#

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace MvcMovie.Models;

public class MovieGenreViewModel
{
    public List<Movie>? Movies { get; set; }
    public SelectList? Genres { get; set; }
    public string? MovieGenre { get; set; }
    public string? SearchString { get; set; }
}
```

The movie-genre view model will contain:

- A list of movies.
- A `SelectList` containing the list of genres. This allows the user to select a genre from the list.
- `MovieGenre`, which contains the selected genre.
- `SearchString`, which contains the text users enter in the search text box.

Replace the `Index` method in `MoviesController.cs` with the following code:

C#

```
// GET: Movies
public async Task<IActionResult> Index(string movieGenre, string
searchString)
{
    if (_context.Movie == null)
    {
        return Problem("Entity set 'MvcMovieContext.Movie'  is null.");
    }

    // Use LINQ to get list of genres.
    IQueryable<string> genreQuery = from m in _context.Movie
                                    orderby m.Genre
                                    select m.Genre;
    var movies = from m in _context.Movie
                 select m;

    if (!string.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s =>
s.Title!.ToUpper().Contains(searchString.ToUpper()));
    }

    if (!string.IsNullOrEmpty(movieGenre))
    {
```

```
        movies = movies.Where(x => x.Genre == movieGenre);
    }

    var movieGenreVM = new MovieGenreViewModel
    {
        Genres = new SelectList(await genreQuery.Distinct().ToListAsync()),
        Movies = await movies.ToListAsync()
    };

    return View(movieGenreVM);
}
```

The following code is a `LINQ` query that retrieves all the genres from the database.

C#

```
// Use LINQ to get list of genres.
IQueryable<string> genreQuery = from m in _context.Movie
                                orderby m.Genre
                                select m.Genre;
```

The `SelectList` of genres is created by projecting the distinct genres (we don't want our select list to have duplicate genres).

When the user searches for the item, the search value is retained in the search box.

Add search by genre to the Index view

Update `Index.cshtml` found in *Views/Movies/* as follows:

CSHTML

```
@model MvcMovie.Models.MovieGenreViewModel

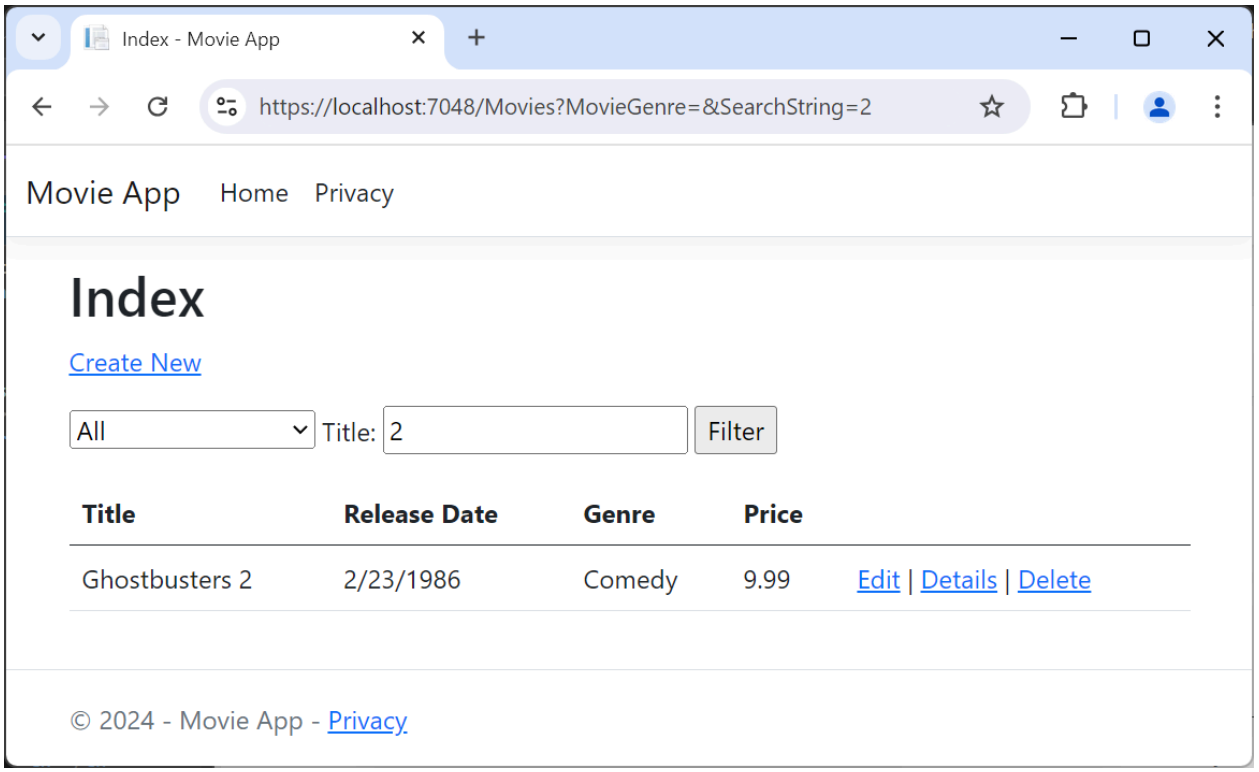
@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-action="Create">Create New</a>
</p>
<form asp-controller="Movies" asp-action="Index" method="get">
    <p>

        <select asp-for="MovieGenre" asp-items="Model.Genres">
            <option value="">All</option>
        </select>
```

```
        <label>Title: <input type="text" asp-for="SearchString" /></label>
        <input type="submit" value="Filter" />
    </p>
</form>



<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Movies![0].Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movies![0].ReleaseDate)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movies![0].Genre)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movies![0].Price)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Movies!)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.Title)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.ReleaseDate)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Genre)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Price)
                </td>
                <td>
                    <a asp-action="Edit" asp-route-id="@item.Id">Edit</a> |
                    <a asp-action="Details" asp-route-
id="@item.Id">Details</a> |
                    <a asp-action="Delete" asp-route-
id="@item.Id">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

Examine the lambda expression used in the following HTML Helper:

```
@Html.DisplayNameFor(model => model.Movies![0].Title)
```

In the preceding code, the `DisplayNameFor` HTML Helper inspects the `Title` property referenced in the lambda expression to determine the display name. Since the lambda expression is inspected rather than evaluated, you don't receive an access violation when `model`, `model.Movies`, or `model.Movies[0]` are `null` or empty. When the lambda expression is evaluated (for example, `@Html.DisplayFor(modelItem => item.Title)`), the model's property values are evaluated. The `!` after `model.Movies` is the null-forgiving operator, which is used to declare that `Movies` isn't null.

Test the app by searching by genre, by movie title, and by both:

Part 8, add a new field to an ASP.NET Core MVC app

Article • 07/26/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Rick Anderson

In this section Entity Framework Migrations is used to:

- Add a new field to the model.
- Migrate the new field to the database.

When Entity Framework (EF) is used to automatically create a database from model classes:

- A table is added to the database to track the schema of the database.
- The database is verified to be in sync with the model classes it was generated from. If they aren't in sync, EF throws an exception. This makes it easier to find inconsistent database/code issues.

Add a Rating Property to the Movie Model

Add a `Rating` property to `Models/Movie.cs`:

C#

```
using System;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace MvcMovie.Models;

public class Movie
{
    public int Id { get; set; }
    public string? Title { get; set; }
```

```
    [Display(Name = "Release Date")]
    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }
    public string? Genre { get; set; }

    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }
    public string? Rating {  get; set; }
}
```

Build the app

Visual Studio

Press Ctrl+Shift+B

Because you've added a new field to the `Movie` class, you need to update the property binding list so this new property will be included. In `MoviesController.cs`, update the `[Bind]` attribute for both the `Create` and `Edit` action methods to include the `Rating` property:

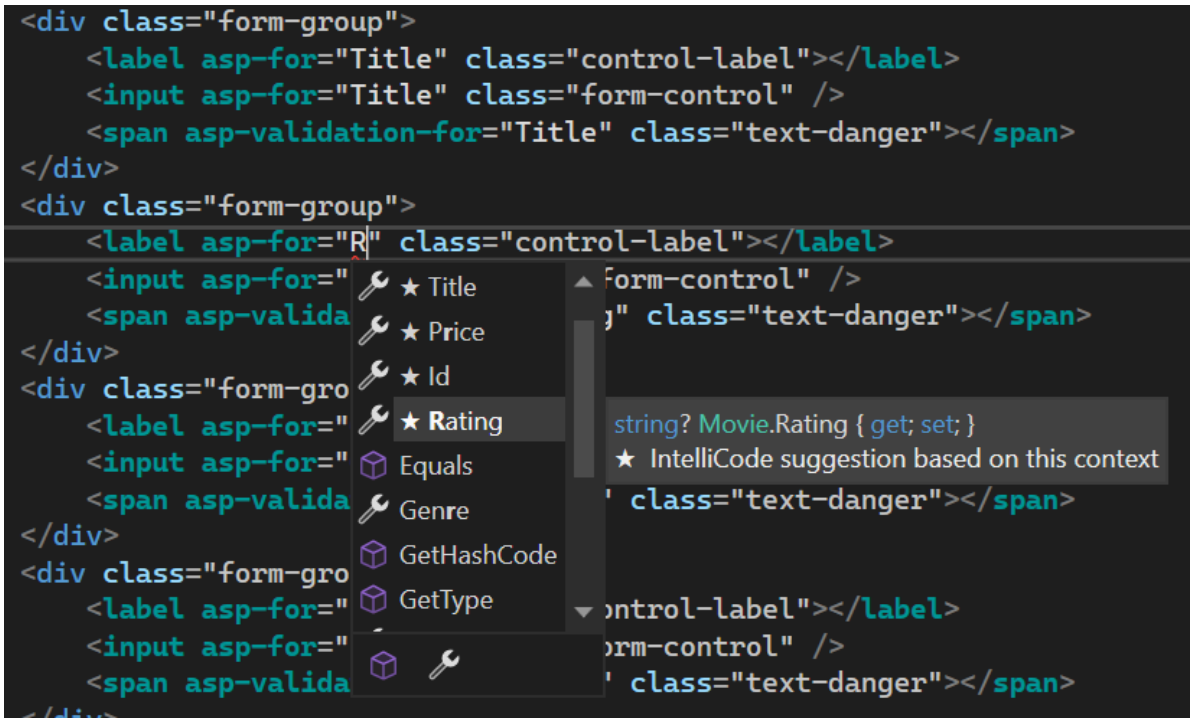
C#

```
[Bind("Id,Title,ReleaseDate,Genre,Price,Rating")]
```

Update the view templates in order to display, create, and edit the new `Rating` property in the browser view.

Edit the `/Views/Movies/Index.cshtml` file and add a `Rating` field:

CSHTML



```
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Movies![0].Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movies![0].ReleaseDate)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movies![0].Genre)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movies![0].Price)
```

```
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movies![0].Rating)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Movies!)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.Title)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.ReleaseDate)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Genre)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Price)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Rating)
                </td>
                <td>
                    <a asp-action="Edit" asp-route-id="@item.Id">Edit</a> |
                    <a asp-action="Details" asp-route-
id="@item.Id">Details</a> |
                    <a asp-action="Delete" asp-route-
id="@item.Id">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

Update the `/Views/Movies/Create.cshtml` with a `Rating` field.

Visual Studio

You can copy/paste the previous "form group" and let intelliSense help you update the fields. IntelliSense works with Tag Helpers.

Add the `Rating` property to the remaining `Create.cshtml`, `Delete.cshtml`, `Details.cshtml`, and `Edit.cshtml` view templates.

Update the `SeedData` class so that it provides a value for the new column. A sample change is shown below, but you'll want to make this change for each `new Movie`.

C#

```
new Movie
{
    Title = "When Harry Met Sally",
    ReleaseDate = DateTime.Parse("1989-1-11"),
    Genre = "Romantic Comedy",
    Rating = "R",
    Price = 7.99M
},
```

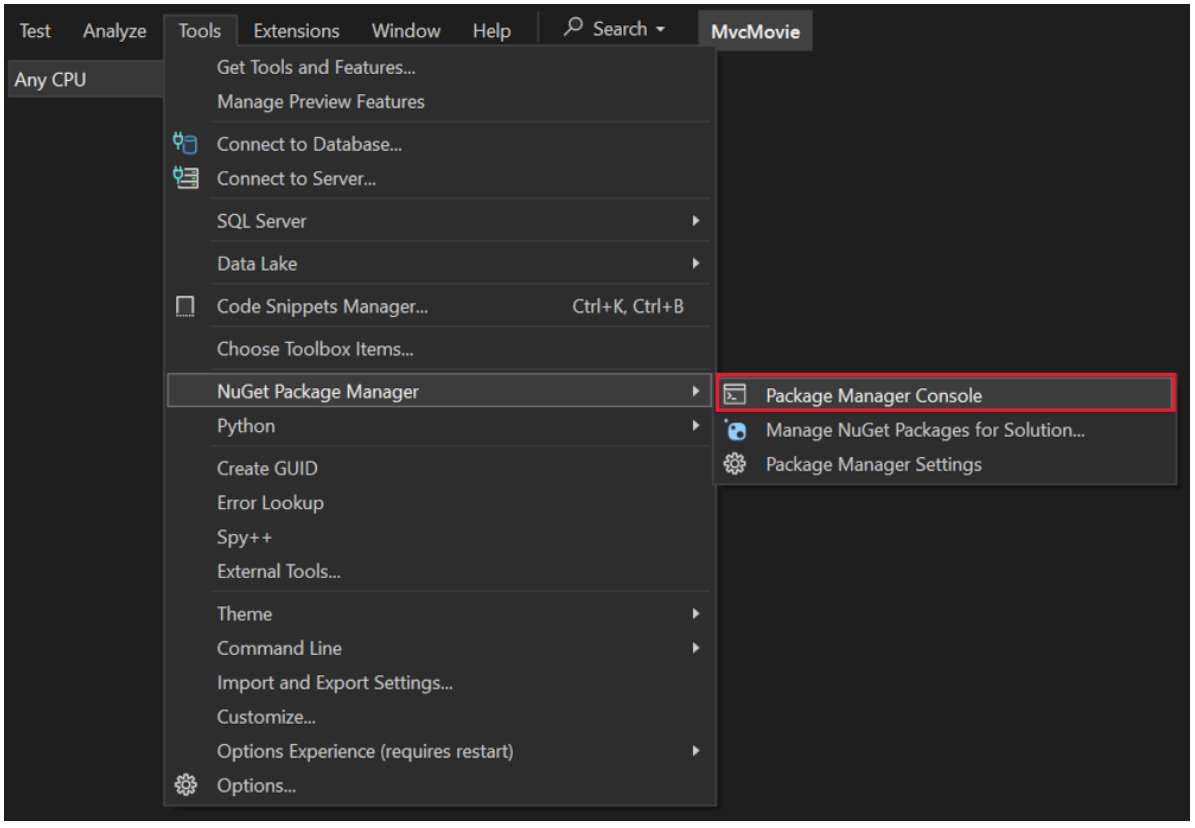
The app won't work until the DB is updated to include the new field. If it's run now, the following `SqlException` is thrown:

```
SqlException: Invalid column name 'Rating'.
```

This error occurs because the updated Movie model class is different than the schema of the Movie table of the existing database. (There's no `Rating` column in the database table.)

There are a few approaches to resolving the error:

1. Have the Entity Framework automatically drop and re-create the database based on the new model class schema. This approach is very convenient early in the development cycle when you're doing active development on a test database; it allows you to quickly evolve the model and database schema together. The downside, though, is that you lose existing data in the database — so you don't want to use this approach on a production database! Using an initializer to automatically seed a database with test data is often a productive way to develop an application. This is a good approach for early development and when using SQLite.



2. Explicitly modify the schema of the existing database so that it matches the model classes. The advantage of this approach is that you keep your data. You can make this change either manually or by creating a database change script.

3. Use Entity Framework Migrations to update the database schema.

For this tutorial, Entity Framework Migrations is used.

Visual Studio

From the **Tools** menu, select **NuGet Package Manager** > **Package Manager Console**.

In the Package Manager Console, enter the following command:

```
PowerShell
```

```
Add-Migration Rating
```

The `Add-Migration` command tells the migration framework to examine the current `Movie` model with the current `Movie` DB schema and create the necessary code to migrate the DB to the new model.

The name "Rating" is arbitrary and is used to name the migration file. It's helpful to use a meaningful name for the migration file.

If all the records in the DB are deleted, the initialize method will seed the DB and include the `Rating` field.

In the Package Manager Console, enter the following command:

PowerShell

```
Update-Database
```

The Update-Database command runs the Up method in migrations that have not been applied.

Run the app and verify you can create, edit, and display movies with a `Rating` field.

Part 9, add validation to an ASP.NET Core MVC app

Article • 07/26/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Rick Anderson

In this section:

- Validation logic is added to the `Movie` model.
- You ensure that the validation rules are enforced any time a user creates or edits a movie.

Keeping things DRY

One of the design tenets of MVC is DRY ("Don't Repeat Yourself"). ASP.NET Core MVC encourages you to specify functionality or behavior only once, and then have it be reflected everywhere in an app. This reduces the amount of code you need to write and makes the code you do write less error prone, easier to test, and easier to maintain.

The validation support provided by MVC and Entity Framework Core is a good example of the DRY principle in action. You can declaratively specify validation rules in one place (in the model class) and the rules are enforced everywhere in the app.

Delete the previously edited data

In the next step, validation rules are added that don't allow null values. Run the app, navigate to `/Movies/Index`, delete all listed movies, and stop the app. The app will use the seed data the next time it is run.

Add validation rules to the movie model

The DataAnnotations namespace provides a set of built-in validation attributes that are applied declaratively to a class or property. DataAnnotations also contains formatting attributes like `DataType` that help with formatting and don't provide any validation.

Update the `Movie` class to take advantage of the built-in validation attributes `Required`, `StringLength`, `RegularExpression`, `Range` and the `DataType` formatting attribute.

C#

```
using System;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace MvcMovie.Models;

public class Movie
{
    public int Id { get; set; }

    [StringLength(60, MinimumLength = 3)]
    [Required]
    public string? Title { get; set; }

    [Display(Name = "Release Date")]
    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }

    [Range(1, 100)]
    [DataType(DataType.Currency)]
    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }

    [RegularExpression(@"^[A-Z]+[a-zA-Z\s]*$")]
    [Required]
    [StringLength(30)]
    public string? Genre { get; set; }

    [RegularExpression(@"^[A-Z]+[a-zA-Z0-9""'\s-]*$")]
    [StringLength(5)]
    [Required]
    public string? Rating { get; set; }
}
```

The validation attributes specify behavior that you want to enforce on the model properties they're applied to:

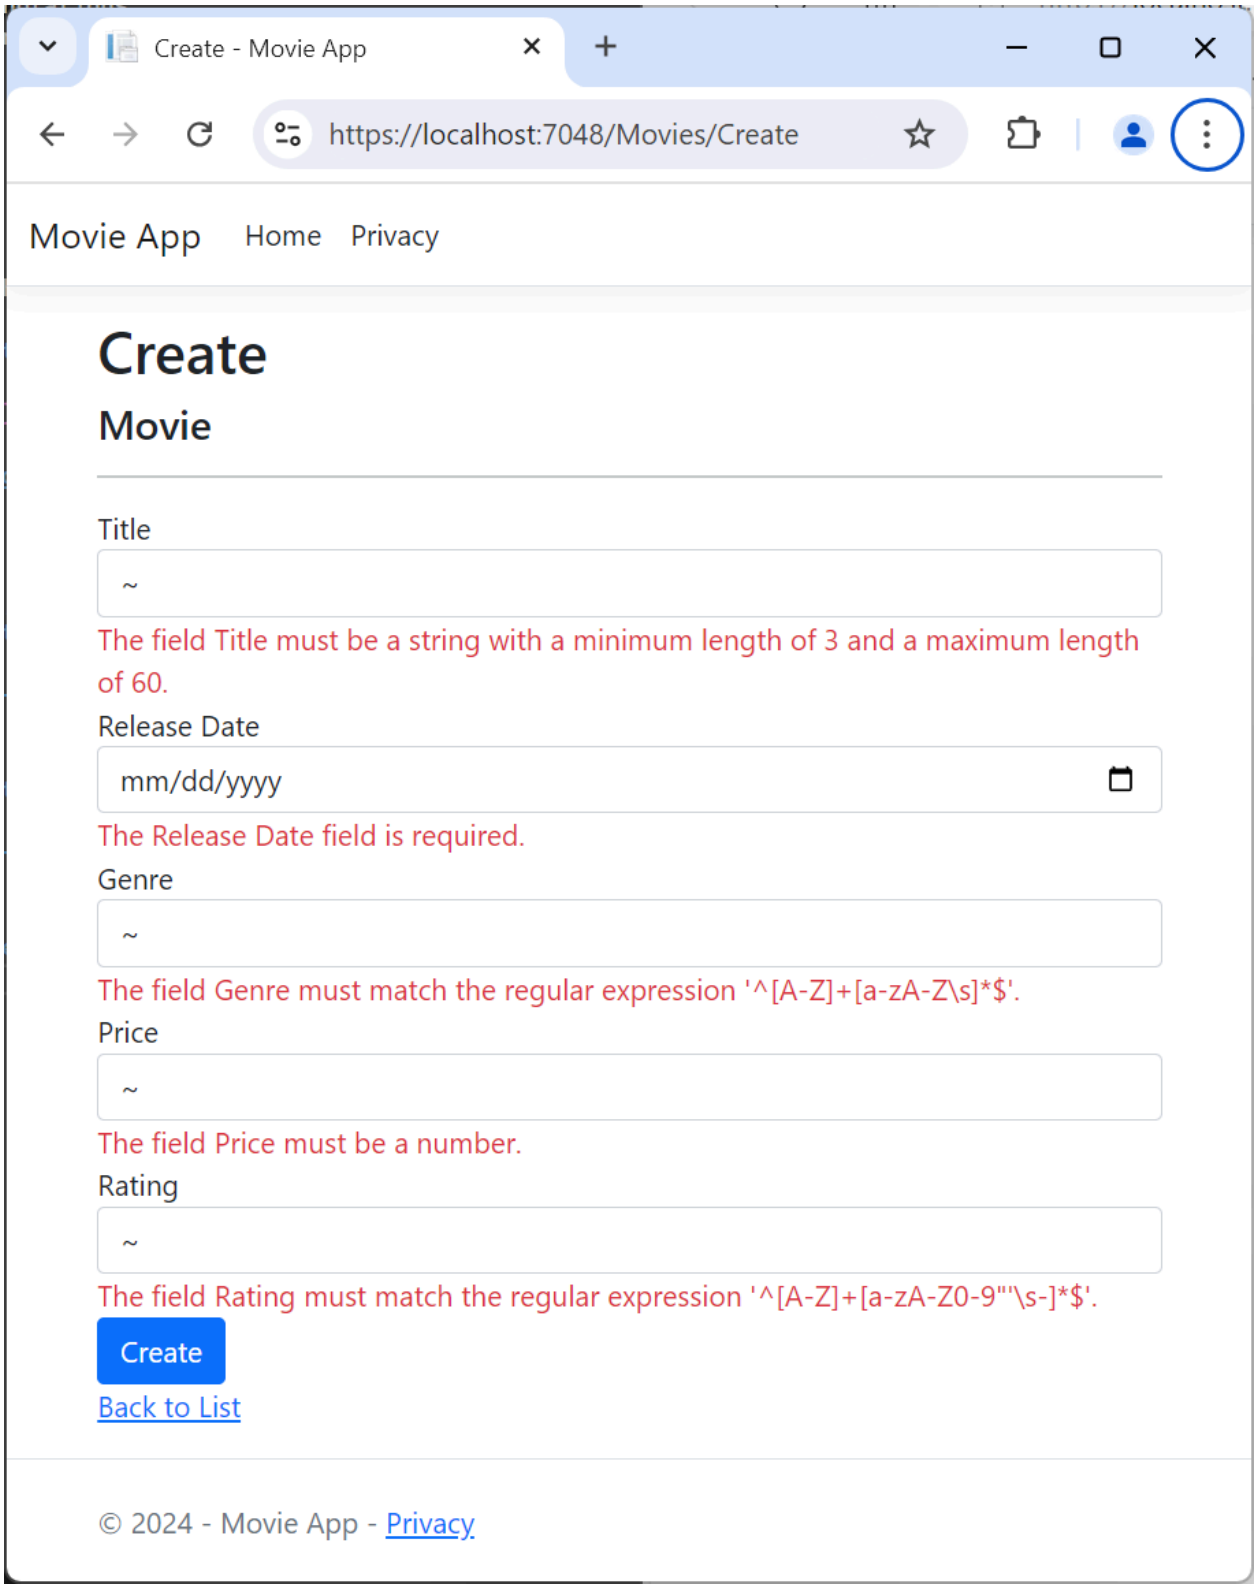
- The `Required` and `MinimumLength` attributes indicate that a property must have a value; but nothing prevents a user from entering white space to satisfy this validation.

- The `RegularExpression` attribute is used to limit what characters can be input. In the preceding code, "Genre":
  - Must only use letters.
  - The first letter is required to be uppercase. White spaces are allowed while numbers, and special characters are not allowed.

- The `RegularExpression` "Rating":
  - Requires that the first character be an uppercase letter.
  - Allows special characters and numbers in subsequent spaces. "PG-13" is valid for a rating, but fails for a "Genre".

- The `Range` attribute constrains a value to within a specified range.

- The `StringLength` attribute lets you set the maximum length of a string property, and optionally its minimum length.



- Value types (such as `decimal`, `int`, `float`, `DateTime`) are inherently required and don't need the `[Required]` attribute.

Having validation rules automatically enforced by ASP.NET Core helps make your app more robust. It also ensures that you can't forget to validate something and inadvertently let bad data into the database.

Validation Error UI

Run the app and navigate to the Movies controller.

Select the **Create New** link to add a new movie. Fill out the form with some invalid values. As soon as jQuery client side validation detects the error, it displays an error message.

> **Note**
>
> You may not be able to enter decimal commas in decimal fields. To support jQuery validation for non-English locales that use a comma (",") for a decimal point, and non US-English date formats, you must take steps to globalize your app. See this GitHub comment 4076 for instructions on adding decimal comma.

Notice how the form has automatically rendered an appropriate validation error message in each field containing an invalid value. The errors are enforced both client-side (using JavaScript and jQuery) and server-side (in case a user has JavaScript disabled).

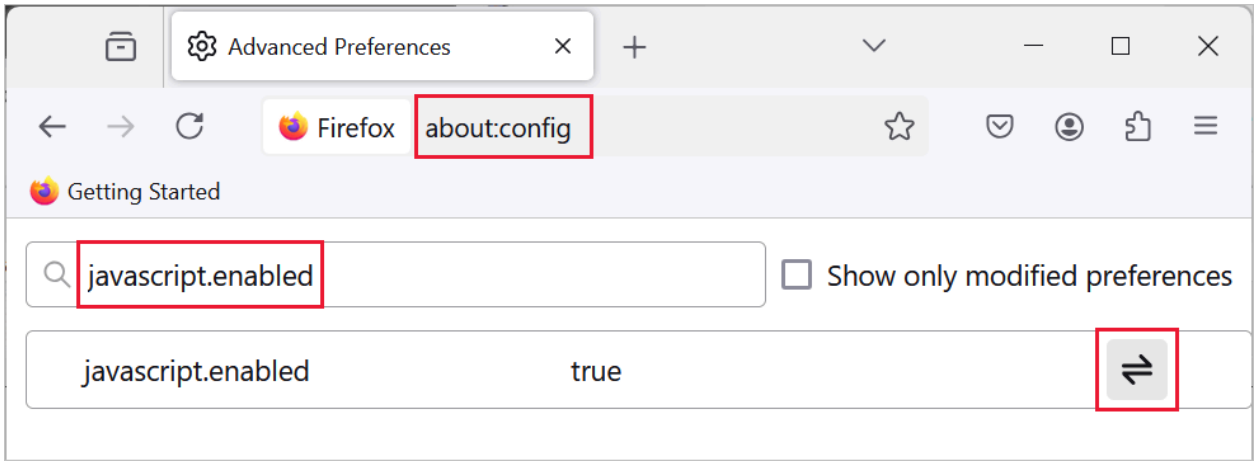
A significant benefit is that you didn't need to change a single line of code in the `MoviesController` class or in the `Create.cshtml` view in order to enable this validation UI. The controller and views you created earlier in this tutorial automatically picked up the validation rules that you specified by using validation attributes on the properties of the `Movie` model class. Test validation using the `Edit` action method, and the same validation is applied.

The form data isn't sent to the server until there are no client side validation errors. You can verify this by putting a break point in the `HTTP Post` method, by using the Fiddler tool, or the F12 Developer tools.

How validation works

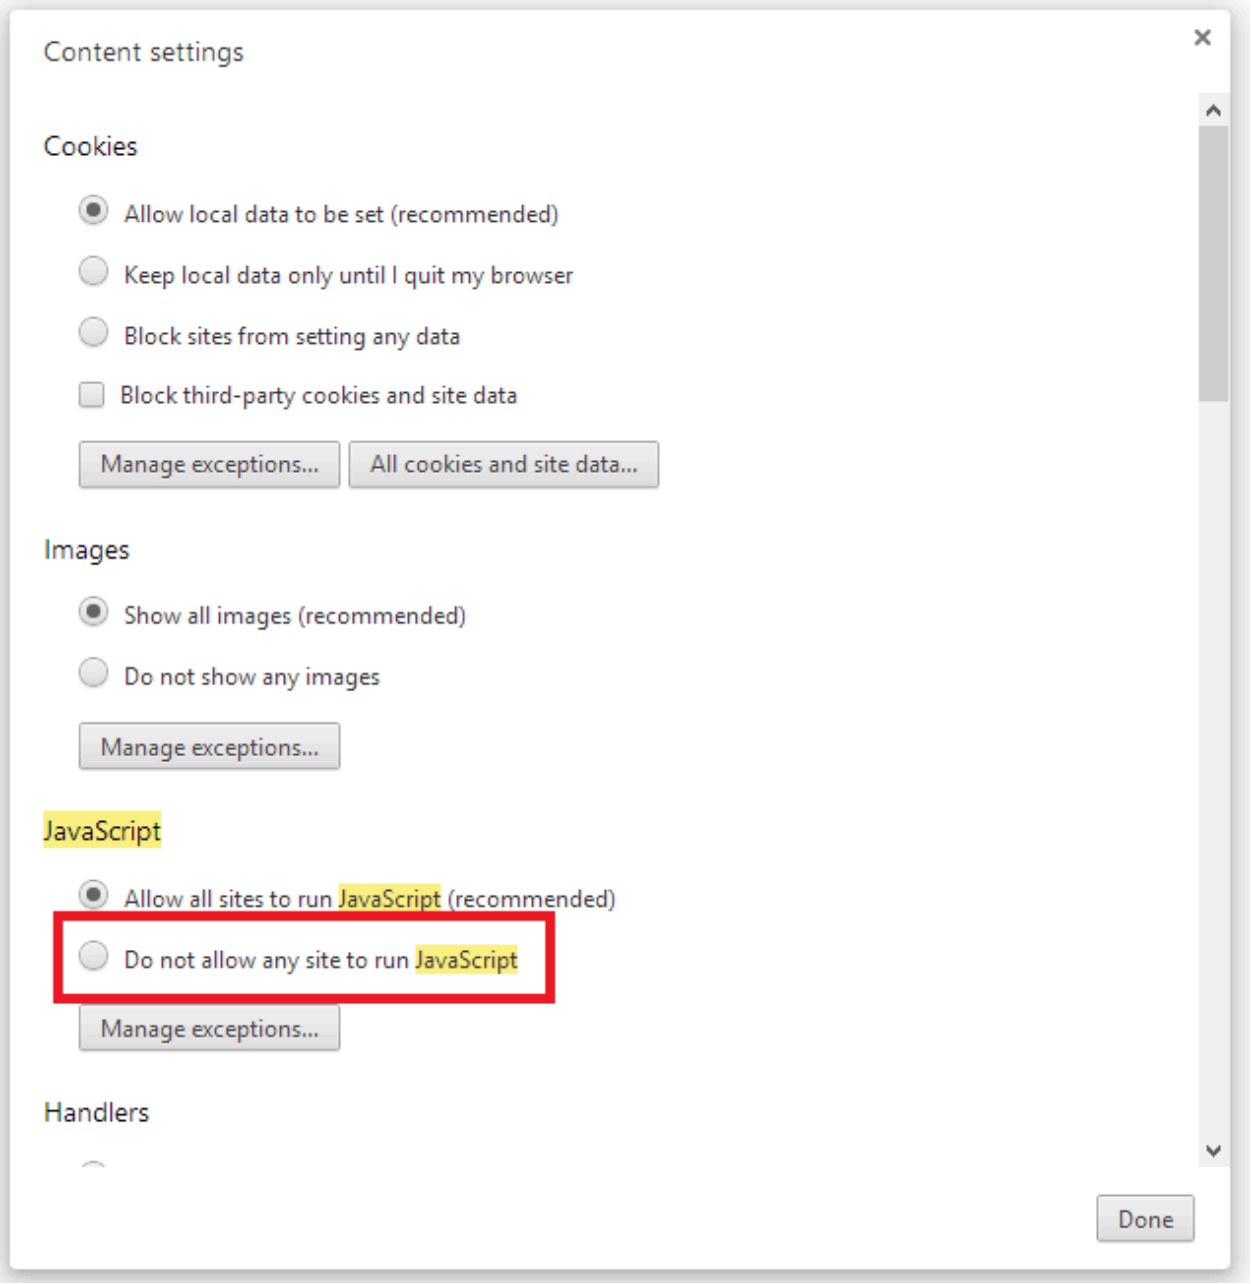
You might wonder how the validation UI was generated without any updates to the code in the controller or views. The following code shows the two `Create` methods.

C#



```
// GET: Movies/Create
public IActionResult Create()
{
    return View();
}

// POST: Movies/Create
// To protect from overposting attacks, enable the specific properties you
want to bind to.
// For more details, see http://go.microsoft.com/fwlink/?LinkId=317598.
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult>
Create([Bind("Id,Title,ReleaseDate,Genre,Price,Rating")] Movie movie)
{
    if (ModelState.IsValid)
    {
        _context.Add(movie);
        await _context.SaveChangesAsync();
        return RedirectToAction(nameof(Index));
    }
    return View(movie);
}
```



The first (HTTP GET) `Create` action method displays the initial Create form. The second (`[HttpPost]`) version handles the form post. The second `Create` method (The `[HttpPost]` version) calls `ModelState.IsValid` to check whether the movie has any validation errors. Calling this method evaluates any validation attributes that have been applied to the object. If the object has validation errors, the `Create` method re-displays the form. If there are no errors, the method saves the new movie in the database. In our movie example, the form isn't posted to the server when there are validation errors detected on the client side; the second `Create` method is never called when there are client side validation errors. If you disable JavaScript in your browser, client validation is disabled and you can test the HTTP POST `Create` method `ModelState.IsValid` detecting any validation errors.

You can set a break point in the `[HttpPost] Create` method and verify the method is never called, client side validation won't submit the form data when validation errors are detected. If you disable JavaScript in your browser, then submit the form with errors, the break point will be hit. You still get full validation without JavaScript.

The following image shows how to disable JavaScript in the Firefox browser.

The following image shows how to disable JavaScript in the Chrome browser.

After you disable JavaScript, post invalid data and step through the debugger.

```
74          // POST: Movies/Create
75          // To protect from overposting attacks, please enable t
76          // more details see http://go.microsoft.com/fwlink/?Lin
77          [HttpPost]
78          [ValidateAntiForgeryToken]
            0 references
79          public async Task<IAc          t> Create([Bind("ID,Title
80          {                              false
81              if (ModelState.IsValid)
82              {
83                  _context.Add(movie);
84                  await _context.SaveChangesAsync();
85                  return RedirectToAction("Index");
86              }
87              return View(movie);
88          }
89
```

A portion of the `Create.cshtml` view template is shown in the following markup:

HTML

```
<h4>Movie</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form asp-action="Create">
            <div asp-validation-summary="ModelOnly" class="text-danger">
</div>
            <div class="form-group">
                <label asp-for="Title" class="control-label"></label>
                <input asp-for="Title" class="form-control" />
                <span asp-validation-for="Title" class="text-danger"></span>
            </div>

            @*Markup removed for brevity.*@
```

The preceding markup is used by the action methods to display the initial form and to redisplay it in the event of an error.

The Input Tag Helper uses the DataAnnotations attributes and produces HTML attributes needed for jQuery Validation on the client side. The Validation Tag Helper displays validation errors. See Validation for more information.

What's really nice about this approach is that neither the controller nor the `Create` view template knows anything about the actual validation rules being enforced or about the specific error messages displayed. The validation rules and the error strings are specified only in the `Movie` class. These same validation rules are automatically applied to the `Edit` view and any other views templates you might create that edit your model.

When you need to change validation logic, you can do so in exactly one place by adding validation attributes to the model (in this example, the `Movie` class). You won't have to worry about different parts of the application being inconsistent with how the rules are enforced — all validation logic will be defined in one place and used everywhere. This keeps the code very clean, and makes it easy to maintain and evolve. And it means that you'll be fully honoring the DRY principle.

Using DataType Attributes

Open the `Movie.cs` file and examine the `Movie` class. The `System.ComponentModel.DataAnnotations` namespace provides formatting attributes in addition to the built-in set of validation attributes. We've already applied a `DataType`

enumeration value to the release date and to the price fields. The following code shows the `ReleaseDate` and `Price` properties with the appropriate `DataType` attribute.

C#

```
[Display(Name = "Release Date")]
[DataType(DataType.Date)]
public DateTime ReleaseDate { get; set; }

[Range(1, 100)]
[DataType(DataType.Currency)]
[Column(TypeName = "decimal(18, 2)")]
public decimal Price { get; set; }
```

The `DataType` attributes only provide hints for the view engine to format the data and supplies elements/attributes such as `<a>` for URL's and `<a href="mailto:EmailAddress.com">` for email. You can use the `RegularExpression` attribute to validate the format of the data. The `DataType` attribute is used to specify a data type that's more specific than the database intrinsic type, they're not validation attributes. In this case we only want to keep track of the date, not the time. The `DataType` Enumeration provides for many data types, such as Date, Time, PhoneNumber, Currency, EmailAddress and more. The `DataType` attribute can also enable the application to automatically provide type-specific features. For example, a `mailto:` link can be created for `DataType.EmailAddress`, and a date selector can be provided for `DataType.Date` in browsers that support HTML5. The `DataType` attributes emit HTML 5 `data-` (pronounced data dash) attributes that HTML 5 browsers can understand. The `DataType` attributes do **not** provide any validation.

`DataType.Date` doesn't specify the format of the date that's displayed. By default, the data field is displayed according to the default formats based on the server's `CultureInfo`.

The `DisplayFormat` attribute is used to explicitly specify the date format:

C#

```
[DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode =
true)]
public DateTime ReleaseDate { get; set; }
```

The `ApplyFormatInEditMode` setting specifies that the formatting should also be applied when the value is displayed in a text box for editing. (You might not want that for some

fields — for example, for currency values, you probably don't want the currency symbol in the text box for editing.)

You can use the `DisplayFormat` attribute by itself, but it's generally a good idea to use the `DataType` attribute. The `DataType` attribute conveys the semantics of the data as opposed to how to render it on a screen, and provides the following benefits that you don't get with DisplayFormat:

- The browser can enable HTML5 features (for example to show a calendar control, the locale-appropriate currency symbol, email links, etc.)
- By default, the browser will render data using the correct format based on your locale.
- The `DataType` attribute can enable MVC to choose the right field template to render the data (the `DisplayFormat` if used by itself uses the string template).

> ⓘ **Note**
>
> jQuery validation doesn't work with the `Range` attribute and `DateTime`. For example, the following code will always display a client side validation error, even when the date is in the specified range:
>
> `[Range(typeof(DateTime), "1/1/1966", "1/1/2020")]`

You will need to disable jQuery date validation to use the `Range` attribute with `DateTime`. It's generally not a good practice to compile hard dates in your models, so using the `Range` attribute and `DateTime` is discouraged.

The following code shows combining attributes on one line:

C#

```
using System;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace MvcMovie.Models;

public class Movie
{
    public int Id { get; set; }
    [StringLength(60, MinimumLength = 3)]
    public string Title { get; set; }
    [Display(Name = "Release Date"), DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }
```

```
    [RegularExpression(@"^[A-Z]+[a-zA-Z\s]*$"), Required, StringLength(30)]
    public string Genre { get; set; }
    [Range(1, 100), DataType(DataType.Currency)]
    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }
    [RegularExpression(@"^[A-Z]+[a-zA-Z0-9""'\s-]*$"), StringLength(5)]
    public string Rating { get; set; }
}
```

In the next part of the series, we review the app and make some improvements to the automatically generated `Details` and `Delete` methods.

Part 10, examine the Details and Delete methods of an ASP.NET Core app

Article • 08/04/2024

By Rick Anderson

Open the Movie controller and examine the `Details` method:

C#

```
// GET: Movies/Details/5
public async Task<IActionResult> Details(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var movie = await _context.Movie
        .FirstOrDefaultAsync(m => m.Id == id);
    if (movie == null)
    {
        return NotFound();
    }

    return View(movie);
}
```

The MVC scaffolding engine that created this action method adds a comment showing an HTTP request that invokes the method. In this case it's a GET request with three URL segments, the `Movies` controller, the `Details` method, and an `id` value. Recall these segments are defined in `Program.cs`.

C#

```
app.MapControllerRoute(
    name: "default",
    pattern: "{controller=Home}/{action=Index}/{id?}");
```

EF makes it easy to search for data using the `FirstOrDefaultAsync` method. An important security feature built into the method is that the code verifies that the search method has found a movie before it tries to do anything with it. For example, a hacker could introduce errors into the site by changing the URL created by the links from `http://localhost:{PORT}/Movies/Details/1` to something like `http://localhost:{PORT}/Movies/Details/12345` (or some other value that doesn't represent an actual movie). If you didn't check for a null movie, the app would throw an exception.

Examine the `Delete` and `DeleteConfirmed` methods.

C#

```
// GET: Movies/Delete/5
public async Task<IActionResult> Delete(int? id)
{

    if (id == null)
    {
        return NotFound();
    }

    var movie = await _context.Movie
        .FirstOrDefaultAsync(m => m.Id == id);
    if (movie == null)
    {
        return NotFound();
    }

    return View(movie);
}

// POST: Movies/Delete/5
[HttpPost, ActionName("Delete")]
[ValidateAntiForgeryToken]
public async Task<IActionResult> DeleteConfirmed(int id)
{
    var movie = await _context.Movie.FindAsync(id);
    if (movie != null)
    {
        _context.Movie.Remove(movie);
    }

    await _context.SaveChangesAsync();
    return RedirectToAction(nameof(Index));
}
```

Note that the `HTTP GET Delete` method doesn't delete the specified movie, it returns a view of the movie where you can submit (HttpPost) the deletion. Performing a delete operation in response to a GET request (or for that matter, performing an edit operation, create operation, or any other operation that changes data) opens up a security hole.

The `[HttpPost]` method that deletes the data is named `DeleteConfirmed` to give the HTTP POST method a unique signature or name. The two method signatures are shown below:

C#

```
// GET: Movies/Delete/5
public async Task<IActionResult> Delete(int? id)
{
```

C#

```
// POST: Movies/Delete/5
[HttpPost, ActionName("Delete")]
[ValidateAntiForgeryToken]
public async Task<IActionResult> DeleteConfirmed(int id)
{
```

The common language runtime (CLR) requires overloaded methods to have a unique parameter signature (same method name but different list of parameters). However, here you need two `Delete` methods -- one for GET and one for POST -- that both have the same parameter signature. (They both need to accept a single integer as a parameter.)

There are two approaches to this problem, one is to give the methods different names. That's what the scaffolding mechanism did in the preceding example. However, this introduces a small problem: ASP.NET maps segments of a URL to action methods by name, and if you rename a method, routing normally wouldn't be able to find that method. The solution is what you see in the example, which is to add the `ActionName("Delete")` attribute to the `DeleteConfirmed` method. That attribute performs mapping for the routing system so that a URL that includes /Delete/ for a POST request will find the `DeleteConfirmed` method.

Another common work around for methods that have identical names and signatures is to artificially change the signature of the POST method to include an extra (unused) parameter. That's what we did in a previous post when we added the `notUsed` parameter. You could do the same thing here for the `[HttpPost] Delete` method:

C#

```
// POST: Movies/Delete/6
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Delete(int id, bool notUsed)
```

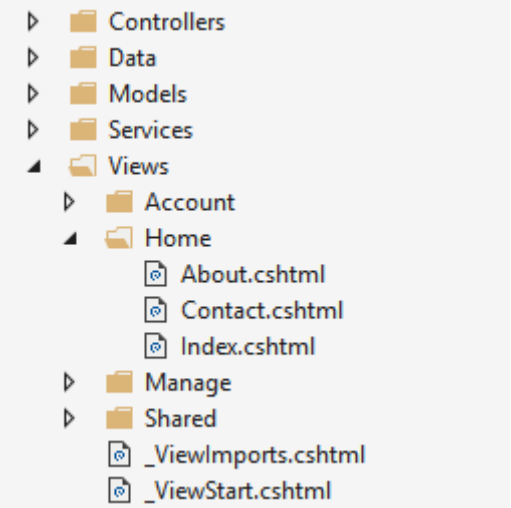
Views in ASP.NET Core MVC



Article • 06/17/2024

By Steve Smith and Dave Brock

This document explains views used in ASP.NET Core MVC applications. For information on Razor Pages, see Introduction to Razor Pages in ASP.NET Core.

In the Model-View-Controller (MVC) pattern, the *view* handles the app's data presentation and user interaction. A view is an HTML template with embedded Razor markup. Razor markup is code that interacts with HTML markup to produce a webpage that's sent to the client.

In ASP.NET Core MVC, views are `.cshtml` files that use the C# programming language in Razor markup. Usually, view files are grouped into folders named for each of the app's controllers. The folders are stored in a `Views` folder at the root of the app:

The `Home` controller is represented by a `Home` folder inside the `Views` folder. The `Home` folder contains the views for the `About`, `Contact`, and `Index` (homepage) webpages. When a user requests one of these three webpages, controller actions in the `Home` controller determine which of the three views is used to build and return a webpage to the user.

Use layouts to provide consistent webpage sections and reduce code repetition. Layouts often contain the header, navigation and menu elements, and the footer. The header and footer usually contain boilerplate markup for many metadata elements and links to script and style assets. Layouts help you avoid this boilerplate markup in your views.

Partial views reduce code duplication by managing reusable parts of views. For example, a partial view is useful for an author biography on a blog website that appears in several views. An author biography is ordinary view content and doesn't require code to

execute in order to produce the content for the webpage. Author biography content is available to the view by model binding alone, so using a partial view for this type of content is ideal.

View components are similar to partial views in that they allow you to reduce repetitive code, but they're appropriate for view content that requires code to run on the server in order to render the webpage. View components are useful when the rendered content requires database interaction, such as for a website shopping cart. View components aren't limited to model binding in order to produce webpage output.

Benefits of using views

Views help to establish separation of concerns within an MVC app by separating the user interface markup from other parts of the app. Following SoC design makes your app modular, which provides several benefits:

- The app is easier to maintain because it's better organized. Views are generally grouped by app feature. This makes it easier to find related views when working on a feature.
- The parts of the app are loosely coupled. You can build and update the app's views separately from the business logic and data access components. You can modify the views of the app without necessarily having to update other parts of the app.
- It's easier to test the user interface parts of the app because the views are separate units.
- Due to better organization, it's less likely that you'll accidentally repeat sections of the user interface.

Creating a view

Views that are specific to a controller are created in the `Views/[ControllerName]` folder. Views that are shared among controllers are placed in the `Views/Shared` folder. To create a view, add a new file and give it the same name as its associated controller action with the `.cshtml` file extension. To create a view that corresponds with the `About` action in the `Home` controller, create an `About.cshtml` file in the `Views/Home` folder:

CSHTML

```
@{
    ViewData["Title"] = "About";
}
<h2>@ViewData["Title"].</h2>
<h3>@ViewData["Message"]</h3>
```

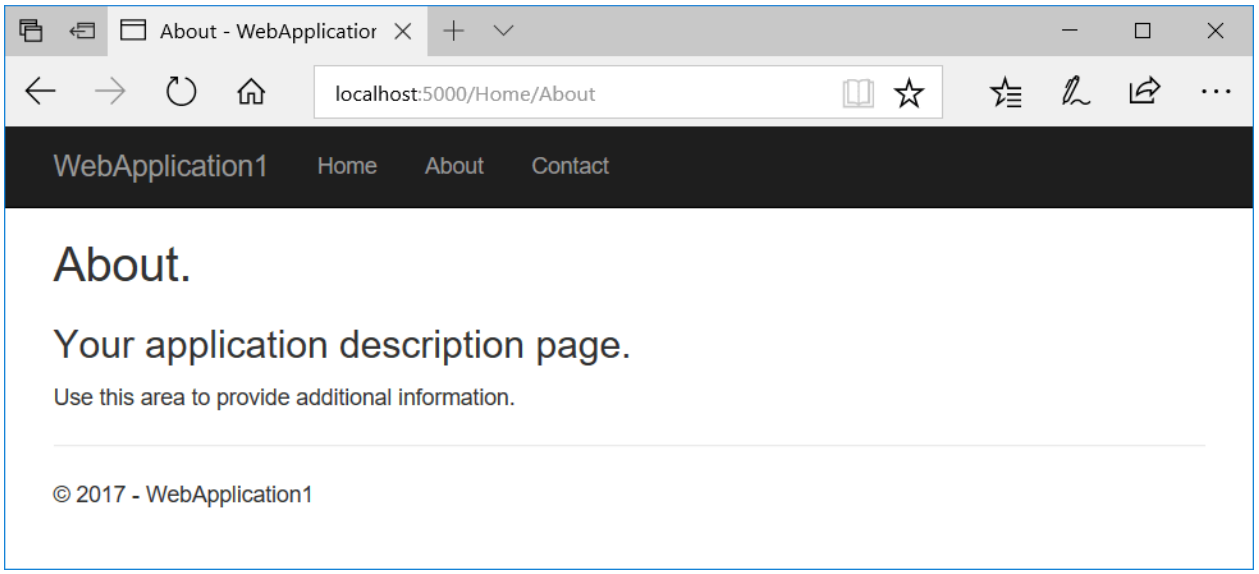
```
<p>Use this area to provide additional information.</p>
```

Razor markup starts with the `@` symbol. Run C# statements by placing C# code within Razor code blocks set off by curly braces (`{ ... }`). For example, see the assignment of "About" to `ViewData["Title"]` shown above. You can display values within HTML by simply referencing the value with the `@` symbol. See the contents of the `<h2>` and `<h3>` elements above.

The view content shown above is only part of the entire webpage that's rendered to the user. The rest of the page's layout and other common aspects of the view are specified in other view files. To learn more, see the Layout topic.

How controllers specify views

Views are typically returned from actions as a ViewResult, which is a type of ActionResult. Your action method can create and return a `ViewResult` directly, but that isn't commonly done. Since most controllers inherit from Controller, you simply use the `View` helper method to return the `ViewResult`:



`HomeController.cs`:

C#

```
public IActionResult About()
{
    ViewData["Message"] = "Your application description page.";

    return View();
}
```

When this action returns, the `About.cshtml` view shown in the last section is rendered as the following webpage:

The `View` helper method has several overloads. You can optionally specify:

- An explicit view to return:

```
C#

return View("Orders");
```

- A model to pass to the view:

```
C#

return View(Orders);
```

- Both a view and a model:

```
C#

return View("Orders", Orders);
```

View discovery

When an action returns a view, a process called *view discovery* takes place. This process determines which view file is used based on the view name.

The default behavior of the `View` method (`return View();`) is to return a view with the same name as the action method from which it's called. For example, the `About` `ActionResult` method name of the controller is used to search for a view file named `About.cshtml`. First, the runtime looks in the `Views/[ControllerName]` folder for the view. If it doesn't find a matching view there, it searches the `Shared` folder for the view.

It doesn't matter if you implicitly return the `ViewResult` with `return View();` or explicitly pass the view name to the `View` method with `return View("<ViewName>");`. In both cases, view discovery searches for a matching view file in this order:

1. `Views/\[ControllerName]/\[ViewName].cshtml`
2. `Views/Shared/\[ViewName].cshtml`

A view file path can be provided instead of a view name. If using an absolute path starting at the app root (optionally starting with "/" or "~/"), the `.cshtml` extension must be specified:

```
C#

return View("Views/Home/About.cshtml");
```

You can also use a relative path to specify views in different directories without the `.cshtml` extension. Inside the `HomeController`, you can return the `Index` view of your `Manage` views with a relative path:

```
C#

return View("../Manage/Index");
```

Similarly, you can indicate the current controller-specific directory with the "./" prefix:

```
C#

return View("./About");
```

Partial views and view components use similar (but not identical) discovery mechanisms.

You can customize the default convention for how views are located within the app by using a custom IViewLocationExpander.

View discovery relies on finding view files by file name. If the underlying file system is case sensitive, view names are probably case sensitive. For compatibility across operating systems, match case between controller and action names and associated view folders and file names. If you encounter an error that a view file can't be found while working with a case-sensitive file system, confirm that the casing matches between the requested view file and the actual view file name.

Follow the best practice of organizing the file structure for your views to reflect the relationships among controllers, actions, and views for maintainability and clarity.

Pass data to views

Pass data to views using several approaches:

- Strongly typed data: viewmodel
- Weakly typed data
  - `ViewData` (`ViewDataAttribute`)
  - `ViewBag`

Strongly-typed data (viewmodel)

The most robust approach is to specify a model type in the view. This model is commonly referred to as a *viewmodel*. You pass an instance of the viewmodel type to the view from the action.

Using a viewmodel to pass data to a view allows the view to take advantage of *strong* type checking. *Strong typing* (or *strongly typed*) means that every variable and constant has an explicitly defined type (for example, `string`, `int`, or `DateTime`). The validity of types used in a view is checked at compile time.

Visual Studio and Visual Studio Code list strongly typed class members using a feature called IntelliSense. When you want to see the properties of a viewmodel, type the variable name for the viewmodel followed by a period (`.`). This helps you write code faster with fewer errors.

Specify a model using the `@model` directive. Use the model with `@Model`:

CSHTML

```
@model WebApplication1.ViewModels.Address

<h2>Contact</h2>
<address>
    @Model.Street<br>
    @Model.City, @Model.State @Model.PostalCode<br>
    <abbr title="Phone">P:</abbr> 425.555.0100
</address>
```

To provide the model to the view, the controller passes it as a parameter:

C#

```
public IActionResult Contact()
{
    ViewData["Message"] = "Your contact page.";
```

```
    var viewModel = new Address()
    {
        Name = "Microsoft",
        Street = "One Microsoft Way",
        City = "Redmond",
        State = "WA",
        PostalCode = "98052-6399"
    };

    return View(viewModel);
}
```

There are no restrictions on the model types that you can provide to a view. We recommend using Plain Old CLR Object (POCO) viewmodels with little or no behavior (methods) defined. Usually, viewmodel classes are either stored in the `Models` folder or a separate `ViewModels` folder at the root of the app. The `Address` viewmodel used in the example above is a POCO viewmodel stored in a file named `Address.cs`:

C#

```
namespace WebApplication1.ViewModels
{
    public class Address
    {
        public string Name { get; set; }
        public string Street { get; set; }
        public string City { get; set; }
        public string State { get; set; }
        public string PostalCode { get; set; }
    }
}
```

Nothing prevents you from using the same classes for both your viewmodel types and your business model types. However, using separate models allows your views to vary independently from the business logic and data access parts of your app. Separation of models and viewmodels also offers security benefits when models use model binding and validation for data sent to the app by the user.

Weakly typed data (`ViewData`, `[ViewData]` attribute, and `ViewBag`)

`ViewBag` *isn't available by default for use in Razor Pages* `PageModel` *classes.*

In addition to strongly typed views, views have access to a *weakly typed* (also called *loosely typed*) collection of data. Unlike strong types, *weak types* (or *loose types*) means

that you don't explicitly declare the type of data you're using. You can use the collection of weakly typed data for passing small amounts of data in and out of controllers and views.

Expand table

Passing data between a ...	Example
Controller and a view	Populating a dropdown list with data.
View and a layout view	Setting the `<title>` element content in the layout view from a view file.
Partial view and a view	A widget that displays data based on the webpage that the user requested.

This collection can be referenced through either the `ViewData` or `ViewBag` properties on controllers and views. The `ViewData` property is a dictionary of weakly typed objects. The `ViewBag` property is a wrapper around `ViewData` that provides dynamic properties for the underlying `ViewData` collection. Note: Key lookups are case-insensitive for both `ViewData` and `ViewBag`.

`ViewData` and `ViewBag` are dynamically resolved at runtime. Since they don't offer compile-time type checking, both are generally more error-prone than using a viewmodel. For that reason, some developers prefer to minimally or never use `ViewData` and `ViewBag`.

`ViewData`

`ViewData` is a ViewDataDictionary object accessed through `string` keys. String data can be stored and used directly without the need for a cast, but you must cast other `ViewData` object values to specific types when you extract them. You can use `ViewData` to pass data from controllers to views and within views, including partial views and layouts.

The following is an example that sets values for a greeting and an address using `ViewData` in an action:

C#

```
public IActionResult SomeAction()
{
    ViewData["Greeting"] = "Hello";
```

```
    ViewData["Address"]  = new Address()
    {
        Name = "Steve",
        Street = "123 Main St",
        City = "Hudson",
        State = "OH",
        PostalCode = "44236"
    };

    return View();
}
```

Work with the data in a view:

CSHTML

```
@{
    // Since Address isn't a string, it requires a cast.
    var address = ViewData["Address"] as Address;
}

@ViewData["Greeting"] World!

<address>
    @address.Name<br>
    @address.Street<br>
    @address.City, @address.State @address.PostalCode
</address>
```

`[ViewData]` attribute

Another approach that uses the ViewDataDictionary is ViewDataAttribute. Properties on controllers or Razor Page models marked with the `[ViewData]` attribute have their values stored and loaded from the dictionary.

In the following example, the Home controller contains a `Title` property marked with `[ViewData]`. The `About` method sets the title for the About view:

C#

```
public class HomeController : Controller
{
    [ViewData]
    public string Title { get; set; }

    public IActionResult About()
    {
        Title = "About Us";
        ViewData["Message"] = "Your application description page.";
```

```
        return View();
    }
}
```

In the layout, the title is read from the ViewData dictionary:

CSHTML

```
<!DOCTYPE html>
<html lang="en">
<head>
    <title>@ViewData["Title"] - WebApplication</title>
    ...
```

`ViewBag`

`ViewBag` *isn't available by default for use in Razor Pages* `PageModel` *classes.*

`ViewBag` is a `Microsoft.AspNetCore.Mvc.ViewFeatures.Internal.DynamicViewData` object that provides dynamic access to the objects stored in `ViewData`. `ViewBag` can be more convenient to work with, since it doesn't require casting. The following example shows how to use `ViewBag` with the same result as using `ViewData` above:

C#

```
public IActionResult SomeAction()
{
    ViewBag.Greeting = "Hello";
    ViewBag.Address  = new Address()
    {
        Name = "Steve",
        Street = "123 Main St",
        City = "Hudson",
        State = "OH",
        PostalCode = "44236"
    };

    return View();
}
```

CSHTML

```
@ViewBag.Greeting World!

<address>
    @ViewBag.Address.Name<br>
```

```
    @ViewBag.Address.Street<br>
    @ViewBag.Address.City, @ViewBag.Address.State
@ViewBag.Address.PostalCode
</address>
```

Using `ViewData` and `ViewBag` simultaneously

`ViewBag` *isn't available by default for use in Razor Pages* `PageModel` *classes.*

Since `ViewData` and `ViewBag` refer to the same underlying `ViewData` collection, you can use both `ViewData` and `ViewBag` and mix and match between them when reading and writing values.

Set the title using `ViewBag` and the description using `ViewData` at the top of an `About.cshtml` view:

CSHTML

```
@{
    Layout = "/Views/Shared/_Layout.cshtml";
    ViewBag.Title = "About Contoso";
    ViewData["Description"] = "Let us tell you about Contoso's philosophy
and mission.";
}
```

Read the properties but reverse the use of `ViewData` and `ViewBag`. In the `_Layout.cshtml` file, obtain the title using `ViewData` and obtain the description using `ViewBag`:

CSHTML

```
<!DOCTYPE html>
<html lang="en">
<head>
    <title>@ViewData["Title"]</title>
    <meta name="description" content="@ViewBag.Description">
    ...
```

Remember that strings don't require a cast for `ViewData`. You can use `@ViewData["Title"]` without casting.

Using both `ViewData` and `ViewBag` at the same time works, as does mixing and matching reading and writing the properties. The following markup is rendered:

HTML

```
<!DOCTYPE html>
<html lang="en">
<head>
    <title>About Contoso</title>
    <meta name="description" content="Let us tell you about Contoso's
philosophy and mission.">
    ...
```

Summary of the differences between `ViewData` and `ViewBag`

`ViewBag` *isn't available by default for use in Razor Pages* `PageModel` *classes.*

- `ViewData`
  - Derives from ViewDataDictionary, so it has dictionary properties that can be useful, such as `ContainsKey`, `Add`, `Remove`, and `Clear`.
  - Keys in the dictionary are strings, so whitespace is allowed. Example: `ViewData["Some Key With Whitespace"]`
  - Any type other than a `string` must be cast in the view to use `ViewData`.
- `ViewBag`
  - Derives from `Microsoft.AspNetCore.Mvc.ViewFeatures.Internal.DynamicViewData`, so it allows the creation of dynamic properties using dot notation (`@ViewBag.SomeKey = <value or object>`), and no casting is required. The syntax of `ViewBag` makes it quicker to add to controllers and views.
  - Simpler to check for null values. Example: `@ViewBag.Person?.Name`

When to use `ViewData` or `ViewBag`

Both `ViewData` and `ViewBag` are equally valid approaches for passing small amounts of data among controllers and views. The choice of which one to use is based on preference. You can mix and match `ViewData` and `ViewBag` objects, however, the code is easier to read and maintain with one approach used consistently. Both approaches are dynamically resolved at runtime and thus prone to causing runtime errors. Some development teams avoid them.

Dynamic views

Views that don't declare a model type using `@model` but that have a model instance passed to them (for example, `return View(Address);`) can reference the instance's properties dynamically:

CSHTML

```
<address>
    @Model.Street<br>
    @Model.City, @Model.State @Model.PostalCode<br>
    <abbr title="Phone">P:</abbr> 425.555.0100
</address>
```

This feature offers flexibility but doesn't offer compilation protection or IntelliSense. If the property doesn't exist, webpage generation fails at runtime.

More view features

Tag Helpers make it easy to add server-side behavior to existing HTML tags. Using Tag Helpers avoids the need to write custom code or helpers within your views. Tag helpers are applied as attributes to HTML elements and are ignored by editors that can't process them. This allows you to edit and render view markup in a variety of tools.

Generating custom HTML markup can be achieved with many built-in HTML Helpers. More complex user interface logic can be handled by View Components. View components provide the same SoC that controllers and views offer. They can eliminate the need for actions and views that deal with data used by common user interface elements.

Like many other aspects of ASP.NET Core, views support dependency injection, allowing services to be injected into views.

CSS isolation

Isolate CSS styles to individual pages, views, and components to reduce or avoid:

- Dependencies on global styles that can be challenging to maintain.
- Style conflicts in nested content.

To add a *scoped CSS file* for a page or view, place the CSS styles in a companion `.cshtml.css` file matching the name of the `.cshtml` file. In the following example, an `Index.cshtml.css` file supplies CSS styles that are only applied to the `Index.cshtml` page or view.

`Pages/Index.cshtml.css` (Razor Pages) or `Views/Index.cshtml.css` (MVC):

CSS

```
h1 {
    color: red;
}
```

CSS isolation occurs at build time. The framework rewrites CSS selectors to match markup rendered by the app's pages or views. The rewritten CSS styles are bundled and produced as a static asset, `{APP ASSEMBLY}.styles.css`. The placeholder `{APP ASSEMBLY}` is the assembly name of the project. A link to the bundled CSS styles is placed in the app's layout.

In the `<head>` content of the app's `Pages/Shared/_Layout.cshtml` (Razor Pages) or `Views/Shared/_Layout.cshtml` (MVC), add or confirm the presence of the link to the bundled CSS styles:

HTML

```
<link rel="stylesheet" href="~/{APP ASSEMBLY}.styles.css" />
```

In the following example, the app's assembly name is `WebApp`:

HTML

```
<link rel="stylesheet" href="WebApp.styles.css" />
```

The styles defined in a scoped CSS file are only applied to the rendered output of the matching file. In the preceding example, any `h1` CSS declarations defined elsewhere in the app don't conflict with the `Index`'s heading style. CSS style cascading and inheritance rules remain in effect for scoped CSS files. For example, styles applied directly to an `<h1>` element in the `Index.cshtml` file override the scoped CSS file's styles in `Index.cshtml.css`.

> **Note**
>
> In order to guarantee CSS style isolation when bundling occurs, importing CSS in Razor code blocks isn't supported.
>
> CSS isolation only applies to HTML elements. CSS isolation isn't supported for Tag Helpers.

Within the bundled CSS file, each page, view, or Razor component is associated with a scope identifier in the format `b-{STRING}`, where the `{STRING}` placeholder is a ten-

character string generated by the framework. The following example provides the style for the preceding `<h1>` element in the `Index` page of a Razor Pages app:

```css
/* /Pages/Index.cshtml.rz.scp.css */
h1[b-3xxtam6d07] {
    color: red;
}
```

In the `Index` page where the CSS style is applied from the bundled file, the scope identifier is appended as an HTML attribute:

```HTML
<h1 b-3xxtam6d07>
```

The identifier is unique to an app. At build time, a project bundle is created with the convention `{STATIC WEB ASSETS BASE PATH}/Project.lib.scp.css`, where the placeholder `{STATIC WEB ASSETS BASE PATH}` is the static web assets base path.

If other projects are utilized, such as NuGet packages or Razor class libraries, the bundled file:

- References the styles using CSS imports.
- Isn't published as a static web asset of the app that consumes the styles.

CSS preprocessor support

CSS preprocessors are useful for improving CSS development by utilizing features such as variables, nesting, modules, mixins, and inheritance. While CSS isolation doesn't natively support CSS preprocessors such as Sass or Less, integrating CSS preprocessors is seamless as long as preprocessor compilation occurs before the framework rewrites the CSS selectors during the build process. Using Visual Studio for example, configure existing preprocessor compilation as a **Before Build** task in the Visual Studio Task Runner Explorer.

Many third-party NuGet packages, such as AspNetCore.SassCompiler, can compile SASS/SCSS files at the beginning of the build process before CSS isolation occurs, and no additional configuration is required.

CSS isolation configuration

CSS isolation permits configuration for some advanced scenarios, such as when there are dependencies on existing tools or workflows.

Customize scope identifier format

In this section, the `{Pages|Views}` placeholder is either `Pages` for Razor Pages apps or `Views` for MVC apps.

By default, scope identifiers use the format `b-{STRING}`, where the `{STRING}` placeholder is a ten-character string generated by the framework. To customize the scope identifier format, update the project file to a desired pattern:

XML

```
<ItemGroup>
  <None Update="{Pages|Views}/Index.cshtml.css" CssScope="custom-scope-
identifier" />
</ItemGroup>
```

In the preceding example, the CSS generated for `Index.cshtml.css` changes its scope identifier from `b-{STRING}` to `custom-scope-identifier`.

Use scope identifiers to achieve inheritance with scoped CSS files. In the following project file example, a `BaseView.cshtml.css` file contains common styles across views. A `DerivedView.cshtml.css` file inherits these styles.

XML

```
<ItemGroup>
  <None Update="{Pages|Views}/BaseView.cshtml.css" CssScope="custom-scope-
identifier" />
  <None Update="{Pages|Views}/DerivedView.cshtml.css" CssScope="custom-
scope-identifier" />
</ItemGroup>
```

Use the wildcard (`*`) operator to share scope identifiers across multiple files:

XML

```
<ItemGroup>
  <None Update="{Pages|Views}/*.cshtml.css" CssScope="custom-scope-
identifier" />
</ItemGroup>
```

Change base path for static web assets

The scoped CSS file is generated at the root of the app. In the project file, use the `StaticWebAssetBasePath` property to change the default path. The following example places the scoped CSS file, and the rest of the app's assets, at the `_content` path:

XML

```
<PropertyGroup>
  <StaticWebAssetBasePath>_content/$(PackageId)</StaticWebAssetBasePath>
</PropertyGroup>
```

Disable automatic bundling

To opt out of how framework publishes and loads scoped files at runtime, use the `DisableScopedCssBundling` property. When using this property, other tools or processes are responsible for taking the isolated CSS files from the `obj` directory and publishing and loading them at runtime:

XML

```
<PropertyGroup>
  <DisableScopedCssBundling>true</DisableScopedCssBundling>
</PropertyGroup>
```

Razor class library (RCL) support

When a Razor class library (RCL) provides isolated styles, the `<link>` tag's `href` attribute points to `{STATIC WEB ASSET BASE PATH}/{PACKAGE ID}.bundle.scp.css`, where the placeholders are:

- `{STATIC WEB ASSET BASE PATH}`: The static web asset base path.
- `{PACKAGE ID}`: The library's package identifier. The package identifier defaults to the project's assembly name if the package identifier isn't specified in the project file.

In the following example:

- The static web asset base path is `_content/ClassLib`.
- The class library's assembly name is `ClassLib`.

`Pages/Shared/_Layout.cshtml` (Razor Pages) or `Views/Shared/_Layout.cshtml` (MVC):

HTML

```
<link href="_content/ClassLib/ClassLib.bundle.scp.css" rel="stylesheet">
```

For more information on RCLs, see the following articles:

- Reusable Razor UI in class libraries with ASP.NET Core
- Consume ASP.NET Core Razor components from a Razor class library (RCL)

Partial views in ASP.NET Core

Article • 05/17/2023

By Steve Smith, Maher JENDOUBI, Rick Anderson, and Scott Sauber

A partial view is a Razor markup file (`.cshtml`) without a @page directive that renders HTML output *within* another markup file's rendered output.

The term *partial view* is used when developing either an MVC app, where markup files are called *views*, or a Razor Pages app, where markup files are called *pages*. This topic generically refers to MVC views and Razor Pages pages as *markup files*.

View or download sample code (how to download)

When to use partial views

Partial views are an effective way to:

- Break up large markup files into smaller components.

  In a large, complex markup file composed of several logical pieces, there's an advantage to working with each piece isolated into a partial view. The code in the markup file is manageable because the markup only contains the overall page structure and references to partial views.

- Reduce the duplication of common markup content across markup files.

  When the same markup elements are used across markup files, a partial view removes the duplication of markup content into one partial view file. When the markup is changed in the partial view, it updates the rendered output of the markup files that use the partial view.

Partial views shouldn't be used to maintain common layout elements. Common layout elements should be specified in _Layout.cshtml files.

Don't use a partial view where complex rendering logic or code execution is required to render the markup. Instead of a partial view, use a view component.

Declare partial views

A partial view is a `.cshtml` markup file without an @page directive maintained within the *Views* folder (MVC) or *Pages* folder (Razor Pages).

In ASP.NET Core MVC, a controller's ViewResult is capable of returning either a view or a partial view. In Razor Pages, a PageModel can return a partial view represented as a PartialViewResult object. Referencing and rendering partial views is described in the Reference a partial view section.

Unlike MVC view or page rendering, a partial view doesn't run `_ViewStart.cshtml`. For more information on `_ViewStart.cshtml`, see Layout in ASP.NET Core.

Partial view file names often begin with an underscore (`_`). This naming convention isn't required, but it helps to visually differentiate partial views from views and pages.

Reference a partial view

Use a partial view in a Razor Pages PageModel

In ASP.NET Core 2.0 or 2.1, the following handler method renders the *_AuthorPartialRP.cshtml* partial view to the response:

```
C#

public IActionResult OnGetPartial() =>
    new PartialViewResult
    {
        ViewName = "_AuthorPartialRP",
        ViewData = ViewData,
    };
```

In ASP.NET Core 2.2 or later, a handler method can alternatively call the Partial method to produce a `PartialViewResult` object:

```
C#

public IActionResult OnGetPartial() =>
    Partial("_AuthorPartialRP");
```

Use a partial view in a markup file

Within a markup file, there are several ways to reference a partial view. We recommend that apps use one of the following asynchronous rendering approaches:

- Partial Tag Helper
- Asynchronous HTML Helper

Partial Tag Helper

The Partial Tag Helper requires ASP.NET Core 2.1 or later.

The Partial Tag Helper renders content asynchronously and uses an HTML-like syntax:

```
CSHTML

<partial name="_PartialName" />
```

When a file extension is present, the Tag Helper references a partial view that must be in the same folder as the markup file calling the partial view:

```
CSHTML

<partial name="_PartialName.cshtml" />
```

The following example references a partial view from the app root. Paths that start with a tilde-slash (`~/`) or a slash (`/`) refer to the app root:

Razor Pages

```
CSHTML

<partial name="~/Pages/Folder/_PartialName.cshtml" />
<partial name="/Pages/Folder/_PartialName.cshtml" />
```

MVC

```
CSHTML

<partial name="~/Views/Folder/_PartialName.cshtml" />
<partial name="/Views/Folder/_PartialName.cshtml" />
```

The following example references a partial view with a relative path:

```
CSHTML

<partial name="../Account/_PartialName.cshtml" />
```

For more information, see Partial Tag Helper in ASP.NET Core.

Asynchronous HTML Helper

When using an HTML Helper, the best practice is to use PartialAsync. `PartialAsync` returns an IHtmlContent type wrapped in a Task<TResult>. The method is referenced by prefixing the awaited call with an `@` character:

CSHTML

```
@await Html.PartialAsync("_PartialName")
```

When the file extension is present, the HTML Helper references a partial view that must be in the same folder as the markup file calling the partial view:

CSHTML

```
@await Html.PartialAsync("_PartialName.cshtml")
```

The following example references a partial view from the app root. Paths that start with a tilde-slash (`~/`) or a slash (`/`) refer to the app root:

Razor Pages

CSHTML

```
@await Html.PartialAsync("~/Pages/Folder/_PartialName.cshtml")
@await Html.PartialAsync("/Pages/Folder/_PartialName.cshtml")
```

MVC

CSHTML

```
@await Html.PartialAsync("~/Views/Folder/_PartialName.cshtml")
@await Html.PartialAsync("/Views/Folder/_PartialName.cshtml")
```

The following example references a partial view with a relative path:

CSHTML

```
@await Html.PartialAsync("../Account/_LoginPartial.cshtml")
```

Alternatively, you can render a partial view with RenderPartialAsync. This method doesn't return an IHtmlContent. It streams the rendered output directly to the response. Because the method doesn't return a result, it must be called within a Razor code block:

CSHTML

```
@{
    await Html.RenderPartialAsync("_AuthorPartial");
}
```

Since `RenderPartialAsync` streams rendered content, it provides better performance in some scenarios. In performance-critical situations, benchmark the page using both approaches and use the approach that generates a faster response.

Synchronous HTML Helper

Partial and RenderPartial are the synchronous equivalents of `PartialAsync` and `RenderPartialAsync`, respectively. The synchronous equivalents aren't recommended because there are scenarios in which they deadlock. The synchronous methods are targeted for removal in a future release.

> **ⓘ Important**
>
> If you need to execute code, use a **view component** instead of a partial view.

Calling `Partial` or `RenderPartial` results in a Visual Studio analyzer warning. For example, the presence of `Partial` yields the following warning message:

> Use of IHtmlHelper.Partial may result in application deadlocks. Consider using <partial> Tag Helper or IHtmlHelper.PartialAsync.

Replace calls to `@Html.Partial` with `@await Html.PartialAsync` or the Partial Tag Helper. For more information on Partial Tag Helper migration, see Migrate from an HTML Helper.

Partial view discovery

When a partial view is referenced by name without a file extension, the following locations are searched in the stated order:

Razor Pages

1. Currently executing page's folder
2. Directory graph above the page's folder
3. `/Shared`
4. `/Pages/Shared`

5. `/Views/Shared`

MVC

1. `/Areas/<Area-Name>/Views/<Controller-Name>`
2. `/Areas/<Area-Name>/Views/Shared`
3. `/Views/Shared`
4. `/Pages/Shared`

The following conventions apply to partial view discovery:

- Different partial views with the same file name are allowed when the partial views are in different folders.
- When referencing a partial view by name without a file extension and the partial view is present in both the caller's folder and the *Shared* folder, the partial view in the caller's folder supplies the partial view. If the partial view isn't present in the caller's folder, the partial view is provided from the *Shared* folder. Partial views in the *Shared* folder are called *shared partial views* or *default partial views*.
- Partial views can be *chained*—a partial view can call another partial view if a circular reference isn't formed by the calls. Relative paths are always relative to the current file, not to the root or parent of the file.

> **Note**
>
> A Razor `section` defined in a partial view is invisible to parent markup files. The `section` is only visible to the partial view in which it's defined.

Access data from partial views

When a partial view is instantiated, it receives a *copy* of the parent's `ViewData` dictionary. Updates made to the data within the partial view aren't persisted to the parent view. `ViewData` changes in a partial view are lost when the partial view returns.

The following example demonstrates how to pass an instance of ViewDataDictionary to a partial view:

CSHTML

```
@await Html.PartialAsync("_PartialName", customViewData)
```

You can pass a model into a partial view. The model can be a custom object. You can pass a model with `PartialAsync` (renders a block of content to the caller) or `RenderPartialAsync` (streams the content to the output):

CSHTML

```
@await Html.PartialAsync("_PartialName", model)
```

Razor Pages

The following markup in the sample app is from the `Pages/ArticlesRP/ReadRP.cshtml` page. The page contains two partial views. The second partial view passes in a model and `ViewData` to the partial view. The `ViewDataDictionary` constructor overload is used to pass a new `ViewData` dictionary while retaining the existing `ViewData` dictionary.

CSHTML

```
@model ReadRPModel

<h2>@Model.Article.Title</h2>
@* Pass the author's name to Pages\Shared\_AuthorPartialRP.cshtml *@
@await Html.PartialAsync("../Shared/_AuthorPartialRP",
Model.Article.AuthorName)
@Model.Article.PublicationDate

@* Loop over the Sections and pass in a section and additional ViewData to
   the strongly typed Pages\ArticlesRP\_ArticleSectionRP.cshtml partial
view. *@
@{
    var index = 0;

    foreach (var section in Model.Article.Sections)
    {
        await Html.PartialAsync("_ArticleSectionRP",
                                section,
                                new ViewDataDictionary(ViewData)
                                {
                                    { "index", index }
                                });

        index++;
    }
}
```

`Pages/Shared/_AuthorPartialRP.cshtml` is the first partial view referenced by the `ReadRP.cshtml` markup file:

CSHTML

```
@model string
<div>
    <h3>@Model</h3>
    This partial view from /Pages/Shared/_AuthorPartialRP.cshtml.
</div>
```

`Pages/ArticlesRP/_ArticleSectionRP.cshtml` is the second partial view referenced by the `ReadRP.cshtml` markup file:

CSHTML

```
@using PartialViewsSample.ViewModels
@model ArticleSection

<h3>@Model.Title Index: @ViewData["index"]</h3>
<div>
    @Model.Content
</div>
```

MVC

The following markup in the sample app shows the `Views/Articles/Read.cshtml` view. The view contains two partial views. The second partial view passes in a model and `ViewData` to the partial view. The `ViewDataDictionary` constructor overload is used to pass a new `ViewData` dictionary while retaining the existing `ViewData` dictionary.

CSHTML

```
@model PartialViewsSample.ViewModels.Article

<h2>@Model.Title</h2>
@* Pass the author's name to Views\Shared\_AuthorPartial.cshtml *@
@await Html.PartialAsync("_AuthorPartial", Model.AuthorName)
@Model.PublicationDate

@* Loop over the Sections and pass in a section and additional ViewData to
   the strongly typed Views\Articles\_ArticleSection.cshtml partial view. *@
@{
    var index = 0;

    foreach (var section in Model.Sections)
    {
        @(await Html.PartialAsync("_ArticleSection",
                                  section,
                                  new ViewDataDictionary(ViewData)
                                  {
                                      { "index", index }
                                  }))
```

```
            index++;
        }
    }
```

`Views/Shared/_AuthorPartial.cshtml` is the first partial view referenced by the `Read.cshtml` markup file:

CSHTML

```
@model string
<div>
    <h3>@Model</h3>
    This partial view from /Views/Shared/_AuthorPartial.cshtml.
</div>
```

`Views/Articles/_ArticleSection.cshtml` is the second partial view referenced by the `Read.cshtml` markup file:

CSHTML

```
@using PartialViewsSample.ViewModels
@model ArticleSection

<h3>@Model.Title Index: @ViewData["index"]</h3>
<div>
    @Model.Content
</div>
```

At runtime, the partials are rendered into the parent markup file's rendered output, which itself is rendered within the shared `_Layout.cshtml`. The first partial view renders the article author's name and publication date:

> Abraham Lincoln
>
> This partial view from <shared partial view file path>. 11/19/1863 12:00:00 AM

The second partial view renders the article's sections:

> Section One Index: 0
>
> Four score and seven years ago ...
>
> Section Two Index: 1
>
> Now we are engaged in a great civil war, testing ...

> Section Three Index: 2
>
> But, in a larger sense, we can not dedicate ...

Handle requests with controllers in ASP.NET Core MVC

Article • 06/17/2024

By Steve Smith and Scott Addie

Controllers, actions, and action results are a fundamental part of how developers build apps using ASP.NET Core MVC.

What is a Controller?

A controller is used to define and group a set of actions. An action (or *action method*) is a method on a controller which handles requests. Controllers logically group similar actions together. This aggregation of actions allows common sets of rules, such as routing, caching, and authorization, to be applied collectively. Requests are mapped to actions through routing. Controllers are activated and disposed on a per request basis.

By convention, controller classes:

- Reside in the project's root-level *Controllers* folder.
- Inherit from `Microsoft.AspNetCore.Mvc.Controller`.

A controller is an instantiable class, usually public, in which at least one of the following conditions is true:

- The class name is suffixed with `Controller`.
- The class inherits from a class whose name is suffixed with `Controller`.
- The `[Controller]` attribute is applied to the class.

A controller class must not have an associated `[NonController]` attribute.

Controllers should follow the Explicit Dependencies Principle. There are a couple of approaches to implementing this principle. If multiple controller actions require the same service, consider using constructor injection to request those dependencies. If the service is needed by only a single action method, consider using Action Injection to request the dependency.

Within the **M**odel-**V**iew-**C**ontroller pattern, a controller is responsible for the initial processing of the request and instantiation of the model. Generally, business decisions should be performed within the model.

The controller takes the result of the model's processing (if any) and returns either the proper view and its associated view data or the result of the API call. Learn more at Overview of ASP.NET Core MVC and Get started with ASP.NET Core MVC and Visual Studio.

The controller is a *UI-level* abstraction. Its responsibilities are to ensure request data is valid and to choose which view (or result for an API) should be returned. In well-factored apps, it doesn't directly include data access or business logic. Instead, the controller delegates to services handling these responsibilities.

Defining Actions

Public methods on a controller, except those with the `[NonAction]` attribute, are actions. Parameters on actions are bound to request data and are validated using model binding. Model validation occurs for everything that's model-bound. The `ModelState.IsValid` property value indicates whether model binding and validation succeeded.

Action methods should contain logic for mapping a request to a business concern. Business concerns should typically be represented as services that the controller accesses through dependency injection. Actions then map the result of the business action to an application state.

Actions can return anything, but frequently return an instance of `IActionResult` (or `Task<IActionResult>` for async methods) that produces a response. The action method is responsible for choosing *what kind of response*. The action result *does the responding*.

Controller Helper Methods

Controllers usually inherit from Controller, although this isn't required. Deriving from `Controller` provides access to three categories of helper methods:

1. Methods resulting in an empty response body

No `Content-Type` HTTP response header is included, since the response body lacks content to describe.

There are two result types within this category: Redirect and HTTP Status Code.

- **HTTP Status Code**

This type returns an HTTP status code. A couple of helper methods of this type are `BadRequest`, `NotFound`, and `Ok`. For example, `return BadRequest();` produces a 400 status code when executed. When methods such as `BadRequest`, `NotFound`, and `Ok` are overloaded, they no longer qualify as HTTP Status Code responders, since content negotiation is taking place.

- **Redirect**

  This type returns a redirect to an action or destination (using `Redirect`, `LocalRedirect`, `RedirectToAction`, or `RedirectToRoute`). For example, `return RedirectToAction("Complete", new {id = 123});` redirects to `Complete`, passing an anonymous object.

  The Redirect result type differs from the HTTP Status Code type primarily in the addition of a `Location` HTTP response header.

2. Methods resulting in a non-empty response body with a predefined content type

Most helper methods in this category include a `ContentType` property, allowing you to set the `Content-Type` response header to describe the response body.

There are two result types within this category: View and Formatted Response.

- **View**

  This type returns a view which uses a model to render HTML. For example, `return View(customer);` passes a model to the view for data-binding.

- **Formatted Response**

  This type returns JSON or a similar data exchange format to represent an object in a specific manner. For example, `return Json(customer);` serializes the provided object into JSON format.

  Other common methods of this type include `File` and `PhysicalFile`. For example, `return PhysicalFile(customerFilePath, "text/xml");` returns PhysicalFileResult.

3. Methods resulting in a non-empty response body formatted in a content type negotiated with the client

This category is better known as **Content Negotiation**. Content negotiation applies whenever an action returns an ObjectResult type or something other than an

IActionResult implementation. An action that returns a non-`IActionResult` implementation (for example, `object`) also returns a Formatted Response.

Some helper methods of this type include `BadRequest`, `CreatedAtRoute`, and `Ok`. Examples of these methods include `return BadRequest(modelState);`, `return CreatedAtRoute("routename", values, newobject);`, and `return Ok(value);`, respectively. Note that `BadRequest` and `Ok` perform content negotiation only when passed a value; without being passed a value, they instead serve as HTTP Status Code result types. The `CreatedAtRoute` method, on the other hand, always performs content negotiation since its overloads all require that a value be passed.

Cross-Cutting Concerns

Applications typically share parts of their workflow. Examples include an app that requires authentication to access the shopping cart, or an app that caches data on some pages. To perform logic before or after an action method, use a *filter*. Using Filters on cross-cutting concerns can reduce duplication.

Most filter attributes, such as `[Authorize]`, can be applied at the controller or action level depending upon the desired level of granularity.

Error handling and response caching are often cross-cutting concerns:

- Handle errors
- Response Caching

Many cross-cutting concerns can be handled using filters or custom middleware.

Routing to controller actions in ASP.NET Core

Article • 06/17/2024

By Ryan Nowak, Kirk Larkin, and Rick Anderson

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

ASP.NET Core controllers use the Routing middleware to match the URLs of incoming requests and map them to actions. Route templates:

- Are defined at startup in `Program.cs` or in attributes.
- Describe how URL paths are matched to actions.
- Are used to generate URLs for links. The generated links are typically returned in responses.

Actions are either conventionally-routed or attribute-routed. Placing a route on the controller or action makes it attribute-routed. See Mixed routing for more information.

This document:

- Explains the interactions between MVC and routing:
  - How typical MVC apps make use of routing features.
  - Covers both:
    - Conventional routing typically used with controllers and views.
    - *Attribute routing* used with REST APIs. If you're primarily interested in routing for REST APIs, jump to the Attribute routing for REST APIs section.
  - See Routing for advanced routing details.
- Refers to the default routing system called endpoint routing. It's possible to use controllers with the previous version of routing for compatibility purposes. See the 2.2-3.0 migration guide for instructions.

Set up conventional route

The ASP.NET Core MVC template generates conventional routing code similar to the following:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllersWithViews();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Home/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapControllerRoute(
    name: "default",
    pattern: "{controller=Home}/{action=Index}/{id?}");

app.Run();
```

MapControllerRoute is used to create a single route. The single route is named `default` route. Most apps with controllers and views use a route template similar to the `default` route. REST APIs should use attribute routing.

C#

```
app.MapControllerRoute(
    name: "default",
    pattern: "{controller=Home}/{action=Index}/{id?}");
```

The route template `"{controller=Home}/{action=Index}/{id?}"`:

- Matches a URL path like `/Products/Details/5`
- Extracts the route values `{ controller = Products, action = Details, id = 5 }` by tokenizing the path. The extraction of route values results in a match if the app has a controller named `ProductsController` and a `Details` action:

```
C#

public class ProductsController : Controller
{
    public IActionResult Details(int id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }
}
```

MyDisplayRouteInfo is provided by the Rick.Docs.Samples.RouteInfo NuGet package and displays route information.

- `/Products/Details/5` model binds the value of `id = 5` to set the `id` parameter to `5`. See Model Binding for more details.
- `{controller=Home}` defines `Home` as the default `controller`.
- `{action=Index}` defines `Index` as the default `action`.
- The `?` character in `{id?}` defines `id` as optional.
  - Default and optional route parameters don't need to be present in the URL path for a match. See Route Template Reference for a detailed description of route template syntax.
- Matches the URL path `/`.
- Produces the route values `{ controller = Home, action = Index }`.

The values for `controller` and `action` make use of the default values. `id` doesn't produce a value since there's no corresponding segment in the URL path. `/` only matches if there exists a `HomeController` and `Index` action:

```
C#

public class HomeController : Controller
{
    public IActionResult Index() { ... }
}
```

Using the preceding controller definition and route template, the `HomeController.Index` action is run for the following URL paths:

- `/Home/Index/17`
- `/Home/Index`

- `/Home`
- `/`

The URL path `/` uses the route template default `Home` controllers and `Index` action. The URL path `/Home` uses the route template default `Index` action.

The convenience method MapDefaultControllerRoute:

```
C#

app.MapDefaultControllerRoute();
```

Replaces:

```
C#

app.MapControllerRoute(
    name: "default",
    pattern: "{controller=Home}/{action=Index}/{id?}");
```

> **ⓘ Important**
>
> Routing is configured using the UseRouting and UseEndpoints middleware. To use controllers:
>
> - Call MapControllers to map attribute routed controllers.
> - Call MapControllerRoute or MapAreaControllerRoute, to map both conventionally routed controllers and attribute routed controllers.
>
> Apps typically don't need to call `UseRouting` or `UseEndpoints`. WebApplicationBuilder configures a middleware pipeline that wraps middleware added in `Program.cs` with `UseRouting` and `UseEndpoints`. For more information, see Routing in ASP.NET Core.

Conventional routing

Conventional routing is used with controllers and views. The `default` route:

```
C#

app.MapControllerRoute(
    name: "default",
```

```
    pattern: "{controller=Home}/{action=Index}/{id?}");
```

The preceding is an example of a *conventional route*. It's called *conventional routing* because it establishes a *convention* for URL paths:

- The first path segment, `{controller=Home}`, maps to the controller name.
- The second segment, `{action=Index}`, maps to the action name.
- The third segment, `{id?}` is used for an optional `id`. The `?` in `{id?}` makes it optional. `id` is used to map to a model entity.

Using this `default` route, the URL path:

- `/Products/List` maps to the `ProductsController.List` action.
- `/Blog/Article/17` maps to `BlogController.Article` and typically model binds the `id` parameter to 17.

This mapping:

- Is based on the controller and action names **only**.
- Isn't based on namespaces, source file locations, or method parameters.

Using conventional routing with the default route allows creating the app without having to come up with a new URL pattern for each action. For an app with CRUD style actions, having consistency for the URLs across controllers:

- Helps simplify the code.
- Makes the UI more predictable.

> ⚠ **Warning**
>
> The `id` in the preceding code is defined as optional by the route template. Actions can execute without the optional ID provided as part of the URL. Generally, when `id` is omitted from the URL:
>
> - `id` is set to `0` by model binding.
> - No entity is found in the database matching `id == 0`.
>
> Attribute routing provides fine-grained control to make the ID required for some actions and not for others. By convention, the documentation includes optional parameters like `id` when they're likely to appear in correct usage.

Most apps should choose a basic and descriptive routing scheme so that URLs are readable and meaningful. The default conventional route

`{controller=Home}/{action=Index}/{id?}`:

- Supports a basic and descriptive routing scheme.
- Is a useful starting point for UI-based apps.
- Is the only route template needed for many web UI apps. For larger web UI apps, another route using Areas is frequently all that's needed.

MapControllerRoute and MapAreaRoute :

- Automatically assign an **order** value to their endpoints based on the order they are invoked.

Endpoint routing in ASP.NET Core:

- Doesn't have a concept of routes.
- Doesn't provide ordering guarantees for the execution of extensibility, all endpoints are processed at once.

Enable Logging to see how the built-in routing implementations, such as Route, match requests.

Attribute routing is explained later in this document.

Multiple conventional routes

Multiple conventional routes can be configured by adding more calls to MapControllerRoute and MapAreaControllerRoute. Doing so allows defining multiple conventions, or to adding conventional routes that are dedicated to a specific action, such as:

C#

```
app.MapControllerRoute(name: "blog",
                pattern: "blog/{*article}",
                defaults: new { controller = "Blog", action = "Article" });
app.MapControllerRoute(name: "default",
               pattern: "{controller=Home}/{action=Index}/{id?}");
```

The `blog` route in the preceding code is a **dedicated conventional route**. It's called a dedicated conventional route because:

- It uses conventional routing.
- It's dedicated to a specific action.

Because `controller` and `action` don't appear in the route template `"blog/{*article}"` as parameters:

- They can only have the default values `{ controller = "Blog", action = "Article" }`.
- This route always maps to the action `BlogController.Article`.

`/Blog`, `/Blog/Article`, and `/Blog/{any-string}` are the only URL paths that match the blog route.

The preceding example:

- `blog` route has a higher priority for matches than the `default` route because it is added first.
- Is an example of Slug style routing where it's typical to have an article name as part of the URL.

> ⚠ **Warning**
>
> In ASP.NET Core, routing doesn't:
>
> - Define a concept called a *route*. `UseRouting` adds route matching to the middleware pipeline. The `UseRouting` middleware looks at the set of endpoints defined in the app, and selects the best endpoint match based on the request.
> - Provide guarantees about the execution order of extensibility like IRouteConstraint or IActionConstraint.
>
> See Routing for reference material on routing.

Conventional routing order

Conventional routing only matches a combination of action and controller that are defined by the app. This is intended to simplify cases where conventional routes overlap. Adding routes using MapControllerRoute, MapDefaultControllerRoute, and MapAreaControllerRoute automatically assign an order value to their endpoints based on the order they are invoked. Matches from a route that appears earlier have a higher priority. Conventional routing is order-dependent. In general, routes with areas should be placed earlier as they're more specific than routes without an area. Dedicated conventional routes with catch-all route parameters like `{*article}` can make a route

too greedy, meaning that it matches URLs that you intended to be matched by other routes. Put the greedy routes later in the route table to prevent greedy matches.

Resolving ambiguous actions

When two endpoints match through routing, routing must do one of the following:

- Choose the best candidate.
- Throw an exception.

For example:

```
C#

public class Products33Controller : Controller
{
    public IActionResult Edit(int id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }

    [HttpPost]
    public IActionResult Edit(int id, Product product)
    {
        return ControllerContext.MyDisplayRouteInfo(id, product.name);
    }
}
```

The preceding controller defines two actions that match:

- The URL path `/Products33/Edit/17`
- Route data `{ controller = Products33, action = Edit, id = 17 }`.

This is a typical pattern for MVC controllers:

- `Edit(int)` displays a form to edit a product.
- `Edit(int, Product)` processes the posted form.

To resolve the correct route:

- `Edit(int, Product)` is selected when the request is an HTTP `POST`.
- `Edit(int)` is selected when the HTTP verb is anything else. `Edit(int)` is generally called via `GET`.

The HttpPostAttribute, `[HttpPost]`, is provided to routing so that it can choose based on the HTTP method of the request. The `HttpPostAttribute` makes `Edit(int, Product)` a

better match than `Edit(int)`.

It's important to understand the role of attributes like `HttpPostAttribute`. Similar attributes are defined for other HTTP verbs. In conventional routing, it's common for actions to use the same action name when they're part of a show form, submit form workflow. For example, see Examine the two Edit action methods.

If routing can't choose a best candidate, an AmbiguousMatchException is thrown, listing the multiple matched endpoints.

Conventional route names

The strings `"blog"` and `"default"` in the following examples are conventional route names:

C#

```
app.MapControllerRoute(name: "blog",
                pattern: "blog/{*article}",
                defaults: new { controller = "Blog", action = "Article" });
app.MapControllerRoute(name: "default",
               pattern: "{controller=Home}/{action=Index}/{id?}");
```

The route names give the route a logical name. The named route can be used for URL generation. Using a named route simplifies URL creation when the ordering of routes could make URL generation complicated. Route names must be unique application wide.

Route names:

- Have no impact on URL matching or handling of requests.
- Are used only for URL generation.

The route name concept is represented in routing as IEndpointNameMetadata. The terms **route name** and **endpoint name**:

- Are interchangeable.
- Which one is used in documentation and code depends on the API being described.

Attribute routing for REST APIs

REST APIs should use attribute routing to model the app's functionality as a set of resources where operations are represented by HTTP verbs.

Attribute routing uses a set of attributes to map actions directly to route templates. The following code is typical for a REST API and is used in the next sample:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers();

var app = builder.Build();

app.UseHttpsRedirection();

app.UseAuthorization();

app.MapControllers();

app.Run();
```

In the preceding code, MapControllers is called to map attribute routed controllers.

In the following example:

- `HomeController` matches a set of URLs similar to what the default conventional route `{controller=Home}/{action=Index}/{id?}` matches.

C#

```
public class HomeController : Controller
{
    [Route("")]
    [Route("Home")]
    [Route("Home/Index")]
    [Route("Home/Index/{id?}")]
    public IActionResult Index(int? id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }

    [Route("Home/About")]
    [Route("Home/About/{id?}")]
    public IActionResult About(int? id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }
}
```

The `HomeController.Index` action is run for any of the URL paths `/`, `/Home`, `/Home/Index`, or `/Home/Index/3`.

This example highlights a key programming difference between attribute routing and conventional routing. Attribute routing requires more input to specify a route. The conventional default route handles routes more succinctly. However, attribute routing allows and requires precise control of which route templates apply to each action.

With attribute routing, the controller and action names play no part in which action is matched, unless token replacement is used. The following example matches the same URLs as the previous example:

C#

```
public class MyDemoController : Controller
{
    [Route("")]
    [Route("Home")]
    [Route("Home/Index")]
    [Route("Home/Index/{id?}")]
    public IActionResult MyIndex(int? id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }

    [Route("Home/About")]
    [Route("Home/About/{id?}")]
    public IActionResult MyAbout(int? id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }
}
```

The following code uses token replacement for `action` and `controller`:

C#

```
public class HomeController : Controller
{
    [Route("")]
    [Route("Home")]
    [Route("[controller]/[action]")]
    public IActionResult Index()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }

    [Route("[controller]/[action]")]
    public IActionResult About()
    {
        return ControllerContext.MyDisplayRouteInfo();
```

```
    }
}
```

The following code applies `[Route("[controller]/[action]")]` to the controller:

C#

```
[Route("[controller]/[action]")]
public class HomeController : Controller
{
    [Route("~/")]
    [Route("/Home")]
    [Route("~/Home/Index")]
    public IActionResult Index()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }

    public IActionResult About()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }
}
```

In the preceding code, the `Index` method templates must prepend `/` or `~/` to the route templates. Route templates applied to an action that begin with `/` or `~/` don't get combined with route templates applied to the controller.

See Route template precedence for information on route template selection.

Reserved routing names

The following keywords are reserved route parameter names when using Controllers or Razor Pages:

- `action`
- `area`
- `controller`
- `handler`
- `page`

Using `page` as a route parameter with attribute routing is a common error. Doing that results in inconsistent and confusing behavior with URL generation.

C#

```
public class MyDemo2Controller : Controller
{
    [Route("/articles/{page}")]
    public IActionResult ListArticles(int page)
    {
        return ControllerContext.MyDisplayRouteInfo(page);
    }
}
```

The special parameter names are used by the URL generation to determine if a URL generation operation refers to a Razor Page or to a Controller.

The following keywords are reserved in the context of a Razor view or a Razor Page:

- `page`
- `using`
- `namespace`
- `inject`
- `section`
- `inherits`
- `model`
- `addTagHelper`
- `removeTagHelper`

These keywords shouldn't be used for link generations, model bound parameters, or top level properties.

HTTP verb templates

ASP.NET Core has the following HTTP verb templates:

- [HttpGet]
- [HttpPost]
- [HttpPut]
- [HttpDelete]
- [HttpHead]
- [HttpPatch]

Route templates

ASP.NET Core has the following route templates:

- All the HTTP verb templates are route templates.
- [Route]

Attribute routing with Http verb attributes

Consider the following controller:

```
C#
```

```
[Route("api/[controller]")]
[ApiController]
public class Test2Controller : ControllerBase
{
    [HttpGet]   // GET /api/test2
    public IActionResult ListProducts()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }

    [HttpGet("{id}")]   // GET /api/test2/xyz
    public IActionResult GetProduct(string id)
    {
       return ControllerContext.MyDisplayRouteInfo(id);
    }

    [HttpGet("int/{id:int}")] // GET /api/test2/int/3
    public IActionResult GetIntProduct(int id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }

    [HttpGet("int2/{id}")]  // GET /api/test2/int2/3
    public IActionResult GetInt2Product(int id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }
}
```

In the preceding code:

- Each action contains the `[HttpGet]` attribute, which constrains matching to HTTP GET requests only.
- The `GetProduct` action includes the `"{id}"` template, therefore `id` is appended to the `"api/[controller]"` template on the controller. The methods template is `"api/[controller]/{id}"`. Therefore this action only matches GET requests for the form `/api/test2/xyz`, `/api/test2/123`, `/api/test2/{any string}`, etc.

  ```
  C#
  ```

```
[HttpGet("{id}")]   // GET /api/test2/xyz
public IActionResult GetProduct(string id)
{
   return ControllerContext.MyDisplayRouteInfo(id);
}
```

- The `GetIntProduct` action contains the `"int/{id:int}"` template. The `:int` portion of the template constrains the `id` route values to strings that can be converted to an integer. A GET request to `/api/test2/int/abc`:
  - Doesn't match this action.
  - Returns a 404 Not Found error.

```
C#

[HttpGet("int/{id:int}")] // GET /api/test2/int/3
public IActionResult GetIntProduct(int id)
{
    return ControllerContext.MyDisplayRouteInfo(id);
}
```

- The `GetInt2Product` action contains `{id}` in the template, but doesn't constrain `id` to values that can be converted to an integer. A GET request to `/api/test2/int2/abc`:
  - Matches this route.
  - Model binding fails to convert `abc` to an integer. The `id` parameter of the method is integer.
  - Returns a 400 Bad Request because model binding failed to convert `abc` to an integer.

```
C#

[HttpGet("int2/{id}")]  // GET /api/test2/int2/3
public IActionResult GetInt2Product(int id)
{
    return ControllerContext.MyDisplayRouteInfo(id);
}
```

Attribute routing can use HttpMethodAttribute attributes such as HttpPostAttribute, HttpPutAttribute, and HttpDeleteAttribute. All of the HTTP verb attributes accept a route template. The following example shows two actions that match the same route template:

```
C#
```

```
[ApiController]
public class MyProductsController : ControllerBase
{
    [HttpGet("/products3")]
    public IActionResult ListProducts()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }

    [HttpPost("/products3")]
    public IActionResult CreateProduct(MyProduct myProduct)
    {
        return ControllerContext.MyDisplayRouteInfo(myProduct.Name);
    }
}
```

Using the URL path `/products3`:

- The `MyProductsController.ListProducts` action runs when the HTTP verb is `GET`.
- The `MyProductsController.CreateProduct` action runs when the HTTP verb is `POST`.

When building a REST API, it's rare that you'll need to use `[Route(...)]` on an action method because the action accepts all HTTP methods. It's better to use the more specific HTTP verb attribute to be precise about what your API supports. Clients of REST APIs are expected to know what paths and HTTP verbs map to specific logical operations.

REST APIs should use attribute routing to model the app's functionality as a set of resources where operations are represented by HTTP verbs. This means that many operations, for example, GET and POST on the same logical resource use the same URL. Attribute routing provides a level of control that's needed to carefully design an API's public endpoint layout.

Since an attribute route applies to a specific action, it's easy to make parameters required as part of the route template definition. In the following example, `id` is required as part of the URL path:

C#

```
[ApiController]
public class Products2ApiController : ControllerBase
{
    [HttpGet("/products2/{id}", Name = "Products_List")]
    public IActionResult GetProduct(int id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
```

```
    }
}
```

The `Products2ApiController.GetProduct(int)` action:

- Is run with URL path like `/products2/3`
- Isn't run with the URL path `/products2`.

The [Consumes] attribute allows an action to limit the supported request content types. For more information, see Define supported request content types with the Consumes attribute.

See Routing for a full description of route templates and related options.

For more information on `[ApiController]`, see ApiController attribute.

Route name

The following code defines a route name of `Products_List`:

C#

```
[ApiController]
public class Products2ApiController : ControllerBase
{
    [HttpGet("/products2/{id}", Name = "Products_List")]
    public IActionResult GetProduct(int id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }
}
```

Route names can be used to generate a URL based on a specific route. Route names:

- Have no impact on the URL matching behavior of routing.
- Are only used for URL generation.

Route names must be unique application-wide.

Contrast the preceding code with the conventional default route, which defines the `id` parameter as optional (`{id?}`). The ability to precisely specify APIs has advantages, such as allowing `/products` and `/products/5` to be dispatched to different actions.

Combining attribute routes

To make attribute routing less repetitive, route attributes on the controller are combined with route attributes on the individual actions. Any route templates defined on the controller are prepended to route templates on the actions. Placing a route attribute on the controller makes **all** actions in the controller use attribute routing.

C#

```
[ApiController]
[Route("products")]
public class ProductsApiController : ControllerBase
{
    [HttpGet]
    public IActionResult ListProducts()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }

    [HttpGet("{id}")]
    public IActionResult GetProduct(int id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }
}
```

In the preceding example:

- The URL path `/products` can match `ProductsApi.ListProducts`
- The URL path `/products/5` can match `ProductsApi.GetProduct(int)`.

Both of these actions only match HTTP `GET` because they're marked with the `[HttpGet]` attribute.

Route templates applied to an action that begin with `/` or `~/` don't get combined with route templates applied to the controller. The following example matches a set of URL paths similar to the default route.

C#

```
[Route("Home")]
public class HomeController : Controller
{
    [Route("")]
    [Route("Index")]
    [Route("/")]
    public IActionResult Index()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }
```

```
    [Route("About")]
    public IActionResult About()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }
}
```

The following table explains the `[Route]` attributes in the preceding code:

Expand table

Attribute	Combines with `[Route("Home")]`	Defines route template
`[Route("")]`	Yes	`"Home"`
`[Route("Index")]`	Yes	`"Home/Index"`
`[Route("/")]`	**No**	`""`
`[Route("About")]`	Yes	`"Home/About"`

Attribute route order

Routing builds a tree and matches all endpoints simultaneously:

- The route entries behave as if placed in an ideal ordering.
- The most specific routes have a chance to execute before the more general routes.

For example, an attribute route like `blog/search/{topic}` is more specific than an attribute route like `blog/{*article}`. The `blog/search/{topic}` route has higher priority, by default, because it's more specific. Using conventional routing, the developer is responsible for placing routes in the desired order.

Attribute routes can configure an order using the Order property. All of the framework provided route attributes include `Order` . Routes are processed according to an ascending sort of the `Order` property. The default order is `0`. Setting a route using `Order = -1` runs before routes that don't set an order. Setting a route using `Order = 1` runs after default route ordering.

Avoid depending on `Order`. If an app's URL-space requires explicit order values to route correctly, then it's likely confusing to clients as well. In general, attribute routing selects the correct route with URL matching. If the default order used for URL generation isn't working, using a route name as an override is usually simpler than applying the `Order` property.

Consider the following two controllers which both define the route matching `/home`:

C#

```
public class HomeController : Controller
{
    [Route("")]
    [Route("Home")]
    [Route("Home/Index")]
    [Route("Home/Index/{id?}")]
    public IActionResult Index(int? id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }

    [Route("Home/About")]
    [Route("Home/About/{id?}")]
    public IActionResult About(int? id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }
}
```

C#

```
public class MyDemoController : Controller
{
    [Route("")]
    [Route("Home")]
    [Route("Home/Index")]
    [Route("Home/Index/{id?}")]
    public IActionResult MyIndex(int? id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }

    [Route("Home/About")]
    [Route("Home/About/{id?}")]
    public IActionResult MyAbout(int? id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }
}
```

Requesting `/home` with the preceding code throws an exception similar to the following:

text

```
AmbiguousMatchException: The request matched multiple endpoints. Matches:
```

```
WebMvcRouting.Controllers.HomeController.Index
WebMvcRouting.Controllers.MyDemoController.MyIndex
```

Adding `Order` to one of the route attributes resolves the ambiguity:

C#

```
[Route("")]
[Route("Home", Order = 2)]
[Route("Home/MyIndex")]
public IActionResult MyIndex()
{
    return ControllerContext.MyDisplayRouteInfo();
}
```

With the preceding code, `/home` runs the `HomeController.Index` endpoint. To get to the `MyDemoController.MyIndex`, request `/home/MyIndex`. **Note**:

- The preceding code is an example or poor routing design. It was used to illustrate the `Order` property.
- The `Order` property only resolves the ambiguity, that template cannot be matched. It would be better to remove the `[Route("Home")]` template.

See Razor Pages route and app conventions: Route order for information on route order with Razor Pages.

In some cases, an HTTP 500 error is returned with ambiguous routes. Use logging to see which endpoints caused the `AmbiguousMatchException`.

Token replacement in route templates [controller], [action], [area]

For convenience, attribute routes support *token replacement* by enclosing a token in square-brackets (`[`, `]`). The tokens `[action]`, `[area]`, and `[controller]` are replaced with the values of the action name, area name, and controller name from the action where the route is defined:

C#

```
[Route("[controller]/[action]")]
public class Products0Controller : Controller
{
    [HttpGet]
    public IActionResult List()
```

```
    {
        return ControllerContext.MyDisplayRouteInfo();
    }

    [HttpGet("{id}")]
    public IActionResult Edit(int id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }
}
```

In the preceding code:

C#

```
[HttpGet]
public IActionResult List()
{
    return ControllerContext.MyDisplayRouteInfo();
}
```

- Matches `/Products0/List`

C#

```
[HttpGet("{id}")]
public IActionResult Edit(int id)
{
    return ControllerContext.MyDisplayRouteInfo(id);
}
```

- Matches `/Products0/Edit/{id}`

Token replacement occurs as the last step of building the attribute routes. The preceding example behaves the same as the following code:

C#

```
public class Products20Controller : Controller
{
    [HttpGet("[controller]/[action]")]  // Matches '/Products20/List'
    public IActionResult List()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }

    [HttpGet("[controller]/[action]/{id}")]   // Matches
'/Products20/Edit/{id}'
```

```
    public IActionResult Edit(int id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }
}
```

If you are reading this in a language other than English, let us know in this GitHub discussion issue if you'd like to see the code comments in your native language.

Attribute routes can also be combined with inheritance. This is powerful combined with token replacement. Token replacement also applies to route names defined by attribute routes. `[Route("[controller]/[action]", Name="[controller]_[action]")]` generates a unique route name for each action:

C#

```
[ApiController]
[Route("api/[controller]/[action]", Name = "[controller]_[action]")]
public abstract class MyBase2Controller : ControllerBase
{
}

public class Products11Controller : MyBase2Controller
{
    [HttpGet]                       // /api/products11/list
    public IActionResult List()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }

    [HttpGet("{id}")]               //    /api/products11/edit/3
    public IActionResult Edit(int id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }
}
```

To match the literal token replacement delimiter `[` or `]`, escape it by repeating the character (`[[` or `]]`).

Use a parameter transformer to customize token replacement

Token replacement can be customized using a parameter transformer. A parameter transformer implements IOutboundParameterTransformer and transforms the value of

parameters. For example, a custom `SlugifyParameterTransformer` parameter transformer changes the `SubscriptionManagement` route value to `subscription-management`:

C#

```
using System.Text.RegularExpressions;

public class SlugifyParameterTransformer : IOutboundParameterTransformer
{
    public string? TransformOutbound(object? value)
    {
        if (value == null) { return null; }

        return Regex.Replace(value.ToString()!,
                             "([a-z])([A-Z])",
                             "$1-$2",
                             RegexOptions.CultureInvariant,

TimeSpan.FromMilliseconds(100)).ToLowerInvariant();
    }
}
```

The RouteTokenTransformerConvention is an application model convention that:

- Applies a parameter transformer to all attribute routes in an application.
- Customizes the attribute route token values as they are replaced.

C#

```
public class SubscriptionManagementController : Controller
{
    [HttpGet("[controller]/[action]")]
    public IActionResult ListAll()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }
}
```

The preceding `ListAll` method matches `/subscription-management/list-all`.

The `RouteTokenTransformerConvention` is registered as an option:

C#

```
using Microsoft.AspNetCore.Mvc.ApplicationModels;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllersWithViews(options =>
```

```
{
    options.Conventions.Add(new RouteTokenTransformerConvention(
                                new SlugifyParameterTransformer()));
});

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Home/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapControllerRoute(name: "default",
                pattern: "{controller=Home}/{action=Index}/{id?}");

app.Run();
```

See MDN web docs on Slug for the definition of Slug.

> ⚠ **Warning**
>
> When using System.Text.RegularExpressions to process untrusted input, pass a timeout. A malicious user can provide input to `RegularExpressions` causing a Denial-of-Service attack. ASP.NET Core framework APIs that use `RegularExpressions` pass a timeout.

Multiple attribute routes

Attribute routing supports defining multiple routes that reach the same action. The most common usage of this is to mimic the behavior of the default conventional route as shown in the following example:

C#

```
[Route("[controller]")]
public class Products13Controller : Controller
{
    [Route("")]     // Matches 'Products13'
    [Route("Index")] // Matches 'Products13/Index'
    public IActionResult Index()
```

```
    {
        return ControllerContext.MyDisplayRouteInfo();
    }
```

Putting multiple route attributes on the controller means that each one combines with each of the route attributes on the action methods:

C#

```
[Route("Store")]
[Route("[controller]")]
public class Products6Controller : Controller
{
    [HttpPost("Buy")]       // Matches 'Products6/Buy' and 'Store/Buy'
    [HttpPost("Checkout")]  // Matches 'Products6/Checkout' and
'Store/Checkout'
    public IActionResult Buy()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }
}
```

All the HTTP verb route constraints implement `IActionConstraint`.

When multiple route attributes that implement IActionConstraint are placed on an action:

- Each action constraint combines with the route template applied to the controller.

C#

```
[Route("api/[controller]")]
public class Products7Controller : ControllerBase
{
    [HttpPut("Buy")]        // Matches PUT 'api/Products7/Buy'
    [HttpPost("Checkout")]  // Matches POST 'api/Products7/Checkout'
    public IActionResult Buy()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }
}
```

Using multiple routes on actions might seem useful and powerful, it's better to keep your app's URL space basic and well defined. Use multiple routes on actions **only** where needed, for example, to support existing clients.

Specifying attribute route optional parameters, default values, and constraints

Attribute routes support the same inline syntax as conventional routes to specify optional parameters, default values, and constraints.

C#

```
public class Products14Controller : Controller
{
    [HttpPost("product14/{id:int}")]
    public IActionResult ShowProduct(int id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }
}
```

In the preceding code, `[HttpPost("product14/{id:int}")]` applies a route constraint. The `Products14Controller.ShowProduct` action is matched only by URL paths like `/product14/3`. The route template portion `{id:int}` constrains that segment to only integers.

See Route Template Reference for a detailed description of route template syntax.

Custom route attributes using IRouteTemplateProvider

All of the route attributes implement IRouteTemplateProvider. The ASP.NET Core runtime:

- Looks for attributes on controller classes and action methods when the app starts.
- Uses the attributes that implement `IRouteTemplateProvider` to build the initial set of routes.

Implement `IRouteTemplateProvider` to define custom route attributes. Each `IRouteTemplateProvider` allows you to define a single route with a custom route template, order, and name:

C#

```
public class MyApiControllerAttribute : Attribute, IRouteTemplateProvider
{
    public string Template => "api/[controller]";
    public int? Order => 2;
    public string Name { get; set; } = string.Empty;
}

[MyApiController]
[ApiController]
public class MyTestApiController : ControllerBase
{
    // GET /api/MyTestApi
    [HttpGet]
    public IActionResult Get()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }
}
```

The preceding `Get` method returns `Order = 2, Template = api/MyTestApi`.

Use application model to customize attribute routes

The application model:

- Is an object model created at startup in `Program.cs`.
- Contains all of the metadata used by ASP.NET Core to route and execute the actions in an app.

The application model includes all of the data gathered from route attributes. The data from route attributes is provided by the `IRouteTemplateProvider` implementation.

Conventions:

- Can be written to modify the application model to customize how routing behaves.
- Are read at app startup.

This section shows a basic example of customizing routing using application model. The following code makes routes roughly line up with the folder structure of the project.

C#

```
public class NamespaceRoutingConvention : Attribute,
IControllerModelConvention
{
    private readonly string _baseNamespace;

    public NamespaceRoutingConvention(string baseNamespace)
    {
```

```
        _baseNamespace = baseNamespace;
    }

    public void Apply(ControllerModel controller)
    {
        var hasRouteAttributes = controller.Selectors.Any(selector =>
                                                    selector.AttributeRouteModel
!= null);
        if (hasRouteAttributes)
        {
            return;
        }

        var namespc = controller.ControllerType.Namespace;
        if (namespc == null)
            return;
        var template = new StringBuilder();
        template.Append(namespc, _baseNamespace.Length + 1,
                        namespc.Length - _baseNamespace.Length - 1);
        template.Replace('.', '/');
        template.Append("/[controller]/[action]/{id?}");

        foreach (var selector in controller.Selectors)
        {
            selector.AttributeRouteModel = new AttributeRouteModel()
            {
                Template = template.ToString()
            };
        }
    }
}
```

The following code prevents the `namespace` convention from being applied to controllers that are attribute routed:

C#

```
public void Apply(ControllerModel controller)
{
    var hasRouteAttributes = controller.Selectors.Any(selector =>
                                            selector.AttributeRouteModel !=
null);
    if (hasRouteAttributes)
    {
        return;
    }
```

For example, the following controller doesn't use `NamespaceRoutingConvention`:

C#

```
[Route("[controller]/[action]/{id?}")]
public class ManagersController : Controller
{
    // /managers/index
    public IActionResult Index()
    {
        var template =
ControllerContext.ActionDescriptor.AttributeRouteInfo?.Template;
        return Content($"Index- template:{template}");
    }

    public IActionResult List(int? id)
    {
        var path = Request.Path.Value;
        return Content($"List- Path:{path}");
    }
}
```

The `NamespaceRoutingConvention.Apply` method:

- Does nothing if the controller is attribute routed.
- Sets the controllers template based on the `namespace`, with the base `namespace` removed.

The `NamespaceRoutingConvention` can be applied in `Program.cs`:

C#

```
using My.Application.Controllers;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllersWithViews(options =>
{
    options.Conventions.Add(
     new NamespaceRoutingConvention(typeof(HomeController).Namespace!));
});

var app = builder.Build();
```

For example, consider the following controller:

C#

```
using Microsoft.AspNetCore.Mvc;

namespace My.Application.Admin.Controllers
{
    public class UsersController : Controller
```

```
    {
        // GET /admin/controllers/users/index
        public IActionResult Index()
        {
            var fullname = typeof(UsersController).FullName;
            var template =

ControllerContext.ActionDescriptor.AttributeRouteInfo?.Template;
            var path = Request.Path.Value;

            return Content($"Path: {path} fullname: {fullname}  template:
{template}");
        }

        public IActionResult List(int? id)
        {
            var path = Request.Path.Value;
            return Content($"Path: {path} ID:{id}");
        }
    }
}
```

In the preceding code:

- The base `namespace` is `My.Application`.
- The full name of the preceding controller is `My.Application.Admin.Controllers.UsersController`.
- The `NamespaceRoutingConvention` sets the controllers template to `Admin/Controllers/Users/[action]/{id?`.

The `NamespaceRoutingConvention` can also be applied as an attribute on a controller:

C#

```
[NamespaceRoutingConvention("My.Application")]
public class TestController : Controller
{
    // /admin/controllers/test/index
    public IActionResult Index()
    {
        var template =
ControllerContext.ActionDescriptor.AttributeRouteInfo?.Template;
        var actionname = ControllerContext.ActionDescriptor.ActionName;
        return Content($"Action- {actionname} template:{template}");
    }

    public IActionResult List(int? id)
    {
        var path = Request.Path.Value;
        return Content($"List- Path:{path}");
```

```
    }
}
```

Mixed routing: Attribute routing vs conventional routing

ASP.NET Core apps can mix the use of conventional routing and attribute routing. It's typical to use conventional routes for controllers serving HTML pages for browsers, and attribute routing for controllers serving REST APIs.

Actions are either conventionally routed or attribute routed. Placing a route on the controller or the action makes it attribute routed. Actions that define attribute routes cannot be reached through the conventional routes and vice-versa. ***Any*** route attribute on the controller makes ***all*** actions in the controller attribute routed.

Attribute routing and conventional routing use the same routing engine.

Routing with special characters

Routing with special characters can lead to unexpected results. For example, consider a controller with the following action method:

C#

```
[HttpGet("{id?}/name")]
public async Task<ActionResult<string>> GetName(string id)
{
    var todoItem = await _context.TodoItems.FindAsync(id);

    if (todoItem == null || todoItem.Name == null)
    {
        return NotFound();
    }

    return todoItem.Name;
}
```

When `string id` contains the following encoded values, unexpected results might occur:

Expand table

ASCII	Encoded
`/`	`%2F`
` `	`+`

Route parameters are not always URL decoded. This problem may be addressed in the future. For more information, see this GitHub issue ;

URL Generation and ambient values

Apps can use routing URL generation features to generate URL links to actions. Generating URLs eliminates hard-coding URLs, making code more robust and maintainable. This section focuses on the URL generation features provided by MVC and only cover basics of how URL generation works. See Routing for a detailed description of URL generation.

The IUrlHelper interface is the underlying element of infrastructure between MVC and routing for URL generation. An instance of `IUrlHelper` is available through the `Url` property in controllers, views, and view components.

In the following example, the `IUrlHelper` interface is used through the `Controller.Url` property to generate a URL to another action.

C#

```
public class UrlGenerationController : Controller
{
    public IActionResult Source()
    {
        // Generates /UrlGeneration/Destination
        var url = Url.Action("Destination");
        return ControllerContext.MyDisplayRouteInfo("", $" URL = {url}");
    }

    public IActionResult Destination()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }
}
```

If the app is using the default conventional route, the value of the `url` variable is the URL path string `/UrlGeneration/Destination`. This URL path is created by routing by combining:

- The route values from the current request, which are called **ambient values**.

- The values passed to `Url.Action` and substituting those values into the route template:

```text
ambient values: { controller = "UrlGeneration", action = "Source" }
values passed to Url.Action: { controller = "UrlGeneration", action =
"Destination" }
route template: {controller}/{action}/{id?}

result: /UrlGeneration/Destination
```

Each route parameter in the route template has its value substituted by matching names with the values and ambient values. A route parameter that doesn't have a value can:

- Use a default value if it has one.
- Be skipped if it's optional. For example, the `id` from the route template `{controller}/{action}/{id?}`.

URL generation fails if any required route parameter doesn't have a corresponding value. If URL generation fails for a route, the next route is tried until all routes have been tried or a match is found.

The preceding example of `Url.Action` assumes conventional routing. URL generation works similarly with attribute routing, though the concepts are different. With conventional routing:

- The route values are used to expand a template.
- The route values for `controller` and `action` usually appear in that template. This works because the URLs matched by routing adhere to a convention.

The following example uses attribute routing:

```C#
public class UrlGenerationAttrController : Controller
{
    [HttpGet("custom")]
    public IActionResult Source()
    {
        var url = Url.Action("Destination");
        return ControllerContext.MyDisplayRouteInfo("", $" URL = {url}");
    }

    [HttpGet("custom/url/to/destination")]
    public IActionResult Destination()
    {
       return ControllerContext.MyDisplayRouteInfo();
```

```
    }
}
```

The `Source` action in the preceding code generates `custom/url/to/destination`.

LinkGenerator was added in ASP.NET Core 3.0 as an alternative to `IUrlHelper`. `LinkGenerator` offers similar but more flexible functionality. Each method on `IUrlHelper` has a corresponding family of methods on `LinkGenerator` as well.

Generating URLs by action name

Url.Action, LinkGenerator.GetPathByAction, and all related overloads all are designed to generate the target endpoint by specifying a controller name and action name.

When using `Url.Action`, the current route values for `controller` and `action` are provided by the runtime:

- The value of `controller` and `action` are part of both ambient values and values. The method `Url.Action` always uses the current values of `action` and `controller` and generates a URL path that routes to the current action.

Routing attempts to use the values in ambient values to fill in information that wasn't provided when generating a URL. Consider a route like `{a}/{b}/{c}/{d}` with ambient values `{ a = Alice, b = Bob, c = Carol, d = David }`:

- Routing has enough information to generate a URL without any additional values.
- Routing has enough information because all route parameters have a value.

If the value `{ d = Donovan }` is added:

- The value `{ d = David }` is ignored.
- The generated URL path is `Alice/Bob/Carol/Donovan`.

Warning: URL paths are hierarchical. In the preceding example, if the value `{ c = Cheryl }` is added:

- Both of the values `{ c = Carol, d = David }` are ignored.
- There is no longer a value for `d` and URL generation fails.
- The desired values of `c` and `d` must be specified to generate a URL.

You might expect to hit this problem with the default route `{controller}/{action}/{id?}`. This problem is rare in practice because `Url.Action` always explicitly specifies a `controller` and `action` value.

Several overloads of Url.Action take a route values object to provide values for route parameters other than `controller` and `action`. The route values object is frequently used with `id`. For example, `Url.Action("Buy", "Products", new { id = 17 })`. The route values object:

- By convention is usually an object of anonymous type.
- Can be an `IDictionary<>` or a POCO).

Any additional route values that don't match route parameters are put in the query string.

C#

```
public IActionResult Index()
{
    var url = Url.Action("Buy", "Products", new { id = 17, color = "red" });
    return Content(url!);
}
```

The preceding code generates `/Products/Buy/17?color=red`.

The following code generates an absolute URL:

C#

```
public IActionResult Index2()
{
    var url = Url.Action("Buy", "Products", new { id = 17 }, protocol:
Request.Scheme);
    // Returns https://localhost:5001/Products/Buy/17
    return Content(url!);
}
```

To create an absolute URL, use one of the following:

- An overload that accepts a `protocol`. For example, the preceding code.
- LinkGenerator.GetUriByAction, which generates absolute URIs by default.

Generate URLs by route

The preceding code demonstrated generating a URL by passing in the controller and action name. `IUrlHelper` also provides the Url.RouteUrl family of methods. These methods are similar to Url.Action, but they don't copy the current values of `action` and `controller` to the route values. The most common usage of `Url.RouteUrl`:

- Specifies a route name to generate the URL.
- Generally doesn't specify a controller or action name.

C#

```
public class UrlGeneration2Controller : Controller
{
    [HttpGet("")]
    public IActionResult Source()
    {
        var url = Url.RouteUrl("Destination_Route");
        return ControllerContext.MyDisplayRouteInfo("", $" URL = {url}");
    }

    [HttpGet("custom/url/to/destination2", Name = "Destination_Route")]
    public IActionResult Destination()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }
```

The following Razor file generates an HTML link to the `Destination_Route`:

CSHTML

```
<h1>Test Links</h1>

<ul>
    <li><a href="@Url.RouteUrl("Destination_Route")">Test
Destination_Route</a></li>
</ul>
```

Generate URLs in HTML and Razor

IHtmlHelper provides the HtmlHelper methods Html.BeginForm and Html.ActionLink to generate `<form>` and `<a>` elements respectively. These methods use the Url.Action method to generate a URL and they accept similar arguments. The `Url.RouteUrl` companions for `HtmlHelper` are `Html.BeginRouteForm` and `Html.RouteLink` which have similar functionality.

TagHelpers generate URLs through the `form` TagHelper and the `<a>` TagHelper. Both of these use `IUrlHelper` for their implementation. See Tag Helpers in forms for more information.

Inside views, the `IUrlHelper` is available through the `Url` property for any ad-hoc URL generation not covered by the above.

URL generation in Action Results

The preceding examples showed using `IUrlHelper` in a controller. The most common usage in a controller is to generate a URL as part of an action result.

The ControllerBase and Controller base classes provide convenience methods for action results that reference another action. One typical usage is to redirect after accepting user input:

C#

```
[HttpPost]
[ValidateAntiForgeryToken]
public IActionResult Edit(int id, Customer customer)
{
    if (ModelState.IsValid)
    {
        // Update DB with new details.
        ViewData["Message"] = $"Successful edit of customer {id}";
        return RedirectToAction("Index");
    }
    return View(customer);
}
```

The action results factory methods such as RedirectToAction and CreatedAtAction follow a similar pattern to the methods on `IUrlHelper`.

Special case for dedicated conventional routes

Conventional routing can use a special kind of route definition called a dedicated conventional route. In the following example, the route named `blog` is a dedicated conventional route:

C#

```
app.MapControllerRoute(name: "blog",
                pattern: "blog/{*article}",
                defaults: new { controller = "Blog", action = "Article" });
app.MapControllerRoute(name: "default",
               pattern: "{controller=Home}/{action=Index}/{id?}");
```

Using the preceding route definitions, `Url.Action("Index", "Home")` generates the URL path `/` using the `default` route, but why? You might guess the route values `{`

`controller = Home, action = Index }` would be enough to generate a URL using `blog`, and the result would be `/blog?action=Index&controller=Home`.

Dedicated conventional routes rely on a special behavior of default values that don't have a corresponding route parameter that prevents the route from being too greedy with URL generation. In this case the default values are `{ controller = Blog, action = Article }`, and neither `controller` nor `action` appears as a route parameter. When routing performs URL generation, the values provided must match the default values. URL generation using `blog` fails because the values `{ controller = Home, action = Index }` don't match `{ controller = Blog, action = Article }`. Routing then falls back to try `default`, which succeeds.

Areas

Areas are an MVC feature used to organize related functionality into a group as a separate:

- Routing namespace for controller actions.
- Folder structure for views.

Using areas allows an app to have multiple controllers with the same name, as long as they have different areas. Using areas creates a hierarchy for the purpose of routing by adding another route parameter, `area` to `controller` and `action`. This section discusses how routing interacts with areas. See Areas for details about how areas are used with views.

The following example configures MVC to use the default conventional route and an `area` route for an `area` named `Blog`:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllersWithViews();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Home/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();
```

```
app.UseRouting();

app.UseAuthorization();

app.MapAreaControllerRoute("blog_route", "Blog",
        "Manage/{controller}/{action}/{id?}");
app.MapControllerRoute("default_route", "{controller}/{action}/{id?}");

app.Run();
```

In the preceding code, MapAreaControllerRoute is called to create the `"blog_route"`. The second parameter, `"Blog"`, is the area name.

When matching a URL path like `/Manage/Users/AddUser`, the `"blog_route"` route generates the route values `{ area = Blog, controller = Users, action = AddUser }`. The `area` route value is produced by a default value for `area`. The route created by `MapAreaControllerRoute` is equivalent to the following:

C#

```
app.MapControllerRoute("blog_route", "Manage/{controller}/{action}/{id?}",
        defaults: new { area = "Blog" }, constraints: new { area = "Blog"
});
app.MapControllerRoute("default_route", "{controller}/{action}/{id?}");
```

`MapAreaControllerRoute` creates a route using both a default value and constraint for `area` using the provided area name, in this case `Blog`. The default value ensures that the route always produces `{ area = Blog, ... }`, the constraint requires the value `{ area = Blog, ... }` for URL generation.

Conventional routing is order-dependent. In general, routes with areas should be placed earlier as they're more specific than routes without an area.

Using the preceding example, the route values `{ area = Blog, controller = Users, action = AddUser }` match the following action:

C#

```
using Microsoft.AspNetCore.Mvc;

namespace MyApp.Namespace1
{
    [Area("Blog")]
    public class UsersController : Controller
    {
        // GET /manage/users/adduser
```

```
        public IActionResult AddUser()
        {
            var area =
ControllerContext.ActionDescriptor.RouteValues["area"];
            var actionName = ControllerContext.ActionDescriptor.ActionName;
            var controllerName =
ControllerContext.ActionDescriptor.ControllerName;

            return Content($"area name:{area}" +
                $" controller:{controllerName}  action name: {actionName}");
        }
    }
}
```

The [Area] attribute is what denotes a controller as part of an area. This controller is in the `Blog` area. Controllers without an `[Area]` attribute are not members of any area, and do **not** match when the `area` route value is provided by routing. In the following example, only the first controller listed can match the route values `{ area = Blog, controller = Users, action = AddUser }`.

C#

```
using Microsoft.AspNetCore.Mvc;

namespace MyApp.Namespace1
{
    [Area("Blog")]
    public class UsersController : Controller
    {
        // GET /manage/users/adduser
        public IActionResult AddUser()
        {
            var area =
ControllerContext.ActionDescriptor.RouteValues["area"];
            var actionName = ControllerContext.ActionDescriptor.ActionName;
            var controllerName =
ControllerContext.ActionDescriptor.ControllerName;

            return Content($"area name:{area}" +
                $" controller:{controllerName}  action name: {actionName}");
        }
    }
}
```

C#

```
using Microsoft.AspNetCore.Mvc;

namespace MyApp.Namespace2
{
```

```
    // Matches { area = Zebra, controller = Users, action = AddUser }
    [Area("Zebra")]
    public class UsersController : Controller
    {
        // GET /zebra/users/adduser
        public IActionResult AddUser()
        {
            var area =
ControllerContext.ActionDescriptor.RouteValues["area"];
            var actionName = ControllerContext.ActionDescriptor.ActionName;
            var controllerName =
ControllerContext.ActionDescriptor.ControllerName;

            return Content($"area name:{area}" +
                $" controller:{controllerName}  action name: {actionName}");
        }
    }
}
```

C#

```
using Microsoft.AspNetCore.Mvc;

namespace MyApp.Namespace3
{
    // Matches { area = string.Empty, controller = Users, action = AddUser }
    // Matches { area = null, controller = Users, action = AddUser }
    // Matches { controller = Users, action = AddUser }
    public class UsersController : Controller
    {
        // GET /users/adduser
        public IActionResult AddUser()
        {
            var area =
ControllerContext.ActionDescriptor.RouteValues["area"];
            var actionName = ControllerContext.ActionDescriptor.ActionName;
            var controllerName =
ControllerContext.ActionDescriptor.ControllerName;

            return Content($"area name:{area}" +
                $" controller:{controllerName}  action name: {actionName}");
        }
    }
}
```

The namespace of each controller is shown here for completeness. If the preceding controllers used the same namespace, a compiler error would be generated. Class namespaces have no effect on MVC's routing.

The first two controllers are members of areas, and only match when their respective area name is provided by the `area` route value. The third controller isn't a member of

any area, and can only match when no value for `area` is provided by routing.

In terms of matching *no value*, the absence of the `area` value is the same as if the value for `area` were null or the empty string.

When executing an action inside an area, the route value for `area` is available as an ambient value for routing to use for URL generation. This means that by default areas act *sticky* for URL generation as demonstrated by the following sample.

C#

```
app.MapAreaControllerRoute(name: "duck_route",
                                    areaName: "Duck",
                                    pattern:
"Manage/{controller}/{action}/{id?}");
app.MapControllerRoute(name: "default",
                               pattern:
"Manage/{controller=Home}/{action=Index}/{id?}");
```

C#

```
using Microsoft.AspNetCore.Mvc;

namespace MyApp.Namespace4
{
    [Area("Duck")]
    public class UsersController : Controller
    {
        // GET /Manage/users/GenerateURLInArea
        public IActionResult GenerateURLInArea()
        {
            // Uses the 'ambient' value of area.
            var url = Url.Action("Index", "Home");
            // Returns /Manage/Home/Index
            return Content(url);
        }

        // GET /Manage/users/GenerateURLOutsideOfArea
        public IActionResult GenerateURLOutsideOfArea()
        {
            // Uses the empty value for area.
            var url = Url.Action("Index", "Home", new { area = "" });
            // Returns /Manage
            return Content(url);
        }
    }
}
```

The following code generates a URL to `/Zebra/Users/AddUser`:

C#

```
public class HomeController : Controller
{
    public IActionResult About()
    {
        var url = Url.Action("AddUser", "Users", new { Area = "Zebra" });
        return Content($"URL: {url}");
    }
```

Action definition

Public methods on a controller, except those with the NonAction attribute, are actions.

Sample code

- MyDisplayRouteInfo is provided by the Rick.Docs.Samples.RouteInfo NuGet package and displays route information.
- View or download sample code (how to download)

Debug diagnostics

For detailed routing diagnostic output, set `Logging:LogLevel:Microsoft` to `Debug`. In the development environment, set the log level in `appsettings.Development.json`:

JSON

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Debug",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  }
}
```

Dependency injection into controllers in ASP.NET Core

Article • 06/17/2024

By Shadi Alnamrouti and Rick Anderson

ASP.NET Core MVC controllers request dependencies explicitly via constructors. ASP.NET Core has built-in support for dependency injection (DI). DI makes apps easier to test and maintain.

View or download sample code (how to download)

Constructor injection

Services are added as a constructor parameter, and the runtime resolves the service from the service container. Services are typically defined using interfaces. For example, consider an app that requires the current time. The following interface exposes the `IDateTime` service:

C#

```
public interface IDateTime
{
    DateTime Now { get; }
}
```

The following code implements the `IDateTime` interface:

C#

```
public class SystemDateTime : IDateTime
{
    public DateTime Now
    {
        get { return DateTime.Now; }
    }
}
```

Add the service to the service container:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddSingleton<IDateTime, SystemDateTime>();

    services.AddControllersWithViews();
}
```

For more information on AddSingleton, see DI service lifetimes.

The following code displays a greeting to the user based on the time of day:

C#

```
public class HomeController : Controller
{
    private readonly IDateTime _dateTime;

    public HomeController(IDateTime dateTime)
    {
        _dateTime = dateTime;
    }

    public IActionResult Index()
    {
        var serverTime = _dateTime.Now;
        if (serverTime.Hour < 12)
        {
            ViewData["Message"] = "It's morning here - Good Morning!";
        }
        else if (serverTime.Hour < 17)
        {
            ViewData["Message"] = "It's afternoon here - Good Afternoon!";
        }
        else
        {
            ViewData["Message"] = "It's evening here - Good Evening!";
        }
        return View();
    }
```

Run the app and a message is displayed based on the time.

Action injection with `FromServices`

The FromServicesAttribute enables injecting a service directly into an action method without using constructor injection:

C#

```
public IActionResult About([FromServices] IDateTime dateTime)
{
    return Content( $"Current server time: {dateTime.Now}");
}
```

Action injection with `FromKeyedServices`

The following code shows how to access keyed services from the DI container by using the [FromKeyedServices] attribute:

C#

```
using Microsoft.AspNetCore.Mvc;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddKeyedSingleton<ICache, BigCache>("big");
builder.Services.AddKeyedSingleton<ICache, SmallCache>("small");
builder.Services.AddControllers();

var app = builder.Build();

app.MapControllers();

app.Run();

public interface ICache
{
    object Get(string key);
}
public class BigCache : ICache
{
    public object Get(string key) => $"Resolving {key} from big cache.";
}

public class SmallCache : ICache
{
    public object Get(string key) => $"Resolving {key} from small cache.";
}

[ApiController]
[Route("/cache")]
public class CustomServicesApiController : Controller
{
    [HttpGet("big")]
    public ActionResult<object> GetBigCache([FromKeyedServices("big")]
ICache cache)
    {
        return cache.Get("data-mvc");
    }
```

```
    [HttpGet("small")]
    public ActionResult<object> GetSmallCache([FromKeyedServices("small")]
ICache cache)
    {
        return cache.Get("data-mvc");
    }
}
```

Access settings from a controller

Accessing app or configuration settings from within a controller is a common pattern. The *options pattern* described in Options pattern in ASP.NET Core is the preferred approach to manage settings. Generally, don't directly inject IConfiguration into a controller.

Create a class that represents the options. For example:

C#

```
public class SampleWebSettings
{
    public string Title { get; set; }
    public int Updates { get; set; }
}
```

Add the configuration class to the services collection:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddSingleton<IDateTime, SystemDateTime>();
    services.Configure<SampleWebSettings>(Configuration);

    services.AddControllersWithViews();
}
```

Configure the app to read the settings from a JSON-formatted file:

C#

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
```

```
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureAppConfiguration((hostingContext, config) =>
            {
                config.AddJsonFile("samplewebsettings.json",
                    optional: false,
                    reloadOnChange: true);
            })
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

The following code requests the `IOptions<SampleWebSettings>` settings from the service container and uses them in the `Index` method:

C#

```
public class SettingsController : Controller
{
    private readonly SampleWebSettings _settings;

    public SettingsController(IOptions<SampleWebSettings> settingsOptions)
    {
        _settings = settingsOptions.Value;
    }

    public IActionResult Index()
    {
        ViewData["Title"] = _settings.Title;
        ViewData["Updates"] = _settings.Updates;
        return View();
    }
}
```

- See Test controller logic in ASP.NET Core to learn how to make code easier to test by explicitly requesting dependencies in controllers.
- Keyed service dependency injection container support
- Replace the default dependency injection container with a third party implementation.

Dependency injection into views in ASP.NET Core

Article • 06/17/2024

ASP.NET Core supports dependency injection into views. This can be useful for view-specific services, such as localization or data required only for populating view elements. Most of the data views display should be passed in from the controller.

View or download sample code (how to download)

Configuration injection

The values in settings files, such as `appsettings.json` and `appsettings.Development.json`, can be injected into a view. Consider the `appsettings.Development.json` from the sample code:

JSON

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft.AspNetCore": "Warning"
    }
  },
  "MyRoot": {
    "MyParent": {
      "MyChildName": "Joe"
    }
  }
}
```

The following markup displays the configuration value in a Razor Pages view:

CSHTML

```
@page
@model PrivacyModel
@using Microsoft.Extensions.Configuration
@inject IConfiguration Configuration
@{
    ViewData["Title"] = "Privacy RP";
}
<h1>@ViewData["Title"]</h1>
```

```
<p>PR Privacy</p>

<h2>
   MyRoot:MyParent:MyChildName:
@Configuration["MyRoot:MyParent:MyChildName"]
</h2>
```

The following markup displays the configuration value in a MVC view:

CSHTML

```
@using Microsoft.Extensions.Configuration
@inject IConfiguration Configuration
@{
    ViewData["Title"] = "Privacy MVC";
}
<h1>@ViewData["Title"]</h1>

<p>MVC Use this page to detail your site's privacy policy.</p>

<h2>
   MyRoot:MyParent:MyChildName:
@Configuration["MyRoot:MyParent:MyChildName"]
</h2>
```

For more information, see Configuration in ASP.NET Core

Service injection

A service can be injected into a view using the `@inject` directive.

CSHTML

```
@using System.Threading.Tasks
@using ViewInjectSample.Model
@using ViewInjectSample.Model.Services
@model IEnumerable<ToDoItem>
@inject StatisticsService StatsService
<!DOCTYPE html>
<html>
<head>
    <title>To Do Items</title>
</head>
<body>
    <div>
        <h1>To Do Items</h1>
        <ul>
            <li>Total Items: @StatsService.GetCount()</li>
            <li>Completed: @StatsService.GetCompletedCount()</li>
            <li>Avg. Priority: @StatsService.GetAveragePriority()</li>
```

```
        </ul>
        <table>
            <tr>
                <th>Name</th>
                <th>Priority</th>
                <th>Is Done?</th>
            </tr>
            @foreach (var item in Model)
            {
                <tr>
                    <td>@item.Name</td>
                    <td>@item.Priority</td>
                    <td>@item.IsDone</td>
                </tr>
            }
        </table>
    </div>
</body>
</html>
```

This view displays a list of `ToDoItem` instances, along with a summary showing overall statistics. The summary is populated from the injected `StatisticsService`. This service is registered for dependency injection in `ConfigureServices` in `Program.cs`:

C#

```
using ViewInjectSample.Helpers;
using ViewInjectSample.Infrastructure;
using ViewInjectSample.Interfaces;
using ViewInjectSample.Model.Services;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllersWithViews();
builder.Services.AddRazorPages();

builder.Services.AddTransient<IToDoItemRepository, ToDoItemRepository>();
builder.Services.AddTransient<StatisticsService>();
builder.Services.AddTransient<ProfileOptionsService>();
builder.Services.AddTransient<MyHtmlHelper>();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Home/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();
```

```
app.UseRouting();

app.MapRazorPages();

app.MapDefaultControllerRoute();

app.Run();
```

The `StatisticsService` performs some calculations on the set of `ToDoItem` instances, which it accesses via a repository:

C#

```
using System.Linq;
using ViewInjectSample.Interfaces;

namespace ViewInjectSample.Model.Services
{
    public class StatisticsService
    {
        private readonly IToDoItemRepository _toDoItemRepository;

        public StatisticsService(IToDoItemRepository toDoItemRepository)
        {
            _toDoItemRepository = toDoItemRepository;
        }

        public int GetCount()
        {
            return _toDoItemRepository.List().Count();
        }

        public int GetCompletedCount()
        {
            return _toDoItemRepository.List().Count(x => x.IsDone);
        }

        public double GetAveragePriority()
        {
            if (_toDoItemRepository.List().Count() == 0)
            {
                return 0.0;
            }

            return _toDoItemRepository.List().Average(x => x.Priority);
        }
    }
}
```

The sample repository uses an in-memory collection. An in-memory implementation shouldn't be used for large, remotely accessed data sets.

The sample displays data from the model bound to the view and the service injected into the view:

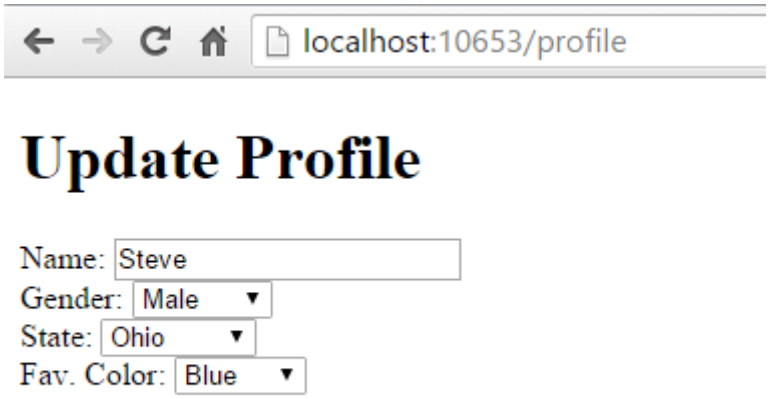
Populating Lookup Data

View injection can be useful to populate options in UI elements, such as dropdown lists. Consider a user profile form that includes options for specifying gender, state, and other preferences. Rendering such a form using a standard approach might require the controller or Razor Page to:

- Request data access services for each of the sets of options.
- Populate a model or `ViewBag` with each set of options to be bound.

An alternative approach injects services directly into the view to obtain the options. This minimizes the amount of code required by the controller or razor Page, moving this view element construction logic into the view itself. The controller action or Razor Page to display a profile editing form only needs to pass the form the profile instance:

C#



```
using Microsoft.AspNetCore.Mvc;
using ViewInjectSample.Model;

namespace ViewInjectSample.Controllers;

public class ProfileController : Controller
{
```

```
    public IActionResult Index()
    {
        // A real app would up profile based on the user.
        var profile = new Profile()
        {
            Name = "Rick",
            FavColor = "Blue",
            Gender = "Male",
            State = new State("Ohio","OH")
        };
        return View(profile);
    }
}
```

The HTML form used to update the preferences includes dropdown lists for three of the properties:

These lists are populated by a service that has been injected into the view:

CSHTML

```
@using System.Threading.Tasks
@using ViewInjectSample.Model.Services
@model ViewInjectSample.Model.Profile
@inject ProfileOptionsService Options
<!DOCTYPE html>
<html>
<head>
    <title>Update Profile</title>
</head>
<body>
<div>
    <h1>Update Profile</h1>
    Name: @Html.TextBoxFor(m => m.Name)
    <br/>
    Gender: @Html.DropDownList("Gender",
           Options.ListGenders().Select(g =>
                new SelectListItem() { Text = g, Value = g }))
    <br/>
```

```
    State: @Html.DropDownListFor(m => m.State!.Code,
           Options.ListStates().Select(s =>
                new SelectListItem() { Text = s.Name, Value = s.Code}))
    <br />

    Fav. Color: @Html.DropDownList("FavColor",
           Options.ListColors().Select(c =>
                new SelectListItem() { Text = c, Value = c }))
    </div>
</body>
</html>
```

The `ProfileOptionsService` is a UI-level service designed to provide just the data needed for this form:

C#

```
namespace ViewInjectSample.Model.Services;

public class ProfileOptionsService
{
    public List<string> ListGenders()
    {
        // Basic sample
        return new List<string>() {"Female", "Male"};
    }

    public List<State> ListStates()
    {
        // Add a few states
        return new List<State>()
        {
            new State("Alabama", "AL"),
            new State("Alaska", "AK"),
            new State("Ohio", "OH")
        };
    }

    public List<string> ListColors()
    {
        return new List<string>() { "Blue","Green","Red","Yellow" };
    }
}
```

Note an unregistered type throws an exception at runtime because the service provider is internally queried via GetRequiredService.

Overriding Services

In addition to injecting new services, this technique can be used to override previously injected services on a page. The figure below shows all of the fields available on the page used in the first example:

The default fields include `Html`, `Component`, and `Url`. To replace the default HTML Helpers with a custom version, use `@inject`:

CSHTML

```
@using System.Threading.Tasks
@using ViewInjectSample.Helpers
@inject MyHtmlHelper Html
<!DOCTYPE html>
<html>
<head>
    <title>My Helper</title>
</head>
<body>
    <div>
        Test: @Html.Value
    </div>
</body>
</html>
```

Unit test controller logic in ASP.NET Core

Article • 06/17/2024

By Steve Smith

Unit tests involve testing a part of an app in isolation from its infrastructure and dependencies. When unit testing controller logic, only the contents of a single action are tested, not the behavior of its dependencies or of the framework itself.

Unit testing controllers

Set up unit tests of controller actions to focus on the controller's behavior. A controller unit test avoids scenarios such as filters, routing, and model binding. Tests that cover the interactions among components that collectively respond to a request are handled by *integration tests*. For more information on integration tests, see Integration tests in ASP.NET Core.

If you're writing custom filters and routes, unit test them in isolation, not as part of tests on a particular controller action.

To demonstrate controller unit tests, review the following controller in the sample app.

View or download sample code (how to download)

The Home controller displays a list of brainstorming sessions and allows the creation of new brainstorming sessions with a POST request:

C#

```
public class HomeController : Controller
{
    private readonly IBrainstormSessionRepository _sessionRepository;

    public HomeController(IBrainstormSessionRepository sessionRepository)
    {
        _sessionRepository = sessionRepository;
    }

    public async Task<IActionResult> Index()
    {
        var sessionList = await _sessionRepository.ListAsync();

        var model = sessionList.Select(session => new
StormSessionViewModel()
```

```
            {
                Id = session.Id,
                DateCreated = session.DateCreated,
                Name = session.Name,
                IdeaCount = session.Ideas.Count
            });

            return View(model);
        }

        public class NewSessionModel
        {
            [Required]
            public string SessionName { get; set; }
        }

        [HttpPost]
        public async Task<IActionResult> Index(NewSessionModel model)
        {
            if (!ModelState.IsValid)
            {
                return BadRequest(ModelState);
            }
            else
            {
                await _sessionRepository.AddAsync(new BrainstormSession()
                {
                    DateCreated = DateTimeOffset.Now,
                    Name = model.SessionName
                });
            }

            return RedirectToAction(actionName: nameof(Index));
        }
    }
```

The preceding controller:

- Follows the Explicit Dependencies Principle.
- Expects dependency injection (DI) to provide an instance of `IBrainstormSessionRepository`.
- Can be tested with a mocked `IBrainstormSessionRepository` service using a mock object framework, such as Moq. A *mocked object* is a fabricated object with a predetermined set of property and method behaviors used for testing. For more information, see Introduction to integration tests.

The `HTTP GET Index` method has no looping or branching and only calls one method. The unit test for this action:

- Mocks the `IBrainstormSessionRepository` service using the `GetTestSessions` method. `GetTestSessions` creates two mock brainstorm sessions with dates and session names.
- Executes the `Index` method.
- Makes assertions on the result returned by the method:
  - A ViewResult is returned.
  - The ViewDataDictionary.Model is a `StormSessionViewModel`.
  - There are two brainstorming sessions stored in the `ViewDataDictionary.Model`.

C#

```
[Fact]
public async Task Index_ReturnsAViewResult_WithAListOfBrainstormSessions()
{
    // Arrange
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.ListAsync())
        .ReturnsAsync(GetTestSessions());
    var controller = new HomeController(mockRepo.Object);

    // Act
    var result = await controller.Index();

    // Assert
    var viewResult = Assert.IsType<ViewResult>(result);
    var model = Assert.IsAssignableFrom<IEnumerable<StormSessionViewModel>>(
        viewResult.ViewData.Model);
    Assert.Equal(2, model.Count());
}
```

C#

```
private List<BrainstormSession> GetTestSessions()
{
    var sessions = new List<BrainstormSession>();
    sessions.Add(new BrainstormSession()
    {
        DateCreated = new DateTime(2016, 7, 2),
        Id = 1,
        Name = "Test One"
    });
    sessions.Add(new BrainstormSession()
    {
        DateCreated = new DateTime(2016, 7, 1),
        Id = 2,
        Name = "Test Two"
    });
    return sessions;
}
```

The Home controller's `HTTP POST Index` method tests verifies that:

- When ModelState.IsValid is `false`, the action method returns a *400 Bad Request* ViewResult with the appropriate data.
- When `ModelState.IsValid` is `true`:
  - The `Add` method on the repository is called.
  - A RedirectToActionResult is returned with the correct arguments.

An invalid model state is tested by adding errors using AddModelError as shown in the first test below:

C#

```
[Fact]
public async Task
IndexPost_ReturnsBadRequestResult_WhenModelStateIsInvalid()
{
    // Arrange
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.ListAsync())
        .ReturnsAsync(GetTestSessions());
    var controller = new HomeController(mockRepo.Object);
    controller.ModelState.AddModelError("SessionName", "Required");
    var newSession = new HomeController.NewSessionModel();

    // Act
    var result = await controller.Index(newSession);

    // Assert
    var badRequestResult = Assert.IsType<BadRequestObjectResult>(result);
    Assert.IsType<SerializableError>(badRequestResult.Value);
}

[Fact]
public async Task
IndexPost_ReturnsARedirectAndAddsSession_WhenModelStateIsValid()
{
    // Arrange
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.AddAsync(It.IsAny<BrainstormSession>()))
        .Returns(Task.CompletedTask)
        .Verifiable();
    var controller = new HomeController(mockRepo.Object);
    var newSession = new HomeController.NewSessionModel()
    {
        SessionName = "Test Name"
    };

    // Act
    var result = await controller.Index(newSession);
```

```
    // Assert
    var redirectToActionResult = Assert.IsType<RedirectToActionResult>
(result);
    Assert.Null(redirectToActionResult.ControllerName);
    Assert.Equal("Index", redirectToActionResult.ActionName);
    mockRepo.Verify();
}
```

When ModelState isn't valid, the same `ViewResult` is returned as for a GET request. The test doesn't attempt to pass in an invalid model. Passing an invalid model isn't a valid approach, since model binding isn't running (although an integration test does use model binding). In this case, model binding isn't tested. These unit tests are only testing the code in the action method.

The second test verifies that when the `ModelState` is valid:

- A new `BrainstormSession` is added (via the repository).
- The method returns a `RedirectToActionResult` with the expected properties.

Mocked calls that aren't called are normally ignored, but calling `Verifiable` at the end of the setup call allows mock validation in the test. This is performed with the call to `mockRepo.Verify`, which fails the test if the expected method wasn't called.

> **Note**
>
> The Moq library used in this sample makes it possible to mix verifiable, or "strict", mocks with non-verifiable mocks (also called "loose" mocks or stubs). Learn more about customizing Mock behavior with Moq.

SessionController in the sample app displays information related to a particular brainstorming session. The controller includes logic to deal with invalid `id` values (there are two `return` scenarios in the following example to cover these scenarios). The final `return` statement returns a new `StormSessionViewModel` to the view (`Controllers/SessionController.cs`):

C#

```
public class SessionController : Controller
{
    private readonly IBrainstormSessionRepository _sessionRepository;

    public SessionController(IBrainstormSessionRepository sessionRepository)
    {
        _sessionRepository = sessionRepository;
    }
```

```
    public async Task<IActionResult> Index(int? id)
    {
        if (!id.HasValue)
        {
            return RedirectToAction(actionName: nameof(Index),
                controllerName: "Home");
        }

        var session = await _sessionRepository.GetByIdAsync(id.Value);
        if (session == null)
        {
            return Content("Session not found.");
        }

        var viewModel = new StormSessionViewModel()
        {
            DateCreated = session.DateCreated,
            Name = session.Name,
            Id = session.Id
        };

        return View(viewModel);
    }
}
```

The unit tests include one test for each `return` scenario in the Session controller `Index` action:

C#

```
[Fact]
public async Task IndexReturnsARedirectToIndexHomeWhenIdIsNull()
{
    // Arrange
    var controller = new SessionController(sessionRepository: null);

    // Act
    var result = await controller.Index(id: null);

    // Assert
    var redirectToActionResult =
        Assert.IsType<RedirectToActionResult>(result);
    Assert.Equal("Home", redirectToActionResult.ControllerName);
    Assert.Equal("Index", redirectToActionResult.ActionName);
}

[Fact]
public async Task
IndexReturnsContentWithSessionNotFoundWhenSessionNotFound()
{
    // Arrange
    int testSessionId = 1;
```

```
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync((BrainstormSession)null);
    var controller = new SessionController(mockRepo.Object);

    // Act
    var result = await controller.Index(testSessionId);

    // Assert
    var contentResult = Assert.IsType<ContentResult>(result);
    Assert.Equal("Session not found.", contentResult.Content);
}

[Fact]
public async Task IndexReturnsViewResultWithStormSessionViewModel()
{
    // Arrange
    int testSessionId = 1;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(GetTestSessions().FirstOrDefault(
            s => s.Id == testSessionId));
    var controller = new SessionController(mockRepo.Object);

    // Act
    var result = await controller.Index(testSessionId);

    // Assert
    var viewResult = Assert.IsType<ViewResult>(result);
    var model = Assert.IsType<StormSessionViewModel>(
        viewResult.ViewData.Model);
    Assert.Equal("Test One", model.Name);
    Assert.Equal(2, model.DateCreated.Day);
    Assert.Equal(testSessionId, model.Id);
}
```

Moving to the Ideas controller, the app exposes functionality as a web API on the `api/ideas` route:

- A list of ideas (`IdeaDTO`) associated with a brainstorming session is returned by the `ForSession` method.
- The `Create` method adds new ideas to a session.

C#

```
[HttpGet("forsession/{sessionId}")]
public async Task<IActionResult> ForSession(int sessionId)
{
    var session = await _sessionRepository.GetByIdAsync(sessionId);
    if (session == null)
    {
        return NotFound(sessionId);
```

```
        }

        var result = session.Ideas.Select(idea => new IdeaDTO()
        {
            Id = idea.Id,
            Name = idea.Name,
            Description = idea.Description,
            DateCreated = idea.DateCreated
        }).ToList();

        return Ok(result);
    }

    [HttpPost("create")]
    public async Task<IActionResult> Create([FromBody]NewIdeaModel model)
    {
        if (!ModelState.IsValid)
        {
            return BadRequest(ModelState);
        }

        var session = await _sessionRepository.GetByIdAsync(model.SessionId);
        if (session == null)
        {
            return NotFound(model.SessionId);
        }

        var idea = new Idea()
        {
            DateCreated = DateTimeOffset.Now,
            Description = model.Description,
            Name = model.Name
        };
        session.AddIdea(idea);

        await _sessionRepository.UpdateAsync(session);

        return Ok(session);
    }
```

Avoid returning business domain entities directly via API calls. Domain entities:

- Often include more data than the client requires.
- Unnecessarily couple the app's internal domain model with the publicly exposed API.

Mapping between domain entities and the types returned to the client can be performed:

- Manually with a LINQ `Select`, as the sample app uses. For more information, see LINQ (Language Integrated Query).

- Automatically with a library, such as AutoMapper.

Next, the sample app demonstrates unit tests for the `Create` and `ForSession` API methods of the Ideas controller.

The sample app contains two `ForSession` tests. The first test determines if `ForSession` returns a NotFoundObjectResult (HTTP Not Found) for an invalid session:

C#

```
[Fact]
public async Task ForSession_ReturnsHttpNotFound_ForInvalidSession()
{
    // Arrange
    int testSessionId = 123;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync((BrainstormSession)null);
    var controller = new IdeasController(mockRepo.Object);

    // Act
    var result = await controller.ForSession(testSessionId);

    // Assert
    var notFoundObjectResult = Assert.IsType<NotFoundObjectResult>(result);
    Assert.Equal(testSessionId, notFoundObjectResult.Value);
}
```

The second `ForSession` test determines if `ForSession` returns a list of session ideas (`<List<IdeaDTO>>`) for a valid session. The checks also examine the first idea to confirm its `Name` property is correct:

C#

```
[Fact]
public async Task ForSession_ReturnsIdeasForSession()
{
    // Arrange
    int testSessionId = 123;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(GetTestSession());
    var controller = new IdeasController(mockRepo.Object);

    // Act
    var result = await controller.ForSession(testSessionId);

    // Assert
```

```
    var okResult = Assert.IsType<OkObjectResult>(result);
    var returnValue = Assert.IsType<List<IdeaDTO>>(okResult.Value);
    var idea = returnValue.FirstOrDefault();
    Assert.Equal("One", idea.Name);
}
```

To test the behavior of the `Create` method when the `ModelState` is invalid, the sample app adds a model error to the controller as part of the test. Don't try to test model validation or model binding in unit tests—just test the action method's behavior when confronted with an invalid `ModelState`:

C#

```
[Fact]
public async Task Create_ReturnsBadRequest_GivenInvalidModel()
{
    // Arrange & Act
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    var controller = new IdeasController(mockRepo.Object);
    controller.ModelState.AddModelError("error", "some error");

    // Act
    var result = await controller.Create(model: null);

    // Assert
    Assert.IsType<BadRequestObjectResult>(result);
}
```

The second test of `Create` depends on the repository returning `null`, so the mock repository is configured to return `null`. There's no need to create a test database (in memory or otherwise) and construct a query that returns this result. The test can be accomplished in a single statement, as the sample code illustrates:

C#

```
[Fact]
public async Task Create_ReturnsHttpNotFound_ForInvalidSession()
{
    // Arrange
    int testSessionId = 123;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync((BrainstormSession)null);
    var controller = new IdeasController(mockRepo.Object);

    // Act
    var result = await controller.Create(new NewIdeaModel());

    // Assert
```

```
    Assert.IsType<NotFoundObjectResult>(result);
}
```

The third `Create` test, `Create_ReturnsNewlyCreatedIdeaForSession`, verifies that the repository's `UpdateAsync` method is called. The mock is called with `Verifiable`, and the mocked repository's `Verify` method is called to confirm the verifiable method is executed. It's not the unit test's responsibility to ensure that the `UpdateAsync` method saved the data—that can be performed with an integration test.

C#

```
[Fact]
public async Task Create_ReturnsNewlyCreatedIdeaForSession()
{
    // Arrange
    int testSessionId = 123;
    string testName = "test name";
    string testDescription = "test description";
    var testSession = GetTestSession();
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(testSession);
    var controller = new IdeasController(mockRepo.Object);

    var newIdea = new NewIdeaModel()
    {
        Description = testDescription,
        Name = testName,
        SessionId = testSessionId
    };
    mockRepo.Setup(repo => repo.UpdateAsync(testSession))
        .Returns(Task.CompletedTask)
        .Verifiable();

    // Act
    var result = await controller.Create(newIdea);

    // Assert
    var okResult = Assert.IsType<OkObjectResult>(result);
    var returnSession = Assert.IsType<BrainstormSession>(okResult.Value);
    mockRepo.Verify();
    Assert.Equal(2, returnSession.Ideas.Count());
    Assert.Equal(testName, returnSession.Ideas.LastOrDefault().Name);
    Assert.Equal(testDescription,
returnSession.Ideas.LastOrDefault().Description);
}
```

Test ActionResult<T>

ActionResult<T> (ActionResult<TValue>) can return a type deriving from `ActionResult` or return a specific type.

The sample app includes a method that returns a `List<IdeaDTO>` for a given session `id`. If the session `id` doesn't exist, the controller returns NotFound:

C#

```
[HttpGet("forsessionactionresult/{sessionId}")]
[ProducesResponseType(200)]
[ProducesResponseType(404)]
public async Task<ActionResult<List<IdeaDTO>>> ForSessionActionResult(int
sessionId)
{
    var session = await _sessionRepository.GetByIdAsync(sessionId);

    if (session == null)
    {
        return NotFound(sessionId);
    }

    var result = session.Ideas.Select(idea => new IdeaDTO()
    {
        Id = idea.Id,
        Name = idea.Name,
        Description = idea.Description,
        DateCreated = idea.DateCreated
    }).ToList();

    return result;
}
```

Two tests of the `ForSessionActionResult` controller are included in the `ApiIdeasControllerTests`.

The first test confirms that the controller returns an `ActionResult` but not a nonexistent list of ideas for a nonexistent session `id`:

- The `ActionResult` type is `ActionResult<List<IdeaDTO>>`.
- The Result is a NotFoundObjectResult.

C#

```
[Fact]
public async Task
ForSessionActionResult_ReturnsNotFoundObjectResultForNonexistentSession()
{
    // Arrange
    var mockRepo = new Mock<IBrainstormSessionRepository>();
```

```
    var controller = new IdeasController(mockRepo.Object);
    var nonExistentSessionId = 999;

    // Act
    var result = await
controller.ForSessionActionResult(nonExistentSessionId);

    // Assert
    var actionResult = Assert.IsType<ActionResult<List<IdeaDTO>>>(result);
    Assert.IsType<NotFoundObjectResult>(actionResult.Result);
}
```

For a valid session `id`, the second test confirms that the method returns:

- An `ActionResult` with a `List<IdeaDTO>` type.
- The ActionResult<T>.Value is a `List<IdeaDTO>` type.
- The first item in the list is a valid idea matching the idea stored in the mock session (obtained by calling `GetTestSession`).

C#

```
[Fact]
public async Task ForSessionActionResult_ReturnsIdeasForSession()
{
    // Arrange
    int testSessionId = 123;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(GetTestSession());
    var controller = new IdeasController(mockRepo.Object);

    // Act
    var result = await controller.ForSessionActionResult(testSessionId);

    // Assert
    var actionResult = Assert.IsType<ActionResult<List<IdeaDTO>>>(result);
    var returnValue = Assert.IsType<List<IdeaDTO>>(actionResult.Value);
    var idea = returnValue.FirstOrDefault();
    Assert.Equal("One", idea.Name);
}
```

The sample app also includes a method to create a new `Idea` for a given session. The controller returns:

- BadRequest for an invalid model.
- NotFound if the session doesn't exist.
- CreatedAtAction when the session is updated with the new idea.

C#

```
[HttpPost("createactionresult")]
[ProducesResponseType(201)]
[ProducesResponseType(400)]
[ProducesResponseType(404)]
public async Task<ActionResult<BrainstormSession>>
CreateActionResult([FromBody]NewIdeaModel model)
{
    if (!ModelState.IsValid)
    {
        return BadRequest(ModelState);
    }

    var session = await _sessionRepository.GetByIdAsync(model.SessionId);

    if (session == null)
    {
        return NotFound(model.SessionId);
    }

    var idea = new Idea()
    {
        DateCreated = DateTimeOffset.Now,
        Description = model.Description,
        Name = model.Name
    };
    session.AddIdea(idea);

    await _sessionRepository.UpdateAsync(session);

    return CreatedAtAction(nameof(CreateActionResult), new { id = session.Id
}, session);
}
```

Three tests of `CreateActionResult` are included in the `ApiIdeasControllerTests`.

The first text confirms that a BadRequest is returned for an invalid model.

C#

```
[Fact]
public async Task CreateActionResult_ReturnsBadRequest_GivenInvalidModel()
{
    // Arrange & Act
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    var controller = new IdeasController(mockRepo.Object);
    controller.ModelState.AddModelError("error", "some error");

    // Act
    var result = await controller.CreateActionResult(model: null);

    // Assert
```

```
    var actionResult = Assert.IsType<ActionResult<BrainstormSession>>
(result);
    Assert.IsType<BadRequestObjectResult>(actionResult.Result);
}
```

The second test checks that a NotFound is returned if the session doesn't exist.

C#

```
[Fact]
public async Task
CreateActionResult_ReturnsNotFoundObjectResultForNonexistentSession()
{
    // Arrange
    var nonExistentSessionId = 999;
    string testName = "test name";
    string testDescription = "test description";
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    var controller = new IdeasController(mockRepo.Object);

    var newIdea = new NewIdeaModel()
    {
        Description = testDescription,
        Name = testName,
        SessionId = nonExistentSessionId
    };

    // Act
    var result = await controller.CreateActionResult(newIdea);

    // Assert
    var actionResult = Assert.IsType<ActionResult<BrainstormSession>>
(result);
    Assert.IsType<NotFoundObjectResult>(actionResult.Result);
}
```

For a valid session `id`, the final test confirms that:

- The method returns an `ActionResult` with a `BrainstormSession` type.
- The ActionResult<T>.Result is a CreatedAtActionResult. `CreatedAtActionResult` is analogous to a *201 Created* response with a `Location` header.
- The ActionResult<T>.Value is a `BrainstormSession` type.
- The mock call to update the session, `UpdateAsync(testSession)`, was invoked. The `Verifiable` method call is checked by executing `mockRepo.Verify()` in the assertions.
- Two `Idea` objects are returned for the session.
- The last item (the `Idea` added by the mock call to `UpdateAsync`) matches the `newIdea` added to the session in the test.

C#

```
[Fact]
public async Task CreateActionResult_ReturnsNewlyCreatedIdeaForSession()
{
    // Arrange
    int testSessionId = 123;
    string testName = "test name";
    string testDescription = "test description";
    var testSession = GetTestSession();
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(testSession);
    var controller = new IdeasController(mockRepo.Object);

    var newIdea = new NewIdeaModel()
    {
        Description = testDescription,
        Name = testName,
        SessionId = testSessionId
    };
    mockRepo.Setup(repo => repo.UpdateAsync(testSession))
        .Returns(Task.CompletedTask)
        .Verifiable();

    // Act
    var result = await controller.CreateActionResult(newIdea);

    // Assert
    var actionResult = Assert.IsType<ActionResult<BrainstormSession>>
(result);
    var createdAtActionResult = Assert.IsType<CreatedAtActionResult>
(actionResult.Result);
    var returnValue = Assert.IsType<BrainstormSession>
(createdAtActionResult.Value);
    mockRepo.Verify();
    Assert.Equal(2, returnValue.Ideas.Count());
    Assert.Equal(testName, returnValue.Ideas.LastOrDefault().Name);
    Assert.Equal(testDescription,
returnValue.Ideas.LastOrDefault().Description);
}
```

ASP.NET Core Blazor

Article • 09/16/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

Welcome to Blazor!

Blazor is a .NET frontend web framework that supports both server-side rendering and client interactivity in a single programming model:

- Create rich interactive UIs using C#.
- Share server-side and client-side app logic written in .NET.
- Render the UI as HTML and CSS for wide browser support, including mobile browsers.
- Build hybrid desktop and mobile apps with .NET and Blazor.

Using .NET for client-side web development offers the following advantages:

- Write code in C#, which can improve productivity in app development and maintenance.
- Leverage the existing .NET ecosystem of .NET libraries.
- Benefit from .NET's performance, reliability, and security.
- Stay productive on Windows, Linux, or macOS with a development environment, such as Visual Studio or Visual Studio Code. Integrate with modern hosting platforms, such as Docker.
- Build on a common set of languages, frameworks, and tools that are stable, feature-rich, and easy to use.

> **Note**
>
> For a Blazor quick start tutorial, see **Build your first Blazor app**.

Components

Blazor apps are based on *components*. A component in Blazor is an element of UI, such as a page, dialog, or data entry form.

Components are .NET C# classes built into .NET assemblies that:

- Define flexible UI rendering logic.
- Handle user events.
- Can be nested and reused.
- Can be shared and distributed as Razor class libraries or NuGet packages.

The component class is usually written in the form of a Razor markup page with a `.razor` file extension. Components in Blazor are formally referred to as *Razor components*, informally as *Blazor components*. Razor is a syntax for combining HTML markup with C# code designed for developer productivity. Razor allows you to switch between HTML markup and C# in the same file with IntelliSense programming support in Visual Studio.

Blazor uses natural HTML tags for UI composition. The following Razor markup demonstrates a component that increments a counter when the user selects a button.

razor

```razor
<PageTitle>Counter</PageTitle>

<h1>Counter</h1>

<p role="status">Current count: @currentCount</p>

<button class="btn btn-primary" @onclick="IncrementCount">Click me</button>

@code {
    private int currentCount = 0;

    private void IncrementCount()
    {
        currentCount++;
    }
}
```

Components render into an in-memory representation of the browser's Document Object Model (DOM) called a *render tree*, which is used to update the UI in a flexible and efficient way.

Build a full-stack web app with Blazor

Blazor Web Apps provide a component-based architecture with server-side rendering and full client-side interactivity in a single solution, where you can switch between server-side and client-side rendering modes and even mix them in the same page.

Blazor Web Apps can quickly deliver UI to the browser by statically rendering HTML content from the server in response to requests. The page loads fast because UI rendering is performed quickly on the server without the need to download a large JavaScript bundle. Blazor can also further improve the user experience with various progressive enhancements to server rendering, such as enhanced navigation with form posts and streaming rendering of asynchronously-generated content.

Blazor supports *interactive* server-side rendering (interactive SSR), where UI interactions are handled from the server over a real-time connection with the browser. Interactive SSR enables a rich user experience like one would expect from a client app but without the need to create API endpoints to access server resources. Page content for interactive pages is prerendered, where content on the server is initially generated and sent to the client without enabling event handlers for rendered controls. The server outputs the HTML UI of the page as soon as possible in response to the initial request, which makes the app feel more responsive to users.

Blazor Web Apps support interactivity with client-side rendering (CSR) that relies on a .NET runtime built with WebAssembly that you can download with your app. When running Blazor on WebAssembly, your .NET code can access the full functionality of the browser and interop with JavaScript. Your .NET code runs in the browser's security sandbox with the protections that the sandbox provides against malicious actions on the client machine.

Blazor apps can entirely target running on WebAssembly in the browser without the involvement of a server. For a *standalone Blazor WebAssembly app*, assets are deployed as static files to a web server or service capable of serving static content to clients. Once downloaded, standalone Blazor WebAssembly apps can be cached and executed offline as a Progressive Web App (PWA).

Build a native client app with Blazor Hybrid

Blazor Hybrid enables using Razor components in a native client app with a blend of native and web technologies for web, mobile, and desktop platforms. Code runs natively in the .NET process and renders web UI to an embedded Web View control using a local interop channel. WebAssembly isn't used in Hybrid apps. Hybrid apps are built with .NET Multi-platform App UI (.NET MAUI), which is a cross-platform framework for creating native mobile and desktop apps with C# and XAML.

The Blazor Hybrid supports Windows Presentation Foundation (WPF) and Windows Forms to transition apps from earlier technology to .NET MAUI.

Blazor is supported in the browsers shown in the following table on both mobile and desktop platforms.

Expand table

Browser	Version
Apple Safari	Current†
Google Chrome	Current†
Microsoft Edge	Current†
Mozilla Firefox	Current†

†*Current* refers to the latest version of the browser.

For Blazor Hybrid apps, we test on and support the latest platform Web View control versions:

- Microsoft Edge WebView2 on Windows
- Chrome on Android
- Safari on iOS and macOS

Tooling for ASP.NET Core Blazor

Article • 09/12/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article describes tools for building Blazor apps using several tools:

- Visual Studio (VS): The most comprehensive integrated development environment (IDE) for .NET developers on Windows. Includes an array of tools and features to elevate and enhance every stage of software development.
- Visual Studio Code (VS Code) is an open source, cross-platform code editor that can be used to develop Blazor apps.
- .NET CLI: The .NET command-line interface (CLI) is a cross-platform toolchain for developing, building, running, and publishing .NET applications. The .NET CLI is included with the .NET SDK and runs on any platform supported by the SDK.

Select the pivot of this article that matches your tooling choice.

To create a Blazor app with Visual Studio, use the following guidance:

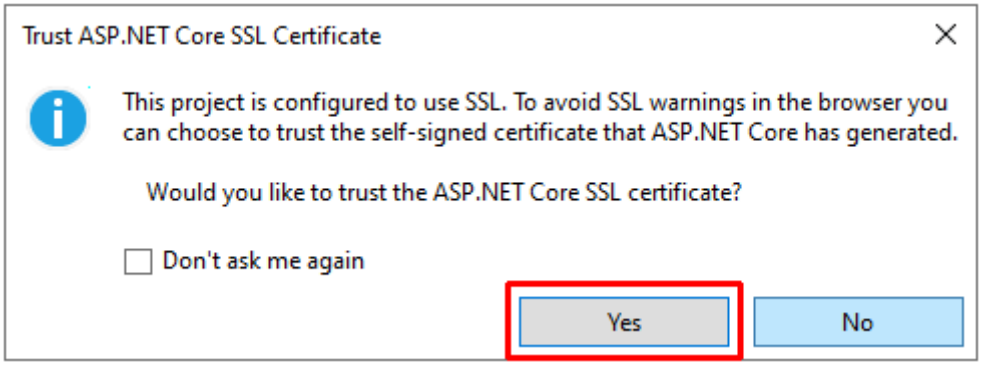
- Install the latest version of Visual Studio with the **ASP.NET and web development** workload.
- Create a new project using one of the available Blazor templates:
  - **Blazor Web App**: Creates a Blazor web app that supports interactive server-side rendering (interactive SSR) and client-side rendering (CSR). The Blazor Web App template is recommended for getting started with Blazor to learn about server-side and client-side Blazor features.
  - **Blazor WebAssembly Standalone App**: Creates a standalone client web app that can be deployed as a static site.

Select **Next**.

- Provide a **Project name** and confirm that the **Location** is correct.

- For more information on the options in the **Additional information** dialog, see the Blazor project templates and template options section.

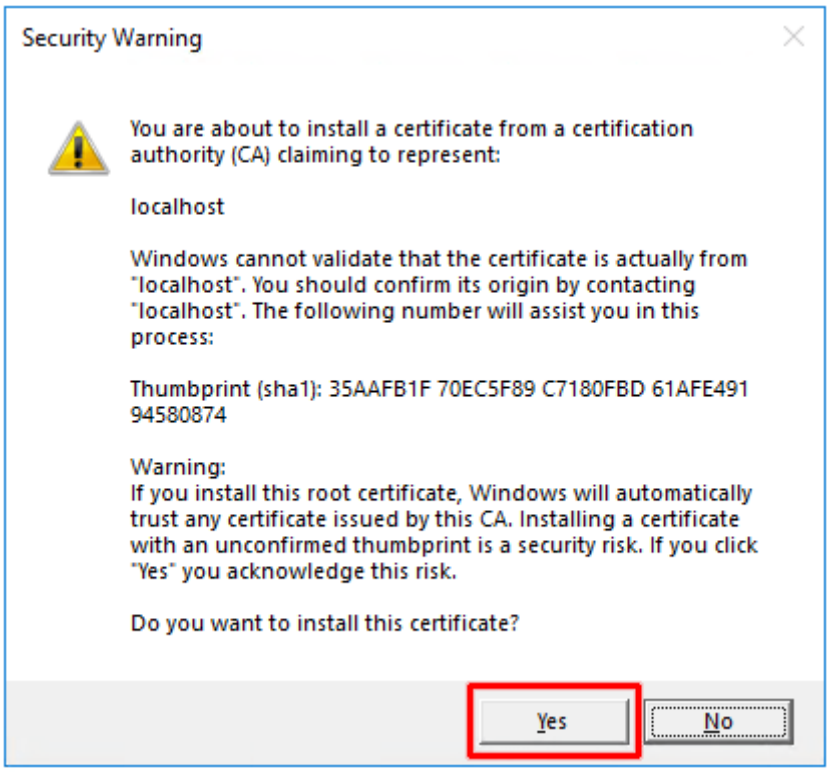
> **Note**
>
> The hosted Blazor WebAssembly project template isn't available in ASP.NET Core 8.0 or later. To create a hosted Blazor WebAssembly app, a **Framework** option earlier than .NET 8.0 must be selected with the **ASP.NET Core Hosted** checkbox.



- Select **Create**.

Run the app

> **Important**
>
> When executing a Blazor Web App, run the app from the solution's server project, which is the project with a name that doesn't end in `.Client`.



Press `Ctrl`+`F5` on the keyboard to run the app without the debugger.

Visual Studio displays the following dialog when a project isn't configured to use SSL:

Select **Yes** if you trust the ASP.NET Core SSL certificate.

The following dialog is displayed:

Select **Yes** to acknowledge the risk and install the certificate.

Visual Studio:

- Compiles and runs the app.
- Launches the default browser at `https://localhost:{PORT}`, which displays the app's UI. The `{PORT}` placeholder is the random port assigned at app creation. If you need to change the port due to a local port conflict, change the port in the project's `Properties/launchSettings.json` file.

Stop the app

Stop the app using either of the following approaches:

- Close the browser window.
- In Visual Studio, either:
  - Use the Stop button in Visual Studio's menu bar:

    
  - Press `Shift`+`F5` on the keyboard.

Visual Studio solution file (`.sln`)

A *solution* is a container to organize one or more related code projects. Solution files use a unique format and aren't intended to be edited directly.

Visual Studio and Visual Studio Code (VS Code) use a solution file (`.sln`) to store settings for a solution. The .NET CLI doesn't organize projects using a solution file, but it can create solution files and list/modify the projects in solution files via the dotnet sln command. Other .NET CLI commands use the path of the solution file for various publishing, testing, and packaging commands.

For more information, see the following resources:

- Introduction to projects and solutions (Visual Studio documentation)
- What are solutions and projects in Visual Studio? (Visual Studio documentation)
- Project management (VS Code documentation)

Blazor project templates and template options

The Blazor framework provides project templates for creating new apps. The templates are used to create new Blazor projects and solutions regardless of the tooling that you select for Blazor development (Visual Studio, Visual Studio Code, or the .NET command-line interface (CLI)):

- Blazor Web App project template: `blazor`
- Standalone Blazor WebAssembly app project template: `blazorwasm`

For more information on Blazor project templates, see ASP.NET Core Blazor project structure.

Rendering terms and concepts used in the following subsections are introduced in the following sections of the *Fundamentals* overview article:

- Client and server rendering concepts
- Static and interactive rendering concepts
- Render modes

Detailed guidance on render modes is provided by the ASP.NET Core Blazor render modes article.

Interactive render mode

- Interactive server-side rendering (interactive SSR) is enabled with the **Server** option.

- To only enable interactivity with client-side rendering (CSR), use the **WebAssembly** option.
- To enable both interactive rendering modes and the ability to automatically switch between them at runtime, use the **Auto (Server and WebAssembly)** (automatic) render mode option.
- If interactivity is set to `None`, the generated app has no interactivity. The app is only configured for static server-side rendering.

The Interactive Auto render mode initially uses interactive SSR while the .NET app bundle and runtime are download to the browser. After the .NET WebAssembly runtime is activated, the render mode switches to Interactive WebAssembly rendering.

The Blazor Web App template enables both static and interactive SSR using a single project. If you also enable CSR, the project includes an additional client project (`.Client`) for your WebAssembly-based components. The built output from the client project is downloaded to the browser and executed on the client. Any components using the WebAssembly or automatic render modes must be built from the client project.

> **ⓘ Important**
>
> When using a Blazor Web App, most of the Blazor documentation example components ***require*** interactivity to function and demonstrate the concepts covered by the articles. When you test an example component provided by an article, make sure that either the app adopts global interactivity or the component adopts an interactive render mode.

Interactivity location

Interactivity location options:

- **Per page/component**: The default sets up interactivity per page or per component.
- **Global**: Using this option sets up interactivity globally for the entire app.

Interactivity location can only be set if **Interactive render mode** isn't `None` and authentication isn't enabled.

Sample pages

To include sample pages and a layout based on Bootstrap styling, use the **Include sample pages** option. Disable this option for project without sample pages and

Bootstrap styling.

Additional guidance on template options

ASP.NET Core Blazor WebAssembly build tools and ahead-of-time (AOT) compilation

Article • 09/27/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article describes the build tools for standalone Blazor WebAssembly apps and how to compile an app ahead of deployment with ahead-of-time (AOT) compilation.

Although the article primarily focuses on standalone Blazor WebAssembly apps, the section on heap size for some mobile device browsers also applies to the client-side project (`.Client`) of a Blazor Web App.

.NET WebAssembly build tools

The .NET WebAssembly build tools are based on Emscripten, a compiler toolchain for the web platform. To install the build tools, use ***either*** of the following approaches:

- For the **ASP.NET and web development** workload in the Visual Studio installer, select the **.NET WebAssembly build tools** option from the list of optional components.
- Execute `dotnet workload install wasm-tools` in an administrative command shell.

> **Note**
>
> .NET WebAssembly build tools for .NET 6 projects
>
> The `wasm-tools` workload installs the build tools for the latest release. However, the current version of the build tools are incompatible with existing projects built with .NET 6. Projects using the build tools that must support both .NET 6 and a later release must use multi-targeting.

Use the `wasm-tools-net6` workload for .NET 6 projects when developing apps with the .NET 7 SDK. To install the `wasm-tools-net6` workload, execute the following command from an administrative command shell:

.NET CLI

```
dotnet workload install wasm-tools-net6
```

Ahead-of-time (AOT) compilation

Blazor WebAssembly supports ahead-of-time (AOT) compilation, where you can compile your .NET code directly into WebAssembly. AOT compilation results in runtime performance improvements at the expense of a larger app size.

Without enabling AOT compilation, Blazor WebAssembly apps run on the browser using a .NET Intermediate Language (IL) interpreter implemented in WebAssembly with partial just-in-time (JIT) runtime support, informally referred to as the *Jiterpreter*. Because the .NET IL code is interpreted, apps typically run slower than they would on a server-side .NET JIT runtime without any IL interpretation. AOT compilation addresses this performance issue by compiling an app's .NET code directly into WebAssembly for native WebAssembly execution by the browser. The AOT performance improvement can yield dramatic improvements for apps that execute CPU-intensive tasks. The drawback to using AOT compilation is that AOT-compiled apps are generally larger than their IL-interpreted counterparts, so they usually take longer to download to the client when first requested.

For guidance on installing the .NET WebAssembly build tools, see ASP.NET Core Blazor WebAssembly build tools and ahead-of-time (AOT) compilation.

To enable WebAssembly AOT compilation, add the `<RunAOTCompilation>` property set to `true` to the Blazor WebAssembly app's project file:

XML

```
<PropertyGroup>
  <RunAOTCompilation>true</RunAOTCompilation>
</PropertyGroup>
```

To compile the app to WebAssembly, publish the app. Publishing the `Release` configuration ensures the .NET Intermediate Language (IL) linking is also run to reduce the size of the published app:

.NET CLI

```
dotnet publish -c Release
```

WebAssembly AOT compilation is only performed when the project is published. AOT compilation isn't used when the project is run during development (`Development` environment) because AOT compilation usually takes several minutes on small projects and potentially much longer for larger projects. Reducing the build time for AOT compilation is under development for future releases of ASP.NET Core.

The size of an AOT-compiled Blazor WebAssembly app is generally larger than the size of the app if compiled into .NET IL:

- Although the size difference depends on the app, most AOT-compiled apps are about twice the size of their IL-compiled versions. This means that using AOT compilation trades off load-time performance for runtime performance. Whether this tradeoff is worth using AOT compilation depends on your app. Blazor WebAssembly apps that are CPU intensive generally benefit the most from AOT compilation.

- The larger size of an AOT-compiled app is due to two conditions:
  - More code is required to represent high-level .NET IL instructions in native WebAssembly.
  - AOT doesn't trim out managed DLLs when the app is published. Blazor requires the DLLs for reflection metadata and to support certain .NET runtime features. Requiring the DLLs on the client increases the download size but provides a more compatible .NET experience.

> **Note**
>
> For Mono /WebAssembly MSBuild properties and targets, see WasmApp.Common.targets (dotnet/runtime GitHub repository). Official documentation for common MSBuild properties is planned per Document blazor msbuild configuration options (dotnet/docs #27395).

Trim .NET IL after ahead-of-time (AOT) compilation

The `WasmStripILAfterAOT` MSBuild option enables removing the .NET Intermediate Language (IL) for compiled methods after performing AOT compilation to

WebAssembly, which reduces the size of the `_framework` folder.

In the app's project file:

```xml
<PropertyGroup>
  <RunAOTCompilation>true</RunAOTCompilation>
  <WasmStripILAfterAOT>true</WasmStripILAfterAOT>
</PropertyGroup>
```

This setting trims away the IL code for most compiled methods, including methods from libraries and methods in the app. Not all compiled methods can be trimmed, as some are still required by the .NET interpreter at runtime.

To report a problem with the trimming option, open an issue on the dotnet/runtime GitHub repository.

Disable the trimming property if it prevents your app from running normally:

```xml
<WasmStripILAfterAOT>false</WasmStripILAfterAOT>
```

Heap size for some mobile device browsers

When building a Blazor app that runs on the client and targets mobile device browsers, especially Safari on iOS, decreasing the maximum memory for the app with the MSBuild property `EmccMaximumHeapSize` may be required. For more information, see Host and deploy ASP.NET Core Blazor WebAssembly.

Runtime relinking

One of the largest parts of a Blazor WebAssembly app is the WebAssembly-based .NET runtime (`dotnet.wasm`) that the browser must download when the app is first accessed by a user's browser. Relinking the .NET WebAssembly runtime trims unused runtime code and thus improves download speed.

Runtime relinking requires installation of the .NET WebAssembly build tools. For more information, see Tooling for ASP.NET Core Blazor.

With the .NET WebAssembly build tools installed, runtime relinking is performed automatically when an app is **published** in the `Release` configuration. The size reduction

is particularly dramatic when disabling globalization. For more information, see ASP.NET Core Blazor globalization and localization.

> **ⓘ Important**
>
> Runtime relinking trims class instance JavaScript-invokable .NET methods unless they're protected. For more information, see **Call .NET methods from JavaScript functions in ASP.NET Core Blazor**.

Single Instruction, Multiple Data (SIMD)

Blazor uses WebAssembly Single Instruction, Multiple Data (SIMD) to improve the throughput of vectorized computations by performing an operation on multiple pieces of data in parallel using a single instruction.

To disable SIMD, for example when targeting old browsers or browsers on mobile devices that don't support SIMD, set the `<WasmEnableSIMD>` property to `false` in the app's project file (`.csproj`):

XML

```
<PropertyGroup>
  <WasmEnableSIMD>false</WasmEnableSIMD>
</PropertyGroup>
```

For more information, see Configuring and hosting .NET WebAssembly applications: SIMD - Single instruction, multiple data and note that the guidance isn't versioned and applies to the latest public release.

Exception handling

Exception handling is enabled by default. To disable exception handling, add the `<WasmEnableExceptionHandling>` property with a value of `false` in the app's project file (`.csproj`):

XML

```
<PropertyGroup>
  <WasmEnableExceptionHandling>false</WasmEnableExceptionHandling>
</PropertyGroup>
```

For more information, see the following resources:

- Configuring and hosting .NET WebAssembly applications: EH - Exception handling
- Exception handling

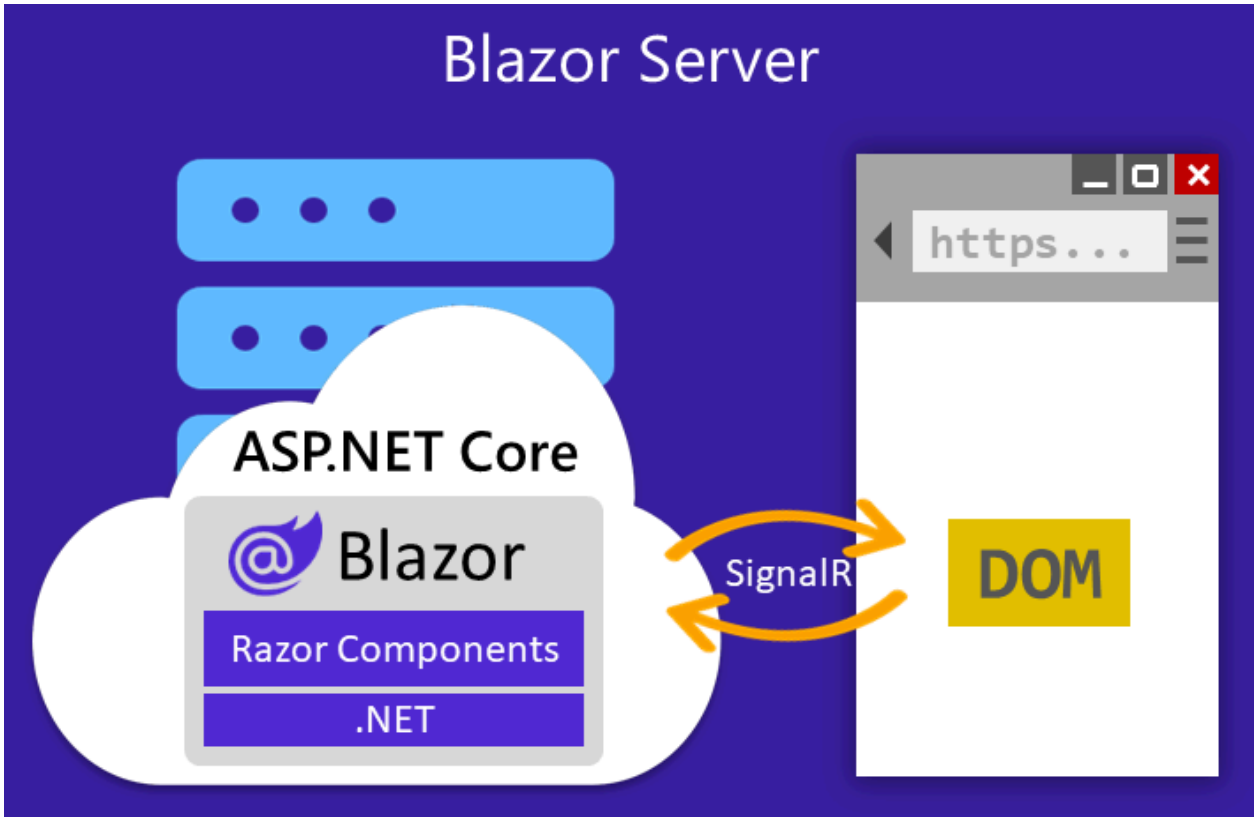
ASP.NET Core Blazor hosting models

Article • 09/10/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article explains Blazor hosting models, primarily focused on Blazor Server and Blazor WebAssembly apps in versions of .NET earlier than .NET 8. The guidance in this article is relevant under all .NET releases for Blazor Hybrid apps that run on native mobile and desktop platforms. Blazor Web Apps in .NET 8 or later are better conceptualized by how Razor components are rendered, which is described as their *render mode*. Render modes are briefly touched on in the *Fundamentals* overview article and covered in detail in ASP.NET Core Blazor render modes of the *Components* node.



Blazor is a web framework for building web UI components (Razor components) that can be hosted in different ways. Razor components can run server-side in ASP.NET Core (*Blazor Server*) versus client-side in the browser on a WebAssembly -based .NET runtime (*Blazor WebAssembly*, *Blazor WASM*). You can also host Razor components in native mobile and desktop apps that render to an embedded Web View control (*Blazor Hybrid*). Regardless of the hosting model, the way you build Razor components *is the same*. The same Razor components can be used with any of the hosting models unchanged.

Blazor Server

With the Blazor Server hosting model, components are executed on the server from within an ASP.NET Core app. UI updates, event handling, and JavaScript calls are handled over a SignalR connection using the WebSockets protocol. The state on the server associated with each connected client is called a *circuit*. Circuits aren't tied to a specific network connection and can tolerate temporary network interruptions and attempts by the client to reconnect to the server when the connection is lost.

In a traditional server-rendered app, opening the same app in multiple browser screens (tabs or `iframes`) typically doesn't translate into additional resource demands on the server. For the Blazor Server hosting model, each browser screen requires a separate

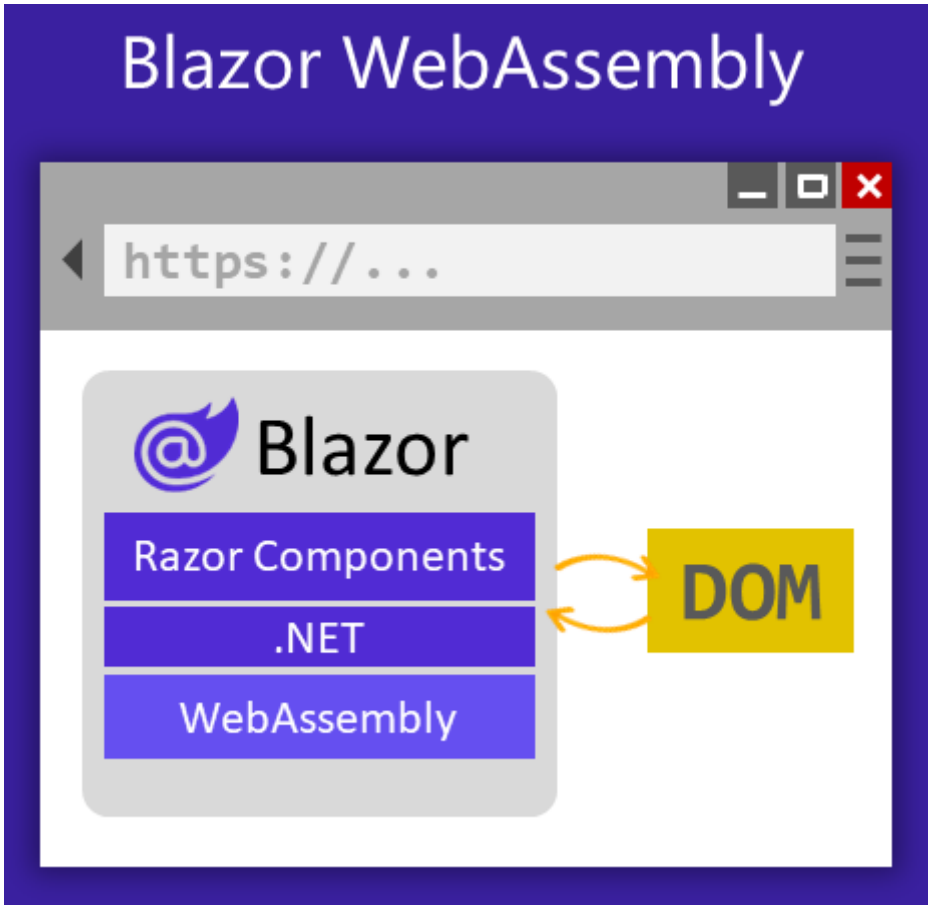
circuit and separate instances of server-managed component state. Blazor considers closing a browser tab or navigating to an external URL a *graceful* termination. In the event of a graceful termination, the circuit and associated resources are immediately released. A client may also disconnect non-gracefully, for instance due to a network interruption. Blazor Server stores disconnected circuits for a configurable interval to allow the client to reconnect.

On the client, the Blazor script establishes the SignalR connection with the server. The script is served from an embedded resource in the ASP.NET Core shared framework.

The Blazor Server hosting model offers several benefits:

- Download size is significantly smaller than when the Blazor WebAssembly hosting model is used, and the app loads much faster.
- The app takes full advantage of server capabilities, including the use of .NET Core APIs.
- .NET Core on the server is used to run the app, so existing .NET tooling, such as debugging, works as expected.
- Thin clients are supported. For example, Blazor Server works with browsers that don't support WebAssembly and on resource-constrained devices.
- The app's .NET/C# code base, including the app's component code, isn't served to clients.

The Blazor Server hosting model has the following limitations:



- Higher latency usually exists. Every user interaction involves a network hop.

- There's no offline support. If the client connection fails, interactivity fails.
- Scaling apps with many users requires server resources to handle multiple client connections and client state.
- An ASP.NET Core server is required to serve the app. Serverless deployment scenarios aren't possible, such as serving the app from a Content Delivery Network (CDN).

We recommend using the Azure SignalR Service for apps that adopt the Blazor Server hosting model. The service allows for scaling up a Blazor Server app to a large number of concurrent SignalR connections.

Blazor WebAssembly

The Blazor WebAssembly hosting model runs components client-side in the browser on a WebAssembly-based .NET runtime. Razor components, their dependencies, and the .NET runtime are downloaded to the browser. Components are executed directly on the browser UI thread. UI updates and event handling occur within the same process. Assets are deployed as static files to a web server or service capable of serving static content to clients.

Blazor web apps can use the Blazor WebAssembly hosting model to enable client-side interactivity. When an app is created that exclusively runs on the Blazor WebAssembly

hosting model without server-side rendering and interactivity, the app is called a *standalone* Blazor WebAssembly app.

When a standalone Blazor WebAssembly app uses a backend ASP.NET Core app to serve its files, the app is called a *hosted* Blazor WebAssembly app. Using hosted Blazor WebAssembly, you get a full-stack web development experience with .NET, including the ability to share code between the client and server apps, support for prerendering, and integration with MVC and Razor Pages. A hosted client app can interact with its backend server app over the network using a variety of messaging frameworks and protocols, such as web API, gRPC-web, and SignalR (Use ASP.NET Core SignalR with Blazor).

A Blazor WebAssembly app built as a Progressive Web App (PWA) uses modern browser APIs to enable many of the capabilities of a native client app, such as working offline, running in its own app window, launching from the host's operating system, receiving push notifications, and automatically updating in the background.

The Blazor script handles:

- Downloading the .NET runtime, Razor components, and the component's dependencies.
- Initialization of the runtime.

The size of the published app, its *payload size*, is a critical performance factor for an app's usability. A large app takes a relatively long time to download to a browser, which diminishes the user experience. Blazor WebAssembly optimizes payload size to reduce download times:

- Unused code is stripped out of the app when it's published by the Intermediate Language (IL) Trimmer.
- HTTP responses are compressed.
- The .NET runtime and assemblies are cached in the browser.

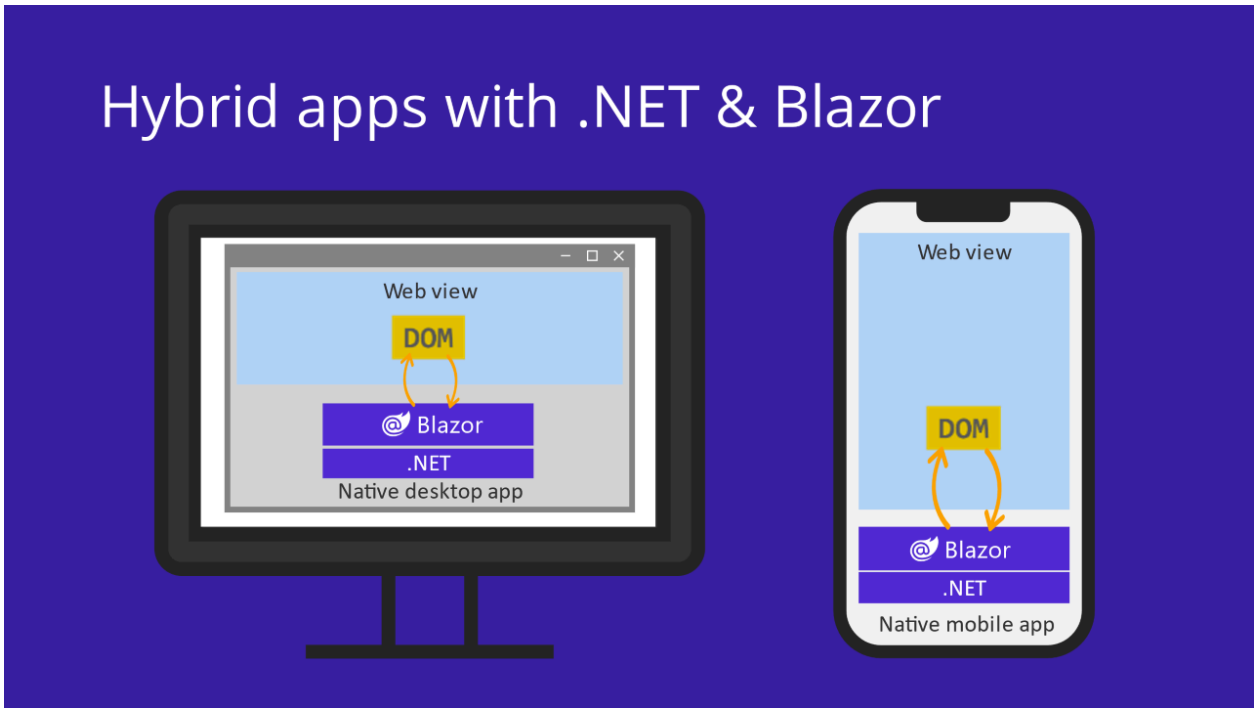
The Blazor WebAssembly hosting model offers several benefits:

- For standalone Blazor WebAssembly apps, there's no .NET server-side dependency after the app is downloaded from the server, so the app remains functional if the server goes offline.
- Client resources and capabilities are fully leveraged.
- Work is offloaded from the server to the client.
- For standalone Blazor WebAssembly apps, an ASP.NET Core web server isn't required to host the app. Serverless deployment scenarios are possible, such as serving the app from a Content Delivery Network (CDN).

The Blazor WebAssembly hosting model has the following limitations:

- Razor components are restricted to the capabilities of the browser.
- Capable client hardware and software (for example, WebAssembly support) is required.
- Download size is larger, and components take longer to load.
- Code sent to the client can't be protected from inspection and tampering by users.

The .NET Intermediate Language (IL) interpreter includes partial just-in-time (JIT) runtime support to achieve improved runtime performance. The JIT interpreter optimizes execution of interpreter bytecodes by replacing them with tiny blobs of WebAssembly code. The JIT interpreter is automatically enabled for Blazor WebAssembly apps except when debugging.



Blazor supports ahead-of-time (AOT) compilation, where you can compile your .NET code directly into WebAssembly. AOT compilation results in runtime performance improvements at the expense of a larger app size. For more information, see ASP.NET Core Blazor WebAssembly build tools and ahead-of-time (AOT) compilation.

The same .NET WebAssembly build tools used for AOT compilation also relink the .NET WebAssembly runtime to trim unused runtime code. Blazor also trims unused code from .NET framework libraries. The .NET compiler further precompresses a standalone Blazor WebAssembly app for a smaller app payload.

WebAssembly-rendered Razor components can use native dependencies built to run on WebAssembly.

Blazor Hybrid

Blazor can also be used to build native client apps using a hybrid approach. Hybrid apps are native apps that leverage web technologies for their functionality. In a Blazor Hybrid app, Razor components run directly in the native app (not on WebAssembly) along with any other .NET code and render web UI based on HTML and CSS to an embedded Web View control through a local interop channel.

Blazor Hybrid apps can be built using different .NET native app frameworks, including .NET MAUI, WPF, and Windows Forms. Blazor provides `BlazorWebView` controls for adding Razor components to apps built with these frameworks. Using Blazor with .NET MAUI offers a convenient way to build cross-platform Blazor Hybrid apps for mobile and desktop, while Blazor integration with WPF and Windows Forms can be a great way to modernize existing apps.

Because Blazor Hybrid apps are native apps, they can support functionality that isn't available with only the web platform. Blazor Hybrid apps have full access to native platform capabilities through normal .NET APIs. Blazor Hybrid apps can also share and reuse components with existing Blazor Server or Blazor WebAssembly apps. Blazor Hybrid apps combine the benefits of the web, native apps, and the .NET platform.

The Blazor Hybrid hosting model offers several benefits:

- Reuse existing components that can be shared across mobile, desktop, and web.
- Leverage web development skills, experience, and resources.
- Apps have full access to the native capabilities of the device.

The Blazor Hybrid hosting model has the following limitations:

- Separate native client apps must be built, deployed, and maintained for each target platform.
- Native client apps usually take longer to find, download, and install over accessing a web app in a browser.

For more information, see ASP.NET Core Blazor Hybrid.

For more information on Microsoft native client frameworks, see the following resources:

- .NET Multi-platform App UI (.NET MAUI)
- Windows Presentation Foundation (WPF)
- Windows Forms

Which Blazor hosting model should I choose?

A component's hosting model is set by its *render mode*, either at compile time or runtime, which is described with examples in ASP.NET Core Blazor render modes. The following table shows the primary considerations for setting the render mode to determine a component's hosting model. For standalone Blazor WebAssembly apps, all of the app's components are rendered on the client with the Blazor WebAssembly hosting model.

Blazor Hybrid apps include .NET MAUI, WPF, and Windows Forms framework apps.

Expand table

Feature	Blazor Server	Blazor WebAssembly (WASM)	Blazor Hybrid
Complete .NET API compatibility	✔	✘	✔
Direct access to server and network resources	✔	✘†	✘†
Small payload size with fast initial load time	✔	✘	✘
Near native execution speed	✔	✔‡	✔
App code secure and private on the server	✔	✘†	✘†
Run apps offline once downloaded	✘	✔	✔
Static site hosting	✘	✔	✘
Offloads processing to clients	✘	✔	✔
Full access to native client capabilities	✘	✘	✔
Web-based deployment	✔	✔	✘

†Blazor WebAssembly and Blazor Hybrid apps can use server-based APIs to access server/network resources and access private and secure app code.
‡Blazor WebAssembly only reaches near-native performance with ahead-of-time (AOT) compilation.

After you choose the app's hosting model, you can generate a Blazor Server or Blazor WebAssembly app from a Blazor project template. For more information, see Tooling for ASP.NET Core Blazor.

To create a Blazor Hybrid app, see the articles under ASP.NET Core Blazor Hybrid tutorials.

Complete .NET API compatibility

Components rendered for the Blazor Server hosting model and Blazor Hybrid apps have complete .NET API compatibility, while components rendered for Blazor WebAssembly are limited to a subset of .NET APIs. When an app's specification requires one or more .NET APIs that are unavailable to WebAssembly-rendered components, then choose to render components for Blazor Server or use Blazor Hybrid.

Direct access to server and network resources

Components rendered for the Blazor Server hosting model have direct access to server and network resources where the app is executing. Because components hosted using Blazor WebAssembly or Blazor Hybrid execute on a client, they don't have direct access to server and network resources. Components can access server and network resources *indirectly* via protected server-based APIs. Server-based APIs might be available via third-party libraries, packages, and services. Take into account the following considerations:

- Third-party libraries, packages, and services might be costly to implement and maintain, weakly supported, or introduce security risks.
- If one or more server-based APIs are developed internally by your organization, additional resources are required to build and maintain them.

Use the Blazor Server hosting model to avoid the need to expose APIs from the server environment.

Small payload size with fast initial load time

Rendering components from the server reduces the app payload size and improves initial load times. When a fast initial load time is desired, use the Blazor Server hosting

model or consider static server-side rendering.

Near native execution speed

Blazor Hybrid apps run using the .NET runtime natively on the target platform, which offers the best possible speed.

Components rendered for the Blazor WebAssembly hosting model, including Progressive Web Apps (PWAs), and standalone Blazor WebAssembly apps run using the .NET runtime for WebAssembly, which is slower than running directly on the platform. Consider using ahead-of-time (AOT) compiled to improve runtime performance when using Blazor WebAssembly.

App code secure and private on the server

Maintaining app code securely and privately on the server is a built-in feature of components rendered for the Blazor Server hosting model. Components rendered using the Blazor WebAssembly or Blazor Hybrid hosting models can use server-based APIs to access functionality that must be kept private and secure. The considerations for developing and maintaining server-based APIs described in the Direct access to server and network resources section apply. If the development and maintenance of server-based APIs isn't desirable for maintaining secure and private app code, render components for the Blazor Server hosting model.

Run apps offline once downloaded

Standalone Blazor WebAssembly apps built as Progressive Web Apps (PWAs) and Blazor Hybrid apps can run offline, which is particularly useful when clients aren't able to connect to the Internet. Components rendered for the Blazor Server hosting model fail to run when the connection to the server is lost. If an app must run offline, standalone Blazor WebAssembly and Blazor Hybrid are the best choices.

Static site hosting

Static site hosting is possible with standalone Blazor WebAssembly apps because they're downloaded to clients as a set of static files. Standalone Blazor WebAssembly apps don't require a server to execute server-side code in order to download and run and can be delivered via a Content Delivery Network (CDN) (for example, Azure CDN).

Although Blazor Hybrid apps are compiled into one or more self-contained deployment assets, the assets are usually provided to clients through a third-party app store. If static

hosting is an app requirement, select standalone Blazor WebAssembly.

Offloads processing to clients

Blazor WebAssembly and Blazor Hybrid apps execute on clients and thus offload processing to clients. Blazor Server apps execute on a server, so server resource demand typically increases with the number of users and the amount of processing required per user. When it's possible to offload most or all of an app's processing to clients and the app processes a significant amount of data, Blazor WebAssembly or Blazor Hybrid is the best choice.

Full access to native client capabilities

Blazor Hybrid apps have full access to native client API capabilities via .NET native app frameworks. In Blazor Hybrid apps, Razor components run directly in the native app, not on WebAssembly. When full client capabilities are a requirement, Blazor Hybrid is the best choice.

Web-based deployment

Blazor web apps are updated on the next app refresh from the browser.

Blazor Hybrid apps are native client apps that typically require an installer and platform-specific deployment mechanism.

Setting a component's hosting model

To set a component's hosting model to Blazor Server or Blazor WebAssembly at compile-time or dynamically at runtime, you set its *render mode*. Render modes are fully explained and demonstrated in the ASP.NET Core Blazor render modes article. We don't recommend that you jump from this article directly to the *Render modes* article without reading the content in the articles between these two articles. For example, render modes are more easily understood by looking at Razor component examples, but basic Razor component structure and function isn't covered until the ASP.NET Core Blazor fundamentals article is reached. It's also helpful to learn about Blazor's project templates and tooling before working with the component examples in the *Render modes* article.

ASP.NET Core Blazor tutorials

Article • 08/26/2024

Build a Blazor todo list app

Article • 10/29/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This tutorial provides a basic working experience for building and modifying a Blazor app. For detailed Blazor guidance, see the Blazor reference documentation.

Learn how to:

- ✓ Create a todo list Blazor app project
- ✓ Modify Razor components
- ✓ Use event handling and data binding in components
- ✓ Use routing in a Blazor app

At the end of this tutorial, you'll have a working todo list app.

Prerequisites

Download and install .NET if it isn't already installed on the system or if the system doesn't have the latest version installed.

Create a Blazor app

Create a new Blazor Web App named `TodoList` in a command shell:

.NET CLI

```
dotnet new blazor -o TodoList
```

The `-o|--output` option creates a folder for the project. If you've created a folder for the project and the command shell is open in that folder, omit the `-o|--output` option and value to create the project.

The preceding command creates a folder named `TodoList` with the `-o|--output` option to hold the app. The `TodoList` folder is the *root folder* of the project. Change directories to the `TodoList` folder with the following command:

.NET CLI

```
cd TodoList
```

Build a todo list Blazor app

Add a new `Todo` Razor component to the app using the following command:

.NET CLI

```
dotnet new razorcomponent -n Todo -o Components/Pages
```

The `-n|--name` option in the preceding command specifies the name of the new Razor component. The new component is created in the project's `Components/Pages` folder with the `-o|--output` option.

> **ⓘ Important**
>
> Razor component file names require a capitalized first letter. Open the `Pages` folder and confirm that the `Todo` component file name starts with a capital letter `T`. The file name should be `Todo.razor`.

Open the `Todo` component in any file editor and make the following changes at the top of the file:

- Add an `@page` Razor directive with a relative URL of `/todo`.
- Enable interactivity on the page so that it isn't just statically rendered. The Interactive Server render mode enables the component to handle UI events from the server.
- Add a page title with the `PageTitle` component, which enables adding an HTML `<title>` element to the page.

`Todo.razor`:

razor

```
@page "/todo"
@rendermode InteractiveServer

<PageTitle>Todo</PageTitle>

<h3>Todo</h3>

@code {

}
```

Save the `Todo.razor` file.

Add the `Todo` component to the navigation bar.

The `NavMenu` component is used in the app's layout. Layouts are components that allow you to avoid duplication of content in an app. The `NavLink` component provides a cue in the app's UI when the component URL is loaded by the app.

In the navigation element (`<nav>`) content of the `NavMenu` component, add the following `<div>` element for the `Todo` component.

In `Components/Layout/NavMenu.razor`:

razor

```
<div class="nav-item px-3">
    <NavLink class="nav-link" href="todo">
        <span class="oi oi-list-rich" aria-hidden="true"></span> Todo
    </NavLink>
</div>
```

Save the `NavMenu.razor` file.

Build and run the app by executing the dotnet watch run command in the command shell from the `TodoList` folder. After the app is running, visit the new Todo page by selecting the **`Todo`** link in the app's navigation bar, which loads the page at `/todo`.

Leave the app running the command shell. Each time a file is saved, the app is automatically rebuilt, and the page in the browser is automatically reloaded.

Add a `TodoItem.cs` file to the root of the project (the `TodoList` folder) to hold a class that represents a todo item. Use the following C# code for the `TodoItem` class.

`TodoItem.cs`:

C#

```
public class TodoItem
{
    public string? Title { get; set; }
    public bool IsDone { get; set; }
}
```

> **Note**
>
> If using Visual Studio to create the `TodoItem.cs` file and `TodoItem` class, use ***either*** of the following approaches:
>
> - Remove the namespace that Visual Studio generates for the class.
> - Use the **Copy** button in the preceding code block and replace the entire contents of the file that Visual Studio generates.

Return to the `Todo` component and perform the following tasks:

- Add a field for the todo items in the `@code` block. The `Todo` component uses this field to maintain the state of the todo list.
- Add unordered list markup and a `foreach` loop to render each todo item as a list item (`<li>`).

`Components/Pages/Todo.razor`:

razor

```
@page "/todo"
@rendermode InteractiveServer

<PageTitle>Todo</PageTitle>

<h3>Todo</h3>

<ul>
    @foreach (var todo in todos)
    {
        <li>@todo.Title</li>
    }
</ul>

@code {
    private List<TodoItem> todos = new();
}
```

The app requires UI elements for adding todo items to the list. Add a text input (`<input>`) and a button (`<button>`) below the unordered list (`<ul>...</ul>`):

razor

```
@page "/todo"
@rendermode InteractiveServer

<PageTitle>Todo</PageTitle>

<h3>Todo</h3>

<ul>
    @foreach (var todo in todos)
    {
        <li>@todo.Title</li>
    }
</ul>

<input placeholder="Something todo" />
<button>Add todo</button>

@code {
    private List<TodoItem> todos = new();
}
```

Save the `TodoItem.cs` file and the updated `Todo.razor` file. In the command shell, the app is automatically rebuilt when the files are saved. The browser reloads the page.

When the **`Add todo`** button is selected, nothing happens because an event handler isn't attached to the button.

Add an `AddTodo` method to the `Todo` component and register the method for the button using the `@onclick` attribute. The `AddTodo` C# method is called when the button is selected:

razor

```
<input placeholder="Something todo" />
<button @onclick="AddTodo">Add todo</button>

@code {
    private List<TodoItem> todos = new();

    private void AddTodo()
    {
        // Todo: Add the todo
    }
}
```

To get the title of the new todo item, add a `newTodo` string field at the top of the `@code` block:

C#

```
private string? newTodo;
```

Modify the text `<input>` element to bind `newTodo` with the `@bind` attribute:

razor

```
<input placeholder="Something todo" @bind="newTodo" />
```

Update the `AddTodo` method to add the `TodoItem` with the specified title to the list. Clear the value of the text input by setting `newTodo` to an empty string:

razor

```
@page "/todo"
@rendermode InteractiveServer

<PageTitle>Todo</PageTitle>

<h3>Todo</h3>

<ul>
    @foreach (var todo in todos)
    {
        <li>@todo.Title</li>
    }
</ul>

<input placeholder="Something todo" @bind="newTodo" />
<button @onclick="AddTodo">Add todo</button>

@code {
    private List<TodoItem> todos = new();
    private string? newTodo;

    private void AddTodo()
    {
        if (!string.IsNullOrWhiteSpace(newTodo))
        {
            todos.Add(new TodoItem { Title = newTodo });
            newTodo = string.Empty;
        }
    }
}
```

Save the `Todo.razor` file. The app is automatically rebuilt in the command shell, and the page reloads in the browser.

The title text for each todo item can be made editable, and a checkbox can help the user keep track of completed items. Add a checkbox input for each todo item and bind its value to the `IsDone` property. Change `@todo.Title` to an `<input>` element bound to `todo.Title` with `@bind`:

razor

```razor
<ul>
      @foreach (var todo in todos)
      {
         <li>
            <input type="checkbox" @bind="todo.IsDone" />
            <input @bind="todo.Title" />
         </li>
      }
</ul>
```

Update the `<h3>` header to show a count of the number of todo items that aren't complete (`IsDone` is `false`). The Razor expression in the following header evaluates each time Blazor rerenders the component.

razor

```razor
<h3>Todo (@todos.Count(todo => !todo.IsDone))</h3>
```

The completed `Todo` component:

razor

```razor
@page "/todo"
@rendermode InteractiveServer

<PageTitle>Todo</PageTitle>

<h1>Todo (@todos.Count(todo => !todo.IsDone))</h1>

<ul>
    @foreach (var todo in todos)
    {
        <li>
            <input type="checkbox" @bind="todo.IsDone" />
            <input @bind="todo.Title" />
        </li>
    }
</ul>
```

```
<input placeholder="Something todo" @bind="newTodo" />
<button @onclick="AddTodo">Add todo</button>

@code {
    private List<TodoItem> todos = new();
    private string? newTodo;

    private void AddTodo()
    {
        if (!string.IsNullOrWhiteSpace(newTodo))
        {
            todos.Add(new TodoItem { Title = newTodo });
            newTodo = string.Empty;
        }
    }
}
```

Save the `Todo.razor` file. The app is automatically rebuilt in the command shell, and the page reloads in the browser.

Add items, edit items, and mark todo items done to test the component.

When finished, shut down the app in the command shell. Many command shells accept the keyboard command `Ctrl`+`C` (Windows) or `⌘`+`C` (macOS) to stop an app.

Publish to Azure

For information on deploying to Azure, see Quickstart: Deploy an ASP.NET web app.

Next steps

In this tutorial, you learned how to:

- ✓ Create a todo list Blazor app project
- ✓ Modify Razor components
- ✓ Use event handling and data binding in components
- ✓ Use routing in a Blazor app

Learn about tooling for ASP.NET Core Blazor:

ASP.NET Core Blazor

Build a Blazor movie database app (Overview)

Article • 09/05/2024

This tutorial explains the basics of building a Blazor Web App with a database, Entity Framework (EF) Core, and user interactivity.

Parts of this series include:

1. Create a Blazor Web App
2. Add and scaffold a model
3. Learn about Razor components
4. Work with a database
5. Add validation
6. Add search
7. Add a new field
8. Add interactivity

At the end of the tutorial, you'll have a Blazor Web App that can display and manage movies in a movie database.

Secure authentication flow required for production apps

This tutorial uses a local database that doesn't require user authentication. Production apps should use the most secure authentication flow available. For more information on authentication for deployed test and production Blazor Web Apps, see the following resources:

- ASP.NET Core Blazor authentication and authorization
- Secure ASP.NET Core server-side Blazor apps and the following articles in the *Server* security node
- Secure an ASP.NET Core Blazor Web App with OpenID Connect (OIDC)

For Microsoft Azure services, we recommend using *managed identities*. Managed identities securely authenticate to Azure services without storing credentials in app code. For more information, see the following resources:

- What are managed identities for Azure resources? (Microsoft Entra documentation)
- Azure services documentation

- Managed identities in Microsoft Entra for Azure SQL
- How to use managed identities for App Service and Azure Functions

Sample app

If you don't intend to create the demonstration app while reading the article, you can refer to the completed sample app in the Blazor samples GitHub repository (dotnet/blazor-samples). Select the latest version folder in the repository. The sample folder for this tutorial's project is named `BlazorWebAppMovies`.

Article code examples

The line breaks of code examples shown in the ASP.NET Core documentation often don't match line breaks in scaffolded code generated by tooling for an app. This is due to an article publishing limitation. Lines of code in articles are generally limited to 85 characters in length, and we manually adjust the line length using line breaks to satisfy our publishing guidelines.

As you work through this tutorial or use any other ASP.NET Core article's code examples, you never need to adjust scaffolded code in your app to match the line breaks displayed in article code examples.

Report a tutorial issue

To open a documentation GitHub issue for an article of the series, use the **Open a documentation issue** link at the bottom of the article. Using the link to create your issue adds important tracking metadata to the issue and automatically pings the author of the article.

Support requests

We welcome feedback on the tutorial's articles, such as bug reports and comments on the article's text, but we're often unable to provide product support. If you run into a problem while following the tutorial, don't immediately open a documentation issue. Check the steps that you've taken against the article and compare your code to the sample app before opening an issue because many problems can be traced to missing a step or not following a step correctly.

For general questions about .NET and Blazor beyond the tutorial and reference documentation or to obtain assistance from the .NET community, converse with

developers in public forums.

Next steps

Next: Create a Blazor Web App

Build a Blazor movie database app (Part 1 - Create a Blazor Web App)

Article • 11/05/2024

This article is the first part of the Blazor movie database app tutorial that teaches you the basics of building an ASP.NET Core Blazor Web App with features to manage a movie database.

This part of the tutorial series covers how to create a Blazor Web App that adopts static server-side rendering (static SSR). Static SSR means that content is rendered on the server and sent to the client for display in response to individual requests.

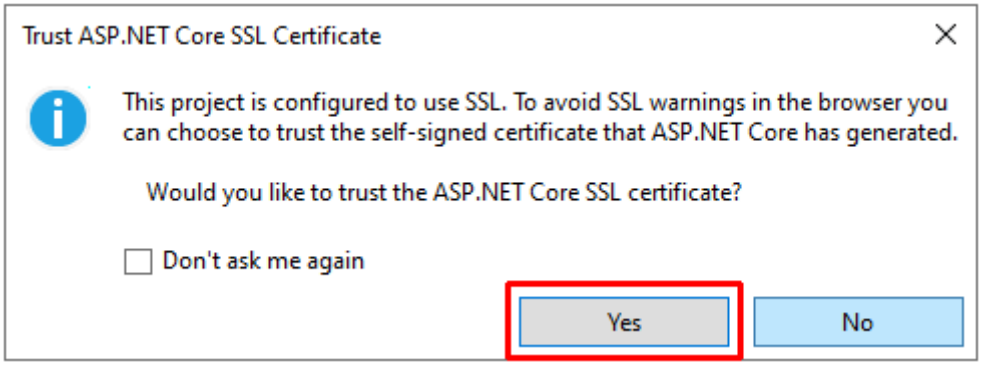
Prerequisites

Visual Studio (latest release) with the **ASP.NET and web development** workload

Create a Blazor Web App

In Visual Studio:

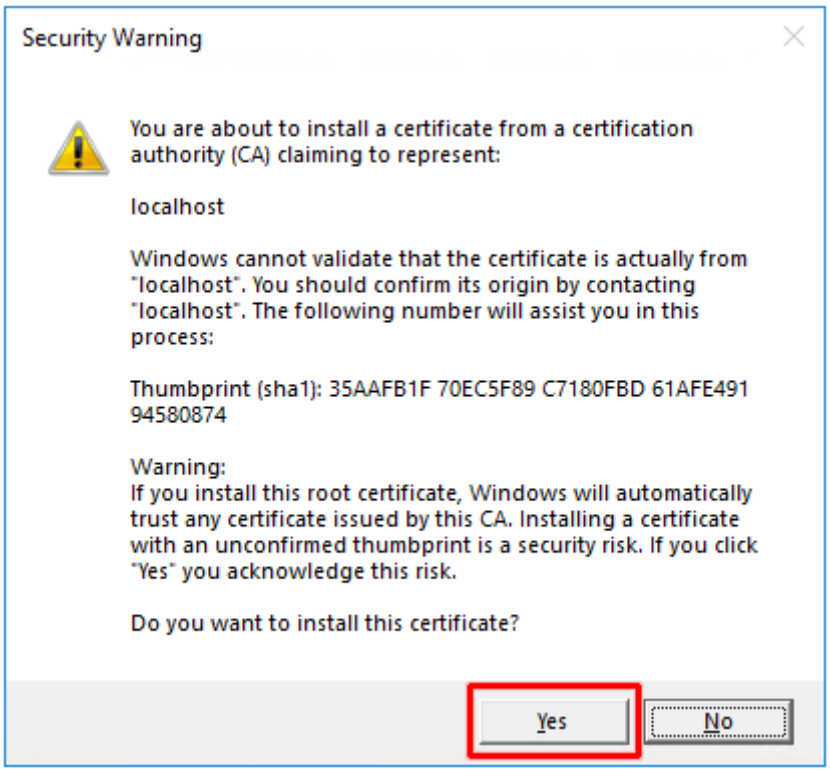
- Select **Create a new project** from the **Start Window** or select **File** > **New** > **Project** from the menu bar.
- In the **Create a new project** dialog, select **Blazor Web App** from the list of project templates. Select the **Next** button.
- In the **Configure your new project** dialog, name the project `BlazorWebAppMovies` in the **Project name** field, including matching the capitalization. Using this exact project name is important to ensure that the namespaces match for code that you copy from the tutorial into the app that you're building.
- Confirm that the **Location** for the app is suitable. Set the **Place solution and project in the same directory** checkbox to match your preferred solution file location. Select the **Next** button.
- In the **Additional information** dialog, use the following settings:
  - **Framework**: Select **.NET 9.0 (Standard Term Support)**.
  - **Authentication type**: **None**
  - **Configure for HTTPS**: Selected
  - **Interactive render mode**: **Server**



- **Interactivity location**: **Per page/component**
- **Include sample pages**: Selected
- **Do not use top-level statements**: Not selected
- Select **Create**.

The Visual Studio instructions in parts of this tutorial series use EF Core commands to add database migrations and update the database. EF Core commands are issued using Visual Studio Connected Services. More information is provided later in this tutorial series.

Run the app



Press F5 on the keyboard to run the app.

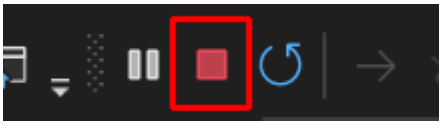
Visual Studio displays the following dialog when a project isn't configured to use SSL:

Select **Yes** if you trust the ASP.NET Core SSL certificate.

The following dialog is displayed:

Select **Yes** to acknowledge the risk and install the certificate.

Visual Studio:



- Compiles and runs the app.
- Launches the default browser at `https://localhost:{PORT}`, which displays the app's UI. The `{PORT}` placeholder is the random port assigned to the app when the app is created. If you need to change the port due to a local port conflict, change the port in the project's `Properties/launchSettings.json` file.

Navigate the pages of the app to confirm that the app is working normally.

Stop the app

Stop the app using either of the following approaches:

- Close the browser window.
- In Visual Studio, either:
  - Use the Stop button in Visual Studio's menu bar:

    
  - Press `Shift`+`F5` on the keyboard.

Examine the project files

The following sections contain an overview of the project's folders and files.

If you're building the app, you don't need to make changes to the project files in the following sections. As you read the descriptions of the folders and files, examine them in the project.

If you're only reading the articles and not building the app, you can refer to the completed sample app in the Blazor samples GitHub repository (dotnet/blazor-samples). Select the latest version folder in the repository. The sample folder for this tutorial's project is named `BlazorWebAppMovies`. The sample app is the *finished version* of the app after following all of the steps of the tutorial series. Code in the sample doesn't always match steps of the tutorial before the end of the series.

`Properties` folder

The `Properties` folder holds development environment configuration in the `launchSettings.json` file.

`wwwroot` folder

The `wwwroot` folder contains static assets, such as image, JavaScript (`.js`), and stylesheet (`.css`) files.

`Components`, `Components/Pages`, and `Components/Layout` folders

These folders contain *Razor components*, often referred to as "components," and supporting files. A component is a self-contained portion of user interface (UI) with optional processing logic. Components can be nested, reused, and shared among projects.

Components are implemented using a combination of C# and HTML markup in Razor component files with the `.razor` file extension.

Typically, components that are nested within other components and not directly reachable ("routable") at a URL are placed in the `Components` folder. Components that are routable via a URL are usually placed in the `Components/Pages` folder.

The `Components/Layout` folder contains the following layout components and stylesheets:

- `MainLayout` component (`MainLayout.razor`): The app's main layout component.
- `MainLayout.razor.css`: Stylesheet for the app's main layout.
- `NavMenu` component (`NavMenu.razor`): Implements sidebar navigation. This component uses several `NavLink` components to render navigation links to other Razor components.
- `NavMenu.razor.css`: Stylesheet for the app's navigation menu.

`Components/_Imports.razor` file

The `_Imports` file (`_Imports.razor`) includes common *Razor directives* to include in the app's Razor components. Razor directives are reserved keywords prefixed with `@` that appear in Razor markup and change the way component markup or component elements are compiled or function.

`Components/App.razor` file

The `App` component (`App.razor`) is the root component of the app that includes:

- HTML markup.
- The `Routes` component.
- The Blazor script (`<script>` tag for `blazor.web.js`).

The root component is the first component that the app loads.

`Components/Routes.razor` file

The `Routes` component (`Routes.razor`) sets up routing for the app.

`appsettings.json` file

The `appsettings.json` file contains configuration data, such as connection strings.

> ⚠ **Warning**
>
> Don't store app secrets, connection strings, credentials, passwords, personal identification numbers (PINs), private C#/.NET code, or private keys/tokens in client-side code, which is ***always insecure***. In test/staging and production

environments, server-side Blazor code and web APIs should use secure authentication flows that avoid maintaining credentials within project code or configuration files. Outside of local development testing, we recommend avoiding the use of environment variables to store sensitive data, as environment variables aren't the most secure approach. For local development testing, the Secret Manager tool is recommended for securing sensitive data. For more information, see Securely maintain sensitive data and credentials.

`Program.cs` file

The `Program.cs` file contains code to create the app and configure the request processing pipeline of the app.

The order of the lines in the Blazor Web App project template changes across releases of .NET, so the order of the lines in the `Program.cs` file might not match the order of the lines covered in this section.

A WebApplicationBuilder creates the app with preconfigured defaults:

```
C#

var builder = WebApplication.CreateBuilder(args);
```

Razor component services are added to the app by calling AddRazorComponents, which enables Razor components to render and execute code on the server:

```
C#

builder.Services.AddRazorComponents();
```

The WebApplication (held by the `app` variable in the following code) is built:

```
C#

var app = builder.Build();
```

Next, the HTTP request pipeline is configured.

In the development environment:

- Exception Handler Middleware (UseExceptionHandler) processes errors and displays a developer exception page during development app runs.

- HTTP Strict Transport Security Protocol (HSTS) Middleware (UseHsts) processes HSTS.

```
C#

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error", createScopeForErrors: true);
    app.UseHsts();
}
```

HTTPS Redirection Middleware (UseHttpsRedirection) enforces the HTTPS protocol by redirecting HTTP requests to HTTPS if an HTTPS port is available:

```
C#

app.UseHttpsRedirection();
```

Antiforgery Middleware (UseAntiforgery) enforces antiforgery protection for form processing:

```
C#

app.UseAntiforgery();
```

Map Static Assets routing endpoint conventions (MapStaticAssets) maps static files, such as images, scripts, and stylesheets, produced during the build as endpoints:

```
C#

app.MapStaticAssets();
```

MapRazorComponents maps components defined in the root `App` component to the given .NET assembly and renders routable components:

```
C#

app.MapRazorComponents<App>();
```

The app is run by calling Run on the WebApplication (`app`):

```
C#
```

```
app.Run();
```

Troubleshoot with the completed sample

If you run into a problem while following the tutorial that you can't resolve from the text, compare your code to the completed project in the Blazor samples repository:

Blazor samples GitHub repository (dotnet/blazor-samples)

Select the latest version folder. The sample folder for this tutorial's project is named `BlazorWebAppMovies`.

Additional resources

When using VS Code or the .NET CLI, this tutorial series adopts insecure HTTP protocol to ease the transition of adopting SSL/HTTPS security for Linux and macOS users. For information on adopting SSL/HTTPS, see Enforce HTTPS in ASP.NET Core.

Next: Add and scaffold a model

Build a Blazor movie database app (Part 2 - Add and scaffold a model)

Article • 10/08/2024

This article is the second part of the Blazor movie database app tutorial that teaches you the basics of building an ASP.NET Core Blazor Web App with features to manage a movie database.

In this part of the tutorial series:

- A class is added to the app representing a movie in a database.
- Entity Framework Core (EF Core) services and tooling create a database context and database. EF Core is an object-relational mapper (O/RM) that simplifies data access. You write model classes first, and EF Core creates the database from the model classes, which is called *scaffolding*.
- Additional tooling scaffolds a Razor component-based UI for interacting with the movie records in the database via the database context.

Add a data model

In **Solution Explorer**, right-click the `BlazorWebAppMovies` project and select **Add** > **New Folder**. Name the folder `Models`.

Right-click the `Models` folder. Select **Add** > **Class**. Name the file `Movie.cs`. Use the following contents for the file.

`Models/Movie.cs`:

C#

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace BlazorWebAppMovies.Models;

public class Movie
{
    public int Id { get; set; }

    public string? Title { get; set; }

    public DateOnly ReleaseDate { get; set; }

    public string? Genre { get; set; }
```

```
    [DataType(DataType.Currency)]
    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }
}
```

The `Movie` class contains:

- A record identifier property (`Id`), which is required by EF Core and the database to track records. In the database, the `Id` property is the database record's primary key.
- Other properties that describe aspects of a movie:
  - Title (`Title`)
  - Release date (`ReleaseDate`)
  - Genre (`Genre`)
  - Price (`Price`)

The question mark on a `string` type indicates that the property is nullable (it can hold a `null` value).

The EF Core database provider selects data types based on the .NET types of the model's properties. The provider also takes into account other metadata provided by System.ComponentModel.DataAnnotations, which are a set of attribute classes placed above a model's property with the following format, where the `{ANNOTATION}` placeholder is the annotation name. You can place multiple annotations on the same line separated by commas inside the brackets, or you can place multiple annotations on separate lines, which is the approach adopted by this tutorial series.

C#

```
[{ANNOTATION}]
```

The `Price` property in the `Movie` class file has two data annotations:

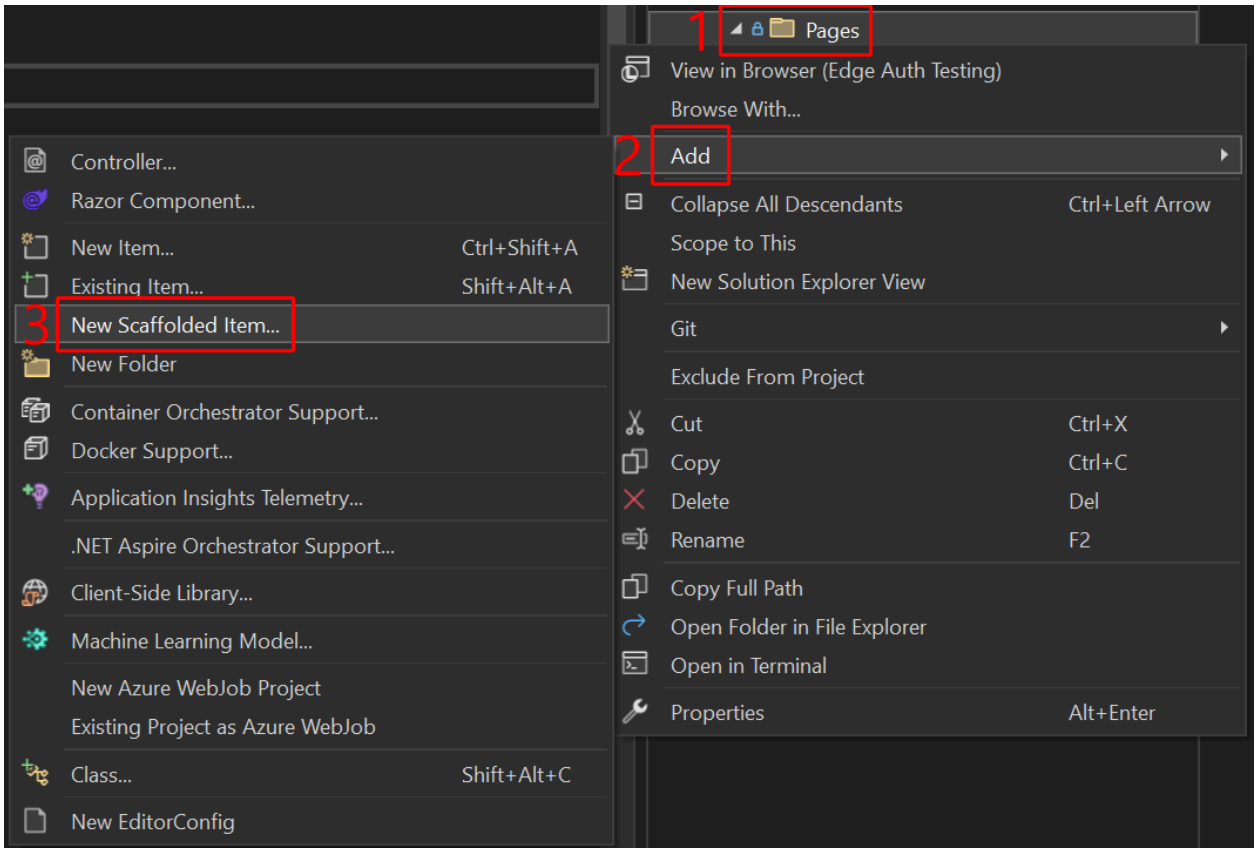
C#

```
[DataType(DataType.Currency)]
[Column(TypeName = "decimal(18, 2)")]
public decimal Price { get; set; }
```

These annotations specify:

- That the property holds a currency data type.

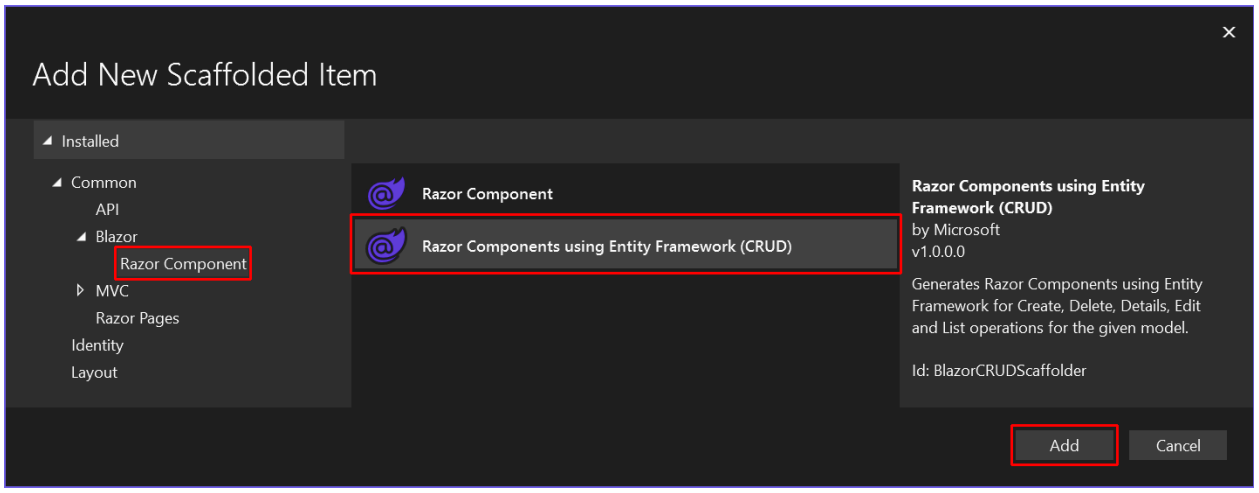
- The database column is a decimal of 18 digits with two decimal places.



More information on data annotations, including adding data annotations for validation, is covered in a later part of the tutorial series.

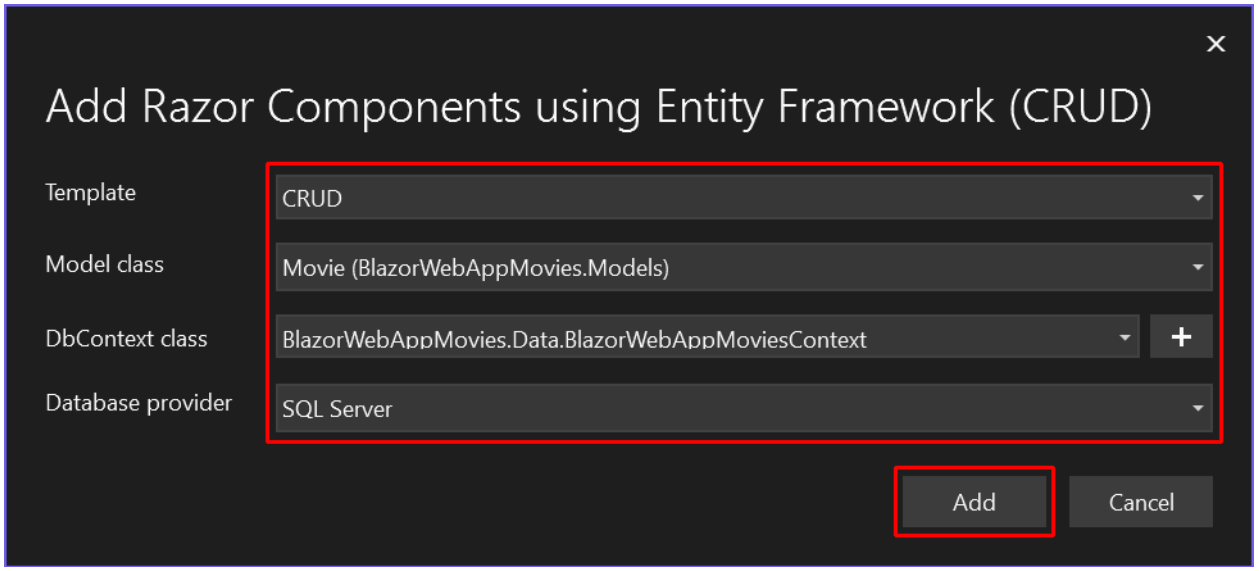
Select **Build** > **Build Solution** from the menu bar or press F6 on the keyboard. Confirm in the **Output** panel that the build succeeded.

Scaffold the model



In this section, the `Movie` model is used to *scaffold* a database context and a UI for managing movies in the database. .NET scaffolding is a code generation framework for .NET applications. You use scaffolding to quickly add database and UI code that interacts with data models.

Right-click on the `Components/Pages` folder and select **Add** > **New Scaffolded Item**:



With the **Add New Scaffold Item** dialog open to **Installed** > **Common** > **Blazor** > **Razor Component**, select **Razor Components using Entity Framework (CRUD)**. Select the **Add** button.

CRUD is an acronym for Create, Read, Update, and Delete. The scaffolder produces create, edit, delete, details, and index components for the app.

Complete the **Add Razor Components using Entity Framework (CRUD)** dialog:

- The **Template** dropdown list includes other templates for specifically creating create, edit, delete, details, and list components. This dropdown list comes in handy when you only need to create a specific type of component scaffolded to a model class. Leave the **Template** dropdown list set to **CRUD** to scaffold a full set of components.
- In the **Model class** dropdown list, select **Movie (BlazorWebAppMovies.Models)**.
- For **DbContext class**, select the + (plus sign) button.
- In the **Add Data Context** modal dialog, the class name `BlazorWebAppMovies.Data.BlazorWebAppMoviesContext` is generated. Use the default generated value. Select the **Add** button.
- After the model dialog closes, the **Database provider** dropdown list defaults to **SQL Server**. When you're building apps in the future, you can select the appropriate provider for the database that you're using. The options include SQLite, PostgreSQL, and Azure Cosmos DB. Leave the **Database provider** dropdown list set to **SQL Server**.
- Select **Add**.

The `appsettings.json` file is updated with the connection string used to connect to a local database. In the following example, the `{CONNECTION STRING}` is the connection string automatically generated by the scaffolder:

JSON

```
"ConnectionStrings": {
  "BlazorWebAppMoviesContext": "{CONNECTION STRING}"
}
```

> ⚠ **Warning**
>
> Don't store app secrets, connection strings, credentials, passwords, personal identification numbers (PINs), private C#/.NET code, or private keys/tokens in client-side code, which is ***always insecure***. In test/staging and production environments, server-side Blazor code and web APIs should use secure authentication flows that avoid maintaining credentials within project code or configuration files. Outside of local development testing, we recommend avoiding the use of environment variables to store sensitive data, as environment variables aren't the most secure approach. For local development testing, the Secret Manager tool is recommended for securing sensitive data. For more information, see Securely maintain sensitive data and credentials.

Files created and updated by scaffolding

The scaffolding process creates the following component files and movie database context class file:

- `Components/Pages/MoviePages`
  - `Create.razor`: Creates new movie entities.
  - `Delete.razor`: Deletes a movie entity.
  - `Details.razor`: Shows movie entity details.
  - `Edit.razor`: Updates a movie entity.
  - `Index.razor`: Lists movie entities (records) in the database.
- `Data/BlazorWebAppMoviesContext.cs`: Database context file (DbContext).

The component files in the `MoviePages` folder are described in greater detail in the next part of this tutorial. The database context is described later in this article.

ASP.NET Core is built with dependency injection, which is a software design pattern for achieving Inversion of Control (IoC) between classes and their dependencies. Services, such as the EF Core database context, are registered with dependency injection during application startup. These services are injected into Razor components for use by the components.

The QuickGrid component is a Razor component for efficiently displaying data in tabular form. The scaffolder places a `QuickGrid` component in the `Index` component (`Components/Pages/Index.razor`) to display movie entities. Calling AddQuickGridEntityFrameworkAdapter on the service collection adds an EF Core adapter for `QuickGrid` to recognize EF Core-supplied IQueryable<T> instances and to resolve database queries asynchronously for efficiency.

In combination with UseDeveloperExceptionPage, AddDatabaseDeveloperPageExceptionFilter captures database-related exceptions that can be resolved by using Entity Framework migrations. When these exceptions occur, an HTML response is generated with details about possible actions to resolve the issue.

The following code is added to the `Program` file by the scaffolder:

C#

```
builder.Services.AddDbContextFactory<BlazorWebAppMoviesContext>(options =>
    options.UseSqlServer(

builder.Configuration.GetConnectionString("BlazorWebAppMoviesContext") ??
        throw new InvalidOperationException(
            "Connection string 'BlazorWebAppMoviesContext' not found.")));

builder.Services.AddQuickGridEntityFrameworkAdapter();

builder.Services.AddDatabaseDeveloperPageExceptionFilter();
```

Static server-side rendering (static SSR) is enabled by calling:

- The service collection extension method AddRazorComponents to register services for server-side rendering (SSR) of Razor components.
- The request pipeline extension method MapRazorComponents, which maps the page components defined in the `App` component to the given assembly and renders the `App` component when a request matches a route to a component:

C#

```
builder.Services.AddRazorComponents()
    .AddInteractiveServerComponents();
```

```
...

app.MapRazorComponents<App>()
    .AddInteractiveServerRenderMode();
```

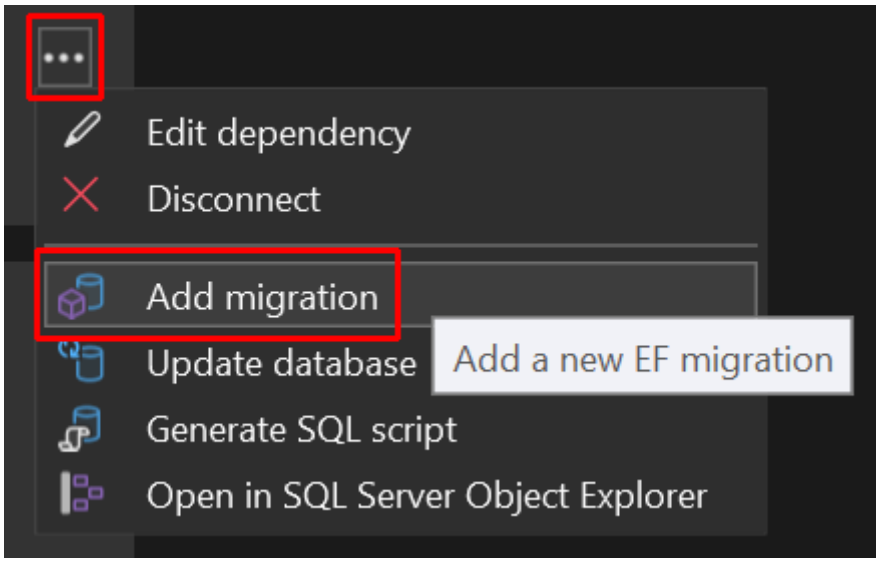
The extension methods AddInteractiveServerComponents and AddInteractiveServerRenderMode make the app capable of adopting interactive SSR, which isn't relevant until the last part of the tutorial series on interactivity. Over the next several articles, the app's components only adopt static SSR.

Create the initial database schema using EF Core's migration feature

The migrations feature in EF Core:

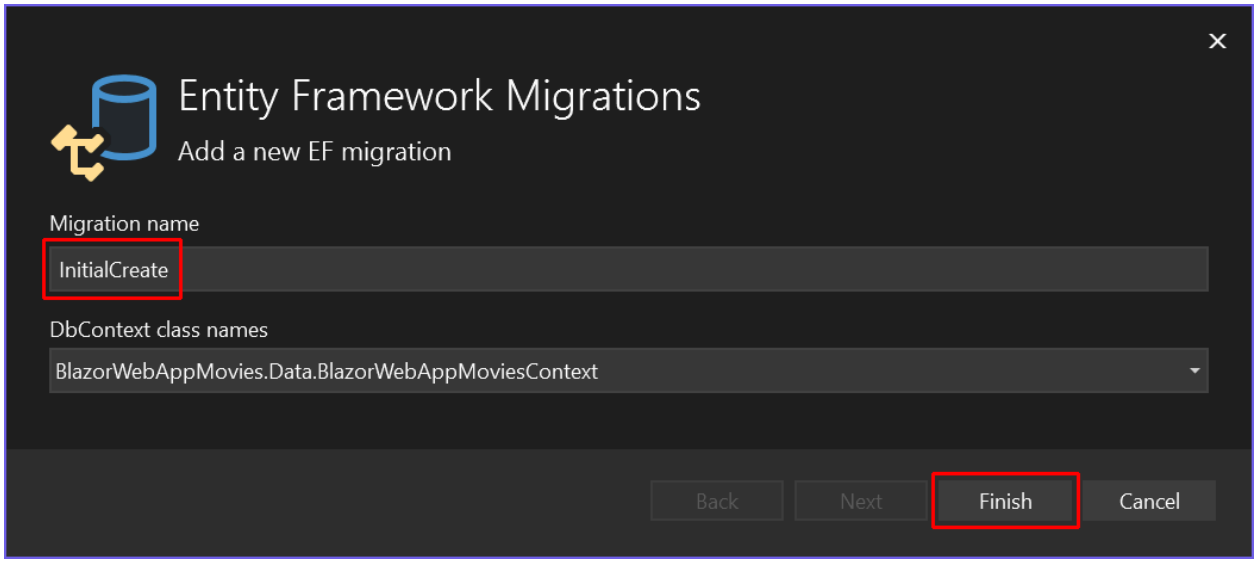
- Creates the initial database schema.
- Incrementally updates the database schema to keep it synchronized with the app's data model. Existing data in the database is preserved.

EF Core adopts the *code-first* approach for database design and maintenance:



- Entity classes are created and updated first in the app.
- The database is created and updated from the app's entity classes.

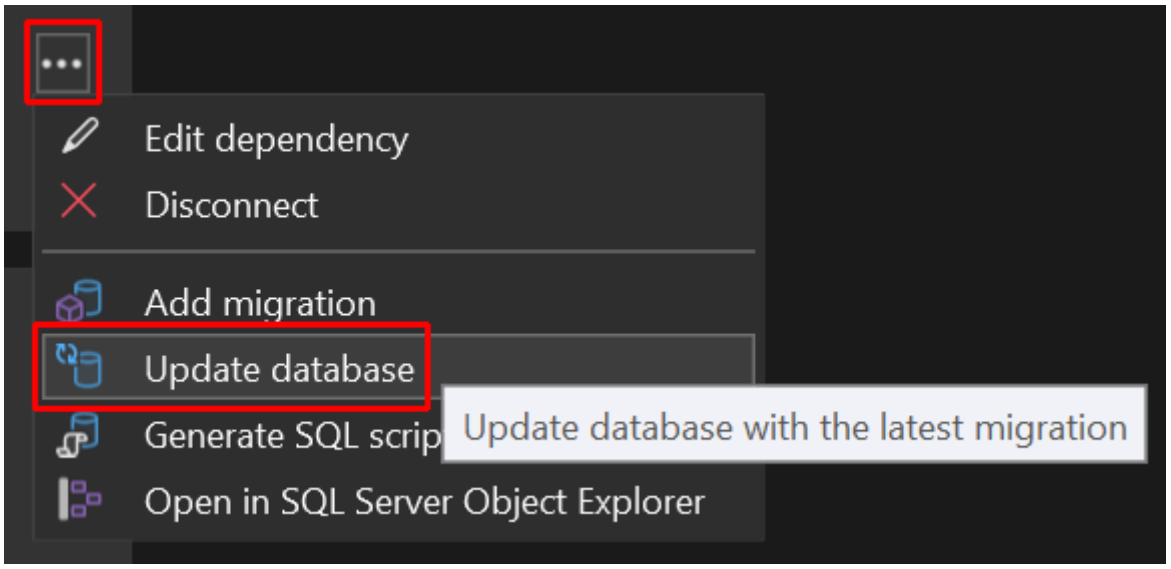
This is the reverse procedure of *database-first* approaches, where the database is designed, built, and updated first. Adopting EF Core's code-first approach speeds up the process of app development because most of the difficult and time-consuming database creation and management procedures are handled transparently by the EF Core tooling, so you can focus on app development.



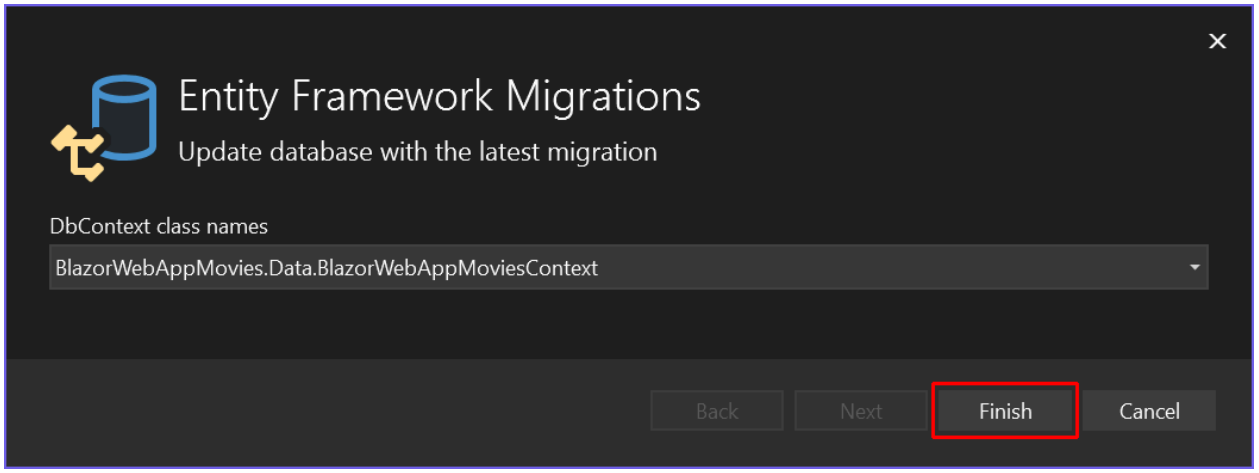
In this section, Visual Studio Connected Services are used to issue EF Core commands that:

- Add an initial migration.
- Update the database using the initial migration.

In **Solution Explorer**, double-click **Connected Services**. In the **SQL Server Express LocalDB** area of **Service Dependencies**, select the ellipsis (`...`) followed by **Add migration**:



Give the migration a **Migration name** of `InitialCreate`, which is a name that describes the migration. Wait for the database context to load in the **DbContext class names** field, which may take a few seconds. Select **Finish** to create the migration:



Select the **Close** button after the operation finishes.

Adding a migration generates code to create the initial database schema. The schema is based on the model specified in DbContext.

Select the ellipsis (`...`) again followed by the **Update database** command:

The **Update database with the latest migration** dialog opens. Wait for the **DbContext class names** field to update and for prior migrations to load, which may take a few seconds. Select the **Finish** button:

The update database command executes the `Up` method migrations that haven't been applied in a migration code file created by the scaffolder. In this case, the command executes the `Up` method in the `Migrations/{TIME STAMP}_InitialCreate.cs` file, which creates the database. The `{TIME STAMP}` placeholder is a time stamp.

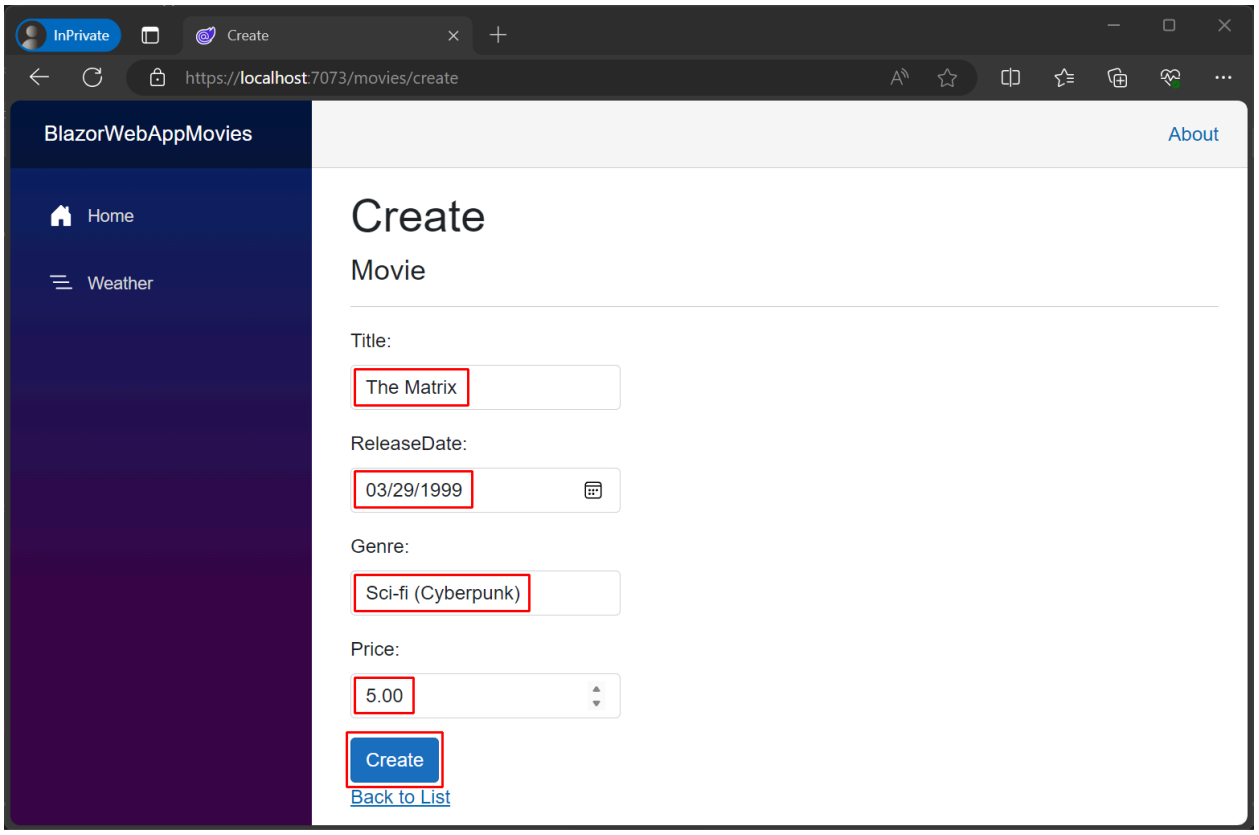
Select the **Close** button after the operation finishes.

The database context `BlazorWebAppMoviesContext` (`Data/BlazorWebAppMoviesContext.cs`):

- Derives from Microsoft.EntityFrameworkCore.DbContext.
- Specifies which entities are included in the data model.
- Coordinates EF Core functionality, such as CRUD operations, for the `Movie` model.
- Contains a DbSet<TEntity> property for the `Movie` entity set. In EF terminology, an entity set typically corresponds to a database table. An entity corresponds to a row in the table.

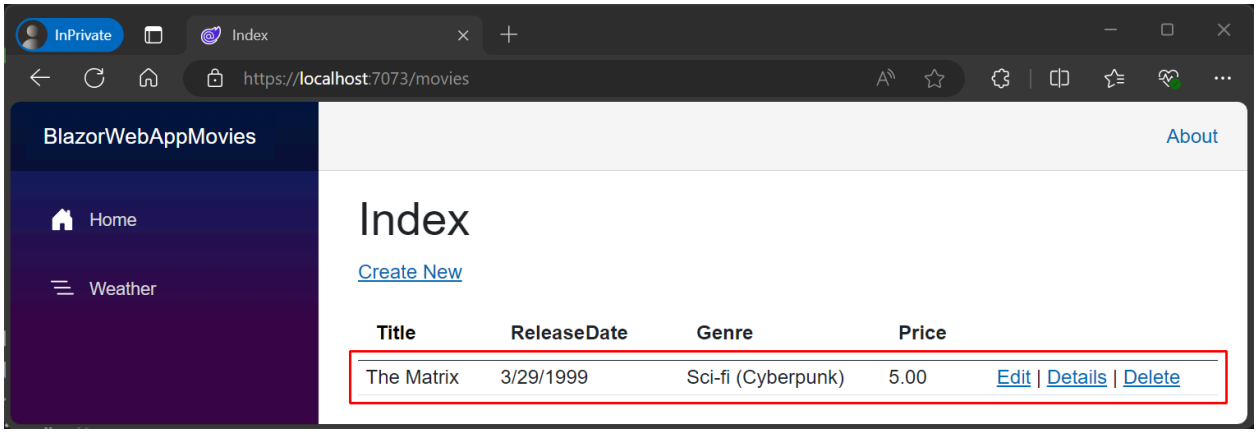
The name of the connection string is passed in to the context by calling a method on a DbContextOptions object. For local development, the connection string is read from the `appsettings.json` file.

> ⚠ **Warning**
>
> Don't store app secrets, connection strings, credentials, passwords, personal identification numbers (PINs), private C#/.NET code, or private keys/tokens in client-side code, which is ***always insecure***. In test/staging and production environments, server-side Blazor code and web APIs should use secure authentication flows that avoid maintaining credentials within project code or configuration files. Outside of local development testing, we recommend avoiding the use of environment variables to store sensitive data, as environment variables aren't the most secure approach. For local development testing, the Secret Manager tool is recommended for securing sensitive data. For more information, see Securely maintain sensitive data and credentials.



Test the app

Run the app.

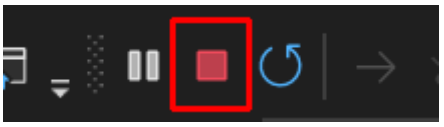


Add `/movies` to the URL in the browser's address bar to navigate to the movies `Index` page.

After the `Index` page loads, select the **Create New** link.

Add a movie to the database. In the following example, the classic sci-fi movie *The Matrix* (©1999 Warner Bros. Entertainment Inc.) is added as the first movie entry. Selecting the **Create** button adds the movie to the database:

When you select the **Create** button, the movie data is posted to the server and saved in the database. When the app returns to the `Index` page, the added entity appears:



Open the `Edit` page. Edit the movie's record and save the changes.

Examine the `Delete` page, but don't delete *The Matrix* movie from the database. The presence of this movie record is valuable in the next step of the tutorial where rendered HTML is studied and some enhancements are made to the data displayed. If you already deleted the movie, add the movie to the database again using the `Create` page before proceeding to the next part of the tutorial series.

Stop the app

Stop the app using either of the following approaches:

- Close the browser window.
- In Visual Studio, either:
  - Use the Stop button in Visual Studio's menu bar:

  - Press `Shift`+`F5` on the keyboard.

Troubleshoot with the completed sample

If you run into a problem while following the tutorial that you can't resolve from the text, compare your code to the completed project in the Blazor samples repository:

Blazor samples GitHub repository (dotnet/blazor-samples)

Select the latest version folder. The sample folder for this tutorial's project is named `BlazorWebAppMovies`.

Next: Learn about Razor components

Build a Blazor movie database app (Part 3 - Learn about Razor components)

Article • 08/26/2024

This article is the third part of the Blazor movie database app tutorial that teaches you the basics of building an ASP.NET Core Blazor Web App with features to manage a movie database.

This part of the tutorial series examines the Razor components in the project that were scaffolded into the app. Improvements are made for the display of movie data.

Razor components

Blazor apps are based on *Razor components*, often referred to as just *components*. A *component* is an element of UI, such as a page, dialog, or data entry form. Components are .NET C# classes built into .NET assemblies.

Razor refers to how components are usually written in the form of a Razor markup page (`.razor` file extension) for client-side UI logic and composition. Razor is a syntax for combining HTML markup with C# code designed for developer productivity.

Although developers and online resources use the term "Blazor components," the documentation uses the formal name "Razor components" (or just "components").

The anatomy of a Razor component has the following general pattern:

- At the top of the component definition (`.razor` file), various Razor directives specify how the component markup is compiled or functions.
- Next, Razor markup specifies how HTML is rendered, which includes ordinary HTML elements.
- Finally, an `@code` block contains C# code to define members for the component class, including component parameters and event handlers.

Consider the following `Welcome` component (`Welcome.razor`):

razor

```
@page "/welcome"

<PageTitle>Welcome!</PageTitle>

<h1>Welcome to Blazor!</h1>
```

```
<p>@welcomeMessage</p>

@code {
    private string welcomeMessage = "We ❤ Blazor!";
}
```

The first line represents an important Razor construct in Razor components, a *Razor directive*. A Razor directive is a reserved keyword prefixed with `@` that appears in Razor markup that changes the way component markup is compiled or functions. The `@page` Razor directive specifies the route template for the component. This component is reached in a browser at the relative URL `/welcome`. By convention, most of a component's directives are placed at the top of the component definition file.

The PageTitle component is a component built into the framework that specifies a page title.

"`Welcome to Blazor!`" is the first rendered body markup of the component per the content of the H1 heading element (`<h1>`).

Next, a welcome message is displayed using Razor syntax by prefixing the at symbol (`@`) to a C# variable (`welcomeMessage`).

The `@code` block contains the C# code of the component. `welcomeMessage` is a private string initialized with a value.

In the following sections of this article:

- Three components for webpage navigation and layout are described, the `NavMenu`, NavLink, and `MainLayout` components.
- The components created by scaffolding for CRUD operations on movie database entities are discussed.

`NavMenu` component for navigation

The `NavMenu` component (`Components/Layout/NavMenu.razor`) implements sidebar navigation using NavLink components, which render navigation links to other Razor components.

A NavLink component behaves like an `<a>` element, except it toggles an `active` CSS class based on whether its `href` matches the current URL. The `active` class helps a user understand which page is the active page among the navigation links displayed.

NavLinkMatch.All assigned to the Match parameter configures the component to display an active CSS class when it matches the entire current URL.

The NavLink component built into the Blazor framework for any Blazor app to use, while the `NavMenu` component is only part of Blazor project templates.

`Components/Layout/NavMenu.razor`:

razor

```razor
<div class="top-row ps-3 navbar navbar-dark">
    <div class="container-fluid">
        <a class="navbar-brand" href="">BlazorWebAppMovies</a>
    </div>
</div>

<input type="checkbox" title="Navigation menu" class="navbar-toggler" />

<div class="nav-scrollable" onclick="document.querySelector('.navbar-
toggler').click()">
    <nav class="flex-column">
        <div class="nav-item px-3">
            <NavLink class="nav-link" href="" Match="NavLinkMatch.All">
                <span class="bi bi-house-door-fill-nav-menu" aria-
hidden="true"></span> Home
            </NavLink>
        </div>

        <div class="nav-item px-3">
            <NavLink class="nav-link" href="weather">
                <span class="bi bi-list-nested-nav-menu" aria-hidden="true">
</span> Weather
            </NavLink>
        </div>
    </nav>
</div>
```

Notice in the `NavMenu` component's first `<div>` element the brand link text (`<a>` element content). Change the brand from `BlazorWebAppMovies` to `Sci-fi Movies`:

diff

```diff
- <a class="navbar-brand" href="">BlazorWebAppMovies</a>
+ <a class="navbar-brand" href="">Sci-fi Movies</a>
```

To allow users to reach the movies `Index` page, add a navigation menu entry to the `NavMenu` component. Immediately after the markup (`<div>`) for the `Weather` component's `NavLink`, add the following markup:

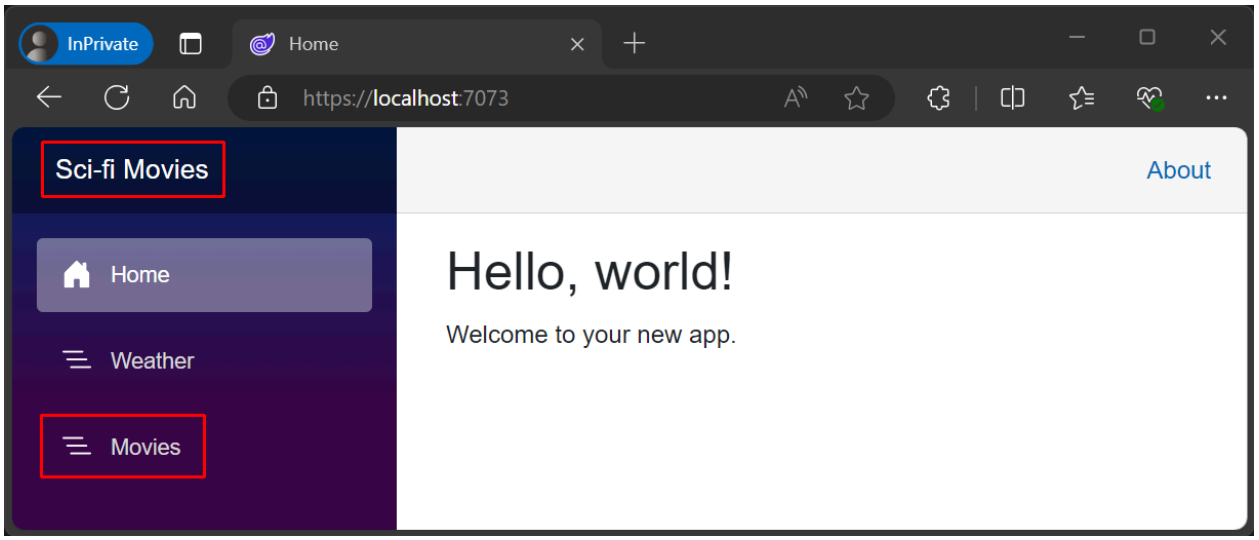
razor

```
<div class="nav-item px-3">
    <NavLink class="nav-link" href="movies">
        <span class="bi bi-list-nested-nav-menu" aria-hidden="true"></span>
Movies
    </NavLink>
</div>
```

The final `NavMenu` component after making the preceding changes:

razor

```
<div class="top-row ps-3 navbar navbar-dark">
    <div class="container-fluid">
        <a class="navbar-brand" href="">Sci-fi Movies</a>
    </div>
</div>



<input type="checkbox" title="Navigation menu" class="navbar-toggler" />

<div class="nav-scrollable" onclick="document.querySelector('.navbar-
toggler').click()">
    <nav class="flex-column">
        <div class="nav-item px-3">
            <NavLink class="nav-link" href="" Match="NavLinkMatch.All">
                <span class="bi bi-house-door-fill-nav-menu" aria-
hidden="true"></span> Home
            </NavLink>
        </div>

        <div class="nav-item px-3">
            <NavLink class="nav-link" href="weather">
                <span class="bi bi-list-nested-nav-menu" aria-hidden="true">
</span> Weather
            </NavLink>
        </div>

        <div class="nav-item px-3">
            <NavLink class="nav-link" href="movies">
                <span class="bi bi-list-nested-nav-menu" aria-hidden="true">
</span> Movies
            </NavLink>
        </div>
    </nav>
</div>
```

Run the app to see the updated brand at the top of the sidebar navigation and a link to reach the movies page (**Movies**):

Stop the app by closing the browser's window.

`MainLayout` component for layout

The `MainLayout` component is the app's default layout. The `MainLayout` component inherits LayoutComponentBase, which is a base class for components that represent a layout. The app's components that use the layout are rendered where the Body (`@Body`) appears in the markup.

`Components/Layout/MainLayout.razor`:

razor

```
@inherits LayoutComponentBase

<div class="page">
    <div class="sidebar">
        <NavMenu />
    </div>

    <main>
        <div class="top-row px-4">
            <a href="https://learn.microsoft.com/aspnet/core/"
target="_blank">About</a>
        </div>

        <article class="content px-4">
            @Body
        </article>
    </main>
</div>
```

The `MainLayout` component adopts the following additional specifications:

- The `NavMenu` component is rendered in the sidebar. Notice that you only need to place an HTML tag with the component name to render a component at that location in Razor markup. This allows you to nest components within each other and within any HTML layout that you implement.
- The `<main>` element's content includes:
  - An **About** link that sends the user to the ASP.NET Core documentation landing page.
  - An `<article>` element with the Body (`@Body`) parameter, where components that use the layout are rendered.

The default layout (`MainLayout` component) is specified in the `Routes` component (`Components/Pages/Routes.razor`):

```razor
<RouteView RouteData="routeData" DefaultLayout="typeof(Layout.MainLayout)"
/>
```

Individual components are free to set their own non-default layout, and a layout can be applied to whole folder of components via an `_Imports.razor` file in the same folder. These features are covered in detail in the Blazor documentation.

Create, Read, Update, Delete (CRUD) components

The following sections explain the composition of the movie CRUD components and how they work.

`Index` component

Open the `Index` component definition file (`Components/Pages/Movies/Index.razor`) and examine the Razor directives at the top of the file.

The `@page` directive's route template indicates the URL for the page is `/movies`.

`@using` directives appear to access the following API:

- Microsoft.EntityFrameworkCore
- Microsoft.AspNetCore.Components.QuickGrid
- `BlazorWebAppMovies.Models`
- `BlazorWebAppMovies.Data`

The database context factory (`IDbContextFactory<BlazorWebAppMoviesContext>`) is injected into the component with the `@inject` directive. The factory approach requires that a database context be disposed, so the component implements the IAsyncDisposable interface with the `@implements` directive.

The page title is set via the Blazor framework's PageTitle component, and an H1 section heading is the first rendered element:

razor

```razor
<PageTitle>Index</PageTitle>

<h1>Index</h1>
```

A link is rendered to navigate to the `Create` page at `/movies/create`:

razor

```razor
<p>
    <a href="movies/create">Create New</a>
</p>
```

The QuickGrid component displays movie entities. The item provider is a `DbSet<Movie>` obtained from the created database context (CreateDbContext) of the injected database context factory (`DbFactory`). For each movie entity, the component displays the movie's title, release date, genre, and price. A column also holds links to edit, see details, and delete each movie entity.

razor

```razor
<QuickGrid Class="table" Items="context.Movie">
    <PropertyColumn Property="movie => movie.Title" />
    <PropertyColumn Property="movie => movie.ReleaseDate" />
    <PropertyColumn Property="movie => movie.Genre" />
    <PropertyColumn Property="movie => movie.Price" />

    <TemplateColumn Context="movie">
        <a href="@($"movies/edit?id={movie.Id}")">Edit</a> |
        <a href="@($"movies/details?id={movie.Id}")">Details</a> |
        <a href="@($"movies/delete?id={movie.Id}")">Delete</a>
    </TemplateColumn>
</QuickGrid>

@code {
    private BlazorWebAppMoviesContext context = default!;

    protected override void OnInitialized()
```

```
    {
        context = DbFactory.CreateDbContext();
    }

    public async ValueTask DisposeAsync() => await context.DisposeAsync();
}
```

In the code block (`@code`):

- The `context` field holds the database context, typed as a `BlazorWebAppMoviesContext`.
- The `OnInitialized` lifecycle method assigns a created database context (CreateDbContext) from the injected factory (`DbFactory`) to the `context` variable.
- The asynchronous `DisposeAsync` method disposes of the database context when the component is disposed.

Notice how the context (`Context`) parameter of the TemplateColumn<TGridItem> specifies a parameter name (`movie`) for the context instance of the column. Specifying a name for the context instance makes the markup more readable (the default name for the context is simply `context`). `Movie` class properties are read from the context instance. For example, the movie identifier (`Id`) is available in `movie.Id`.

The at symbol (`@`) with parentheses (`@(...)`), which is called an *explicit Razor expression*, allows the `href` of each link to include the movie entity's `Id` property in the link query string as an *interpolated string* (`$...{...}...`). For a movie identifier (`Id`) of 7, the string value provided to the `href` to edit that movie is `movies/edit?id=7`. When the link is followed, the `id` field is read from the query string by the `Edit` component to load the movie.

For the movie example from the last part of the tutorial series, *The Matrix©*, the QuickGrid component renders the following HTML markup (some elements and attributes aren't present to simplify display). See how the explicit Razor expressions and interpolated strings produced the `href` values for the links to other pages. The movie's identifier in the database happens to be `3` for this example, so the `id` is `3` in the query strings for the `Edit`, `Details`, and `Delete` pages. You may see a different value when you run the app.

HTML

```
<table>
    <thead>
        <tr>
            <th>Title</th>
            <th>ReleaseDate</th>
```

```
            <th>Genre</th>
            <th>Price</th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        <tr>
            <td>The Matrix</td>
            <td>3/29/1999</td>
            <td>Sci-fi (Cyberpunk)</td>
            <td>5.00</td>
            <td>
                <a href="movies/edit?id=3">Edit</a> |
                <a href="movies/details?id=3">Details</a> |
                <a href="movies/delete?id=3">Delete</a>
            </td>
        </tr>
    </tbody>
</table>
```

The column names are taken from the `Movie` model properties, so the release date doesn't have a space between the words. Add a Title to the PropertyColumn<TGridItem,TProp> with a value that includes a space between the words:

razor

```
<PropertyColumn Property="movie => movie.ReleaseDate" Title="Release Date"
/>
```

Run the app to see that the column displays two words for the release date.

Stop the app by closing the browser's window.

`Details` component

Open the `Details` component definition file (`Components/Pages/Movies/Details.razor`).

The `@page` directive at the top of the file indicates the relative URL for the page is `/movies/details`. As before, the database context is injected, and namespaces are provided to access API (`BlazorWebAppMovies.Models` and `Microsoft.EntityFrameworkCore`). The `Details` component also injects the app's NavigationManager, which is used for a variety of navigation-related operations in components.

razor

```
@page "/movies/details"
@using Microsoft.EntityFrameworkCore
@using BlazorWebAppMovies.Models
@inject IDbContextFactory<BlazorWebAppMovies.Data.BlazorWebAppMoviesContext>
DbFactory
@inject NavigationManager NavigationManager
```

Details for a movie entity are only shown if the movie, located by its identifier (`Id`) from the query string, has been loaded for display. The presence of the movie in `movie` is checked with an `@if` Razor statement:

razor

```
@if (movie is null)
{
    <p><em>Loading...</em></p>
}
```

When the movie is loaded, it's displayed as a description list (MDN documentation) along with two links:

- The first link provides the user an opportunity to edit the entity.
- The second link allows the user to return to the movies `Index` page.

CSS classes aren't shown in the following example to simplify the Razor markup for display:

razor

```
<dl>
    <dt>Title</dt>
    <dd>@movie.Title</dd>
    <dt>ReleaseDate</dt>
    <dd>@movie.ReleaseDate</dd>
    <dt>Genre</dt>
    <dd>@movie.Genre</dd>
    <dt>Price</dt>
    <dd>@movie.Price</dd>
</dl>
<div>
    <a href="@($"/movies/edit?id={movie.Id}")">Edit</a> |
    <a href="@($"/movies")">Back to List</a>
</div>
</div>
```

Add a space to the content of the description term element (`<dt>`) for the movie's release date to separate the words:

diff

```
- <dt class="col-sm-2">ReleaseDate</dt>
+ <dt class="col-sm-2">Release Date</dt>
```

Examine the C# of the component's `@code` block:

C#

```
private Movie? movie;

[SupplyParameterFromQuery]
private int Id { get; set; }

protected override async Task OnInitializedAsync()
{
    using var context = DbFactory.CreateDbContext();
    movie = await context.Movie.FirstOrDefaultAsync(m => m.Id == Id);

    if (movie is null)
    {
        NavigationManager.NavigateTo("notfound");
    }
}
```

The `movie` variable is a private field of type `Movie`, which is a null-reference type (`?`), meaning that `movie` might be set to `null`.

The `Id` is a *component parameter* supplied from the component's query string due to the presence of the [SupplyParameterFromQuery] attribute. If the identifier is missing, `Id` defaults to zero (`0`).

`OnInitializedAsync` is the first component lifecycle method that we've seen. This method is executed when the component loads. FirstOrDefaultAsync is called on the database set (`DbSet<Movie>`) to retrieve the movie entity with and `Id` equal to the `Id` parameter that was set by the query string. If `movie` is `null`, NavigationManager.NavigateTo is used to navigate to a `notfound` endpoint.

There isn't an actual `notfound` endpoint (Razor component) in the app. When adopting server-side rendering (SSR), Blazor doesn't have a mechanism to return a 404 (Not Found) status code. As a temporary workaround, a 404 is generated by navigating to a non-existent endpoint. This scaffolded code is for your further implementation of a suitable result when not finding an entity. For example, you could have the component direct the user to a page where they can file an inquiry with your support team, or you could remove the injected NavigationManager and NavigationManager.NavigateTo

code and replace it with Razor markup and code that displays a message to the user that the entity wasn't found.

`Create` component

Open the `Create` component definition file (`Components/Pages/Movies/Create.razor`).

The component uses a built-in component called an EditForm, which renders a form for user input and includes validation features.

CSS classes aren't present in the following example to simplify the display:

razor

```
<EditForm method="post" Model="Movie" OnValidSubmit="AddMovie"
FormName="create" Enhance>
    <DataAnnotationsValidator />
    <ValidationSummary />
    <div>
        <label for="title">Title:</label>
        <InputText id="title" @bind-Value="Movie.Title" />
        <ValidationMessage For="() => Movie.Title" />
    </div>
    <div>
        <label for="releasedate">ReleaseDate:</label>
        <InputDate id="releasedate" @bind-Value="Movie.ReleaseDate" />
        <ValidationMessage For="() => Movie.ReleaseDate" />
    </div>
    <div>
        <label for="genre">Genre:</label>
        <InputText id="genre" @bind-Value="Movie.Genre" />
        <ValidationMessage For="() => Movie.Genre" />
    </div>
    <div>
        <label for="price">Price:</label>
        <InputNumber id="price" @bind-Value="Movie.Price" />
        <ValidationMessage For="() => Movie.Price" />
    </div>
    <button type="submit">Create</button>
</EditForm>
```

Add a space to the content of the label element (`<label>`) for the movie's release date to separate the words:

diff

```
- <label for="releasedate" class="form-label">ReleaseDate:</label>
+ <label for="releasedate" class="form-label">Release Date:</label>
```

The Model parameter is assigned the model, in this case `Movie`. OnValidSubmit specifies a method to invoke (`AddMovie`) when the form is submitted and the data is valid. By convention, every form should assign a FormName to prevent form collisions when multiple forms are present on a page. The Enhance flag activates a Blazor feature for server-side rendering (SSR) that submits the form without performing a full-page reload.

For validation:

- The DataAnnotationsValidator adds data annotations validation support, which is covered later in this tutorial series.
- The ValidationSummary component displays a list of validation messages.
- The ValidationMessage<TValue> components hold validation messages for the form's fields.

Blazor includes several form element components to assist you with creating forms, including EditForm and various input components, such as InputText, InputDate<TValue>, and InputNumber<TValue>. Each input component is bound to a model property with `@bind-Value` Razor syntax, where `Value` is a property in each input component.

In the component's `@code` block, C# code includes a `Movie` component parameter tied to the form via the [SupplyParameterFromForm] attribute.

The `AddMovie` method:

- Is called when the form is submitted.
- Adds the movie data bound to the form's model (`Movie`) if form validation passes.
- SaveChangesAsync is called on the database context to save the movie.
- NavigationManager is used to return the user to the movies `Index` page.

C#

```
@code {
    [SupplyParameterFromForm]
    private Movie Movie { get; set; } = new();

    private async Task AddMovie()
    {
        using var context = DbFactory.CreateDbContext();
        context.Movie.Add(Movie);
        await context.SaveChangesAsync();
        NavigationManager.NavigateTo("/movies");
    }
}
```

> ⚠ **Warning**
>
> Although it isn't a concern for the app in this tutorial, binding form data to entity data models can be susceptible to overposting attacks. Additional information on this subject appears later in this article.

`Delete` component

Open the `Delete` component definition file (`Components/Pages/Movies/Delete.razor`).

Add a space to the content of the description term element (`<dt>`) for the movie's release date to separate the words:

diff

```
- <dt class="col-sm-2">ReleaseDate</dt>
+ <dt class="col-sm-2">Release Date</dt>
```

Examine the Razor markup for the submit button of the EditForm (CSS class removed for simplicity):

razor

```
<button type="submit" disabled="@(movie is null)">Delete</button>
```

The **Delete** button sets its disabled HTML attribute (MDN documentation) based on the presence of the movie (not `null`) using an explicit Razor expression (`@(...)`).

In the C# code of the `@code` block, the `DeleteMovie` method removes the movie, saves the changes to the database, and navigates the user to the movies `Index` page. The exclamation point on the movie field (`movie!`) is the null-forgiving operator (C# Language Reference), which suppresses nullable warnings for `movie`.

C#

```
private async Task DeleteMovie()
{
    using var context = DbFactory.CreateDbContext();
    context.Movie.Remove(movie!);
    await context.SaveChangesAsync();
    NavigationManager.NavigateTo("/movies");
}
```

`Edit` component

Open the `Edit` component definition file (`Components/Pages/Movies/Edit.razor`).

Add a space to the content of the label element (`<label>`) for the movie's release date to separate the words:

diff

```
- <label for="releasedate" class="form-label">ReleaseDate:</label>
+ <label for="releasedate" class="form-label">Release Date:</label>
```

The component uses an EditForm similar to the `Create` component.

The movie entity's identifier `Id` is stored in a hidden field of the form:

razor

```
<input type="hidden" name="Movie.Id" value="@Movie.Id" />
```

Examine the C# code of the `@code` block:

C#

```
private async Task UpdateMovie()
{
    using var context = DbFactory.CreateDbContext();
    context.Attach(Movie!).State = EntityState.Modified;

    try
    {
        await context.SaveChangesAsync();
    }
    catch (DbUpdateConcurrencyException)
    {
        if (!MovieExists(Movie!.Id))
        {
            NavigationManager.NavigateTo("notfound");
        }
        else
        {
            throw;
        }
    }

    NavigationManager.NavigateTo("/movies");
}

private bool MovieExists(int id)
```

```
{
    using var context = DbFactory.CreateDbContext();
    return context.Movie.Any(e => e.Id == id);
}
```

The movie entity's EntityState is set to Modified, which signifies that the entity is tracked by the context, exists in the database, and that some or all of its property values are modified.

If there's a concurrency exception and the movie entity no longer exists at the time that changes are saved, the component redirects to the non-existent endpoint (`notfound`), which results in returning a 404 (Not Found) status code. You could change this code to notify the user that the movie no longer exists in the database or create a dedicated *Not Found* component and navigate the user to that endpoint. If the movie exists and a concurrency exception is thrown, for example when another user has already modified the entity, the exception is rethrown by the component with the throw statement (C# Language Reference). Additional guidance on handling concurrency with EF Core in Blazor apps is provided by the Blazor documentation.

> ⚠ **Warning**
>
> Although it isn't a concern for the app in this tutorial, binding form data to entity data models can be susceptible to overposting attacks. Additional information on this subject appears in the next section.

Mitigate overposting attacks

Statically-rendered server-side forms, such as those in the `Create` and `Edit` components, can be vulnerable to an *overposting* attack, also known as a *mass assignment* attack. An overposting attack occurs when a malicious user issues an HTML form POST to the server that processes data for properties that aren't part of the rendered form and that the developer doesn't wish to allow users to modify. The term "overposting" literally means that the malicious user has *over*-POSTed with the form.

In the example `Create` and `Edit` components of this tutorial, the `Movie` model doesn't include restricted properties for create and update operations, so overposting isn't a concern. However, it's important to keep overposting in mind when working with static SSR-based Blazor forms that you create and modify in the future.

To mitigate overposting, we recommend using a separate view model/data transfer object (DTO) for the form and database with create (insert) and update operations.

When the form is submitted, only properties of the view model/DTO are used by the component and C# code to modify the database. Any extra data included by a malicious user is discarded, so the malicious user is prevented from conducting an overposting attack.

Troubleshoot with the completed sample

If you run into a problem while following the tutorial that you can't resolve from the text, compare your code to the completed project in the Blazor samples repository:

Blazor samples GitHub repository (dotnet/blazor-samples)

Select the latest version folder. The sample folder for this tutorial's project is named `BlazorWebAppMovies`.

Build a Blazor movie database app (Part 4 - Work with a database)

Article • 10/08/2024

This article is the fourth part of the Blazor movie database app tutorial that teaches you the basics of building an ASP.NET Core Blazor Web App with features to manage a movie database.

This part of the tutorial series focuses on the database context and directly working with the database's schema and data. Seeding the database with data is also covered.

Secure authentication flow required for production apps

This tutorial uses a local database that doesn't require user authentication. Production apps should use the most secure authentication flow available. For more information on authentication for deployed test and production Blazor Web Apps, see the following resources:

- ASP.NET Core Blazor authentication and authorization
- Secure ASP.NET Core server-side Blazor apps and the following articles in the *Server* security node
- Secure an ASP.NET Core Blazor Web App with OpenID Connect (OIDC)

For Microsoft Azure services, we recommend using *managed identities*. Managed identities securely authenticate to Azure services without storing credentials in app code. For more information, see the following resources:

- What are managed identities for Azure resources? (Microsoft Entra documentation)
- Azure services documentation
  - Managed identities in Microsoft Entra for Azure SQL
  - How to use managed identities for App Service and Azure Functions

Database context

The database context, `BlazorWebAppMoviesContext`, connects to the database and maps model objects to database records. The database context was created in the second part of this series. The scaffolded database context code appears in the `Program` file:

C#

```
builder.Services.AddDbContextFactory<BlazorWebAppMoviesContext>(options =>
    options.UseSqlServer(

builder.Configuration.GetConnectionString("BlazorWebAppMoviesContext") ??
        throw new InvalidOperationException(
            "Connection string 'BlazorWebAppMoviesContext' not found.")));
```

AddDbContextFactory registers a factory for the given context as a service in the app's service collection.

UseSqlServer or UseSqlite configures the context to connect to either a Microsoft SQL Server or SQLite database. Other providers are available to connect to additional types of databases.

GetConnectionString uses the ASP.NET Core Configuration system to read the `ConnectionStrings` key for the connection string name provided, which in the preceding example is `BlazorWebAppMoviesContext`.

For local development, configuration obtains the database connection string from the app settings file (`appsettings.json`). The `{CONNECTION STRING}` placeholder in the following example is the connection string:

JSON

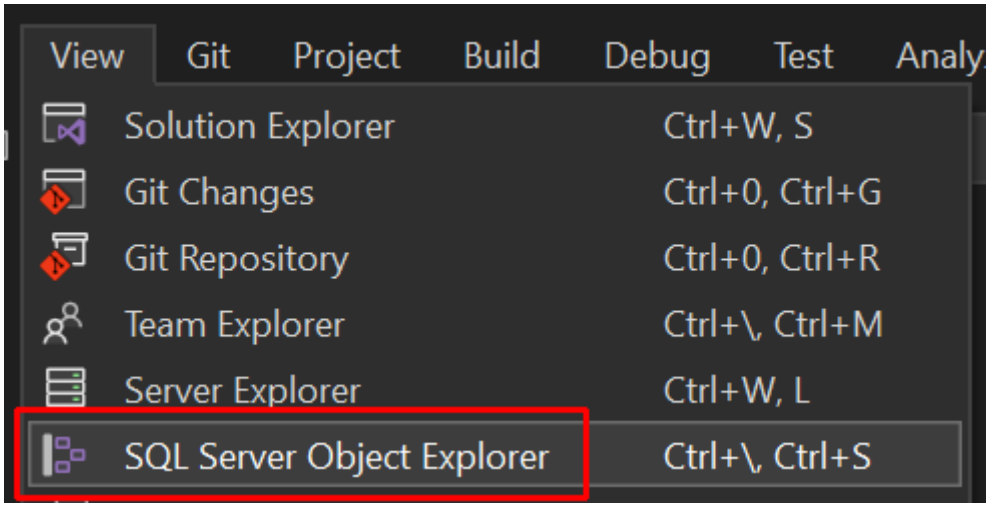
```
"ConnectionStrings": {
  "BlazorWebAppMoviesContext": "{CONNECTION STRING}"
}
```

The following is an example connection string:

> Server=(localdb)\mssqllocaldb;Database=BlazorWebAppMoviesContext-00001111-aaaa-2222-bbbb-3333cccc4444;Trusted_Connection=True;MultipleActiveResultSets=true

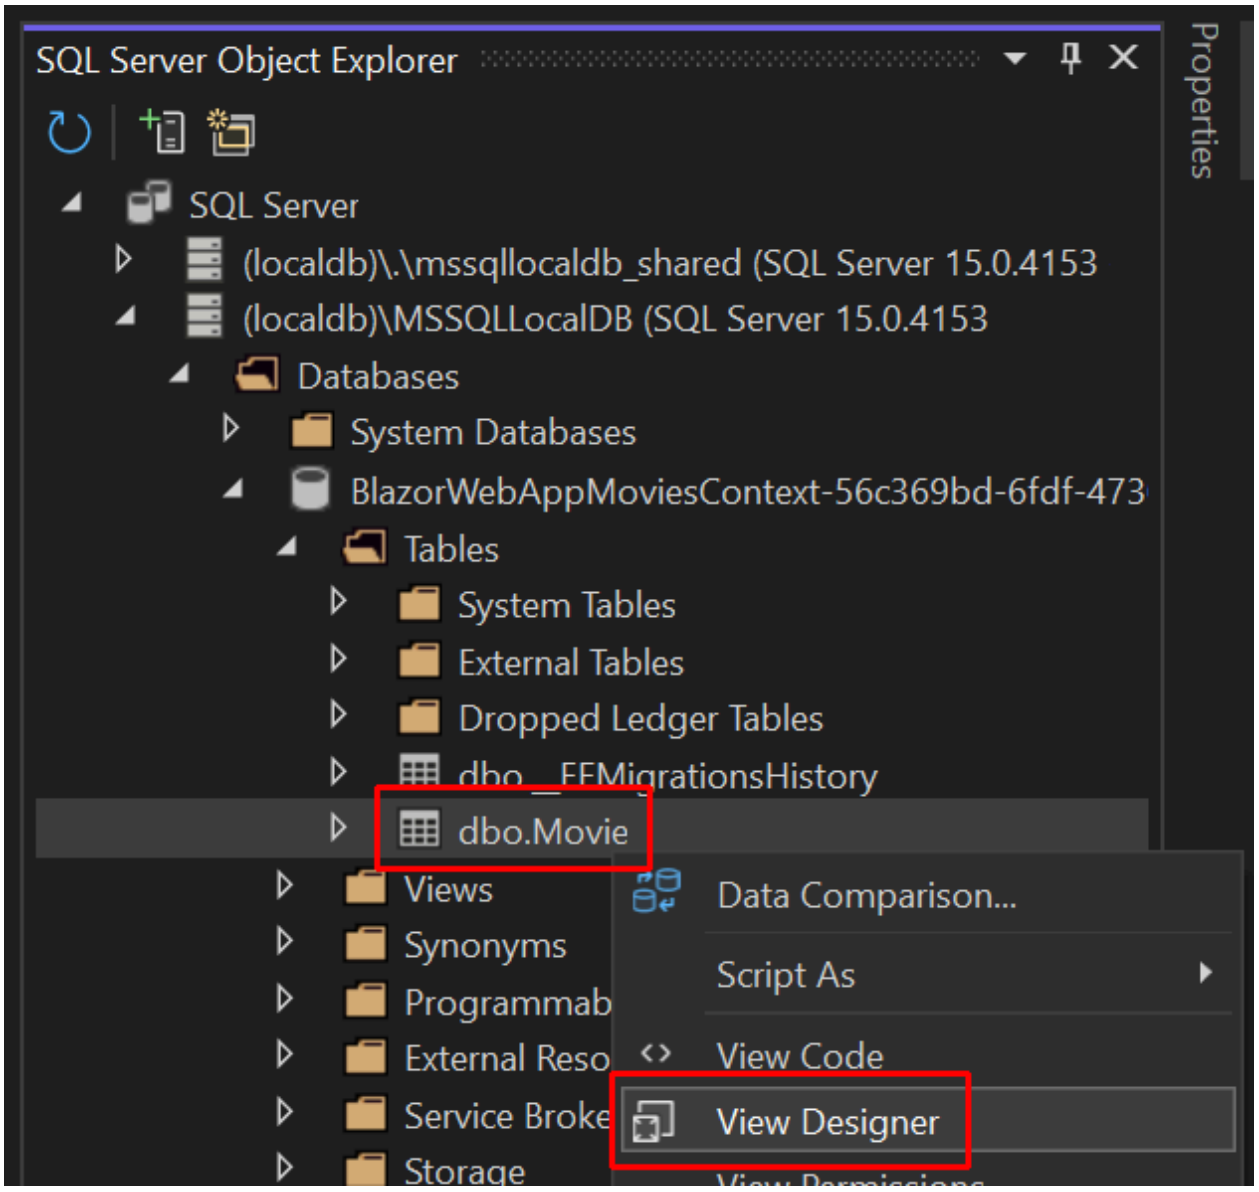
When the app is deployed to a test/staging or production server, securely store the connection string outside of the project's configuration files.

> **⚠ Warning**
>
> Don't store app secrets, connection strings, credentials, passwords, personal identification numbers (PINs), private C#/.NET code, or private keys/tokens in client-side code, which is ***always insecure***. In test/staging and production



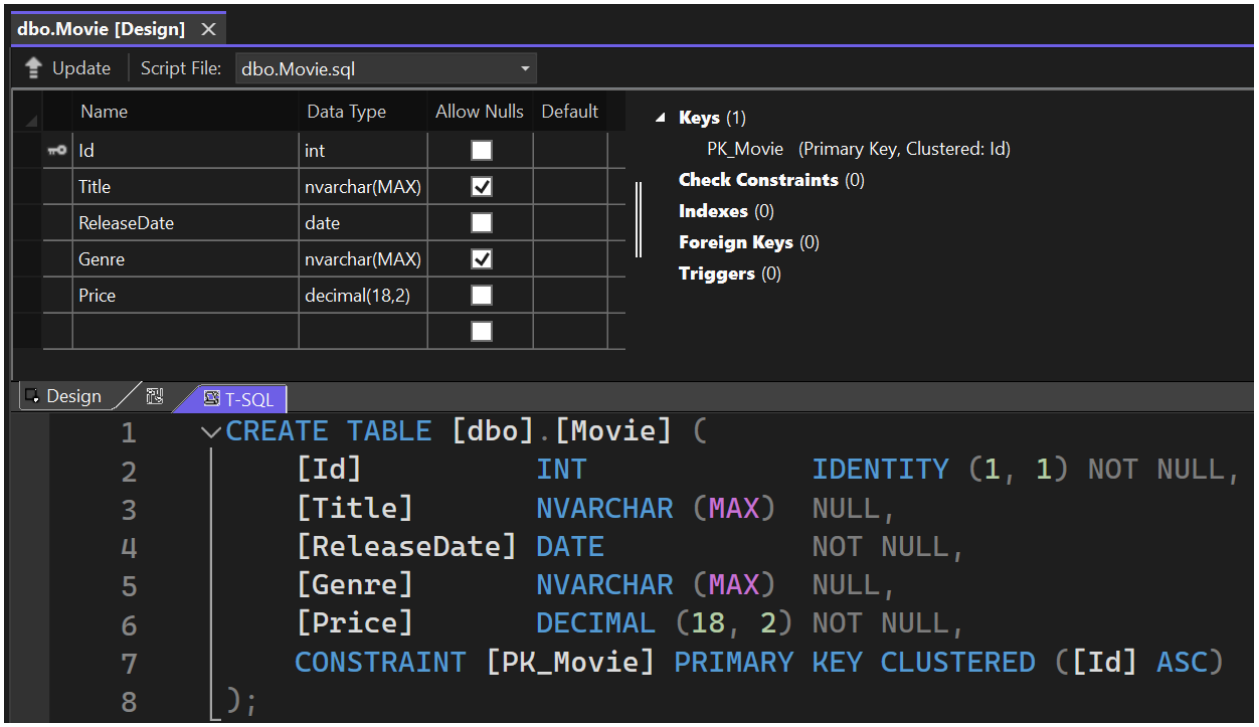
environments, server-side Blazor code and web APIs should use secure authentication flows that avoid maintaining credentials within project code or configuration files. Outside of local development testing, we recommend avoiding the use of environment variables to store sensitive data, as environment variables aren't the most secure approach. For local development testing, the Secret Manager tool is recommended for securing sensitive data. For more information, see Securely maintain sensitive data and credentials.

Database technology



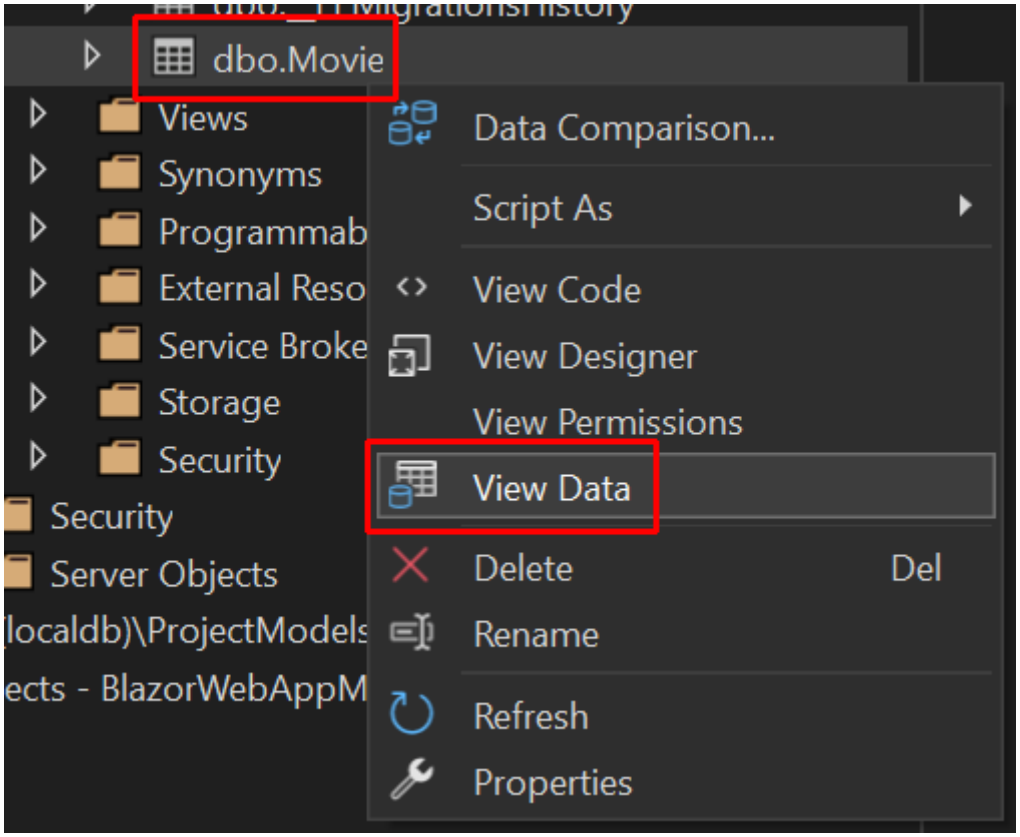
The Visual Studio version of this tutorial uses SQL Server.

SQL Server Express LocalDB is a lightweight version of the SQL Server Express database engine that's targeted for program development. LocalDB starts on demand and runs in user mode, so there's no complex configuration. Master database files (`*.mdf`) are placed in the `C:/Users/{USER}` directory, where the `{USER}` placeholder is the system's user ID.

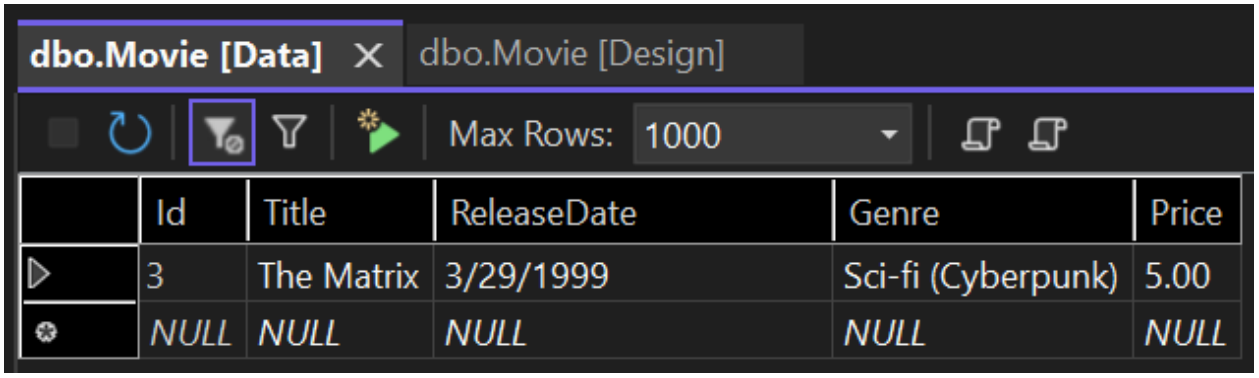


From the **View** menu, open **SQL Server Object Explorer** (SSOX).

Right-click on the `Movie` table and select **View Designer**:



The **View Designer** opens:



Note the key icon next to `ID`. EF creates a property named `ID` for the primary key.

Right-click on the `Movie` table and select **View Data**:

The table's data opens in a new tab in Visual Studio:

Seed the database

Seeding code can create a set of records for development testing or even be used to create the initial data for a new production database.

Create a new class named `SeedData` in the `Data` folder with the following code.

`Data/SeedData.cs`:

```
C#
```

```
using Microsoft.EntityFrameworkCore;
using BlazorWebAppMovies.Models;

namespace BlazorWebAppMovies.Data;

public class SeedData
{
    public static void Initialize(IServiceProvider serviceProvider)
    {
        using var context = new BlazorWebAppMoviesContext(
            serviceProvider.GetRequiredService<
                DbContextOptions<BlazorWebAppMoviesContext>>());

        if (context == null || context.Movie == null)
        {
            throw new NullReferenceException(
                "Null BlazorWebAppMoviesContext or Movie DbSet");
        }

        if (context.Movie.Any())
        {
            return;
        }

        context.Movie.AddRange(
            new Movie
            {
                Title = "Mad Max",
                ReleaseDate = new DateOnly(1979, 4, 12),
                Genre = "Sci-fi (Cyberpunk)",
                Price = 2.51M,
            },
            new Movie
            {
                Title = "The Road Warrior",
                ReleaseDate = new DateOnly(1981, 12, 24),
                Genre = "Sci-fi (Cyberpunk)",
                Price = 2.78M,
            },
            new Movie
            {
                Title = "Mad Max: Beyond Thunderdome",
                ReleaseDate = new DateOnly(1985, 7, 10),
                Genre = "Sci-fi (Cyberpunk)",
                Price = 3.55M,
            },
            new Movie
            {
                Title = "Mad Max: Fury Road",
                ReleaseDate = new DateOnly(2015, 5, 15),
                Genre = "Sci-fi (Cyberpunk)",
                Price = 8.43M,
            },
            new Movie
```

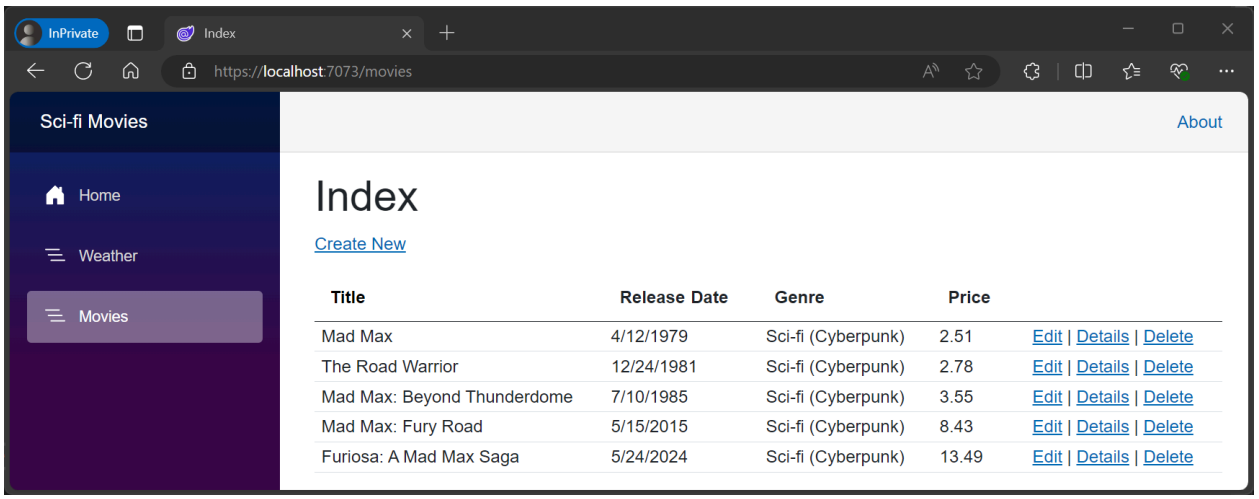
```
            {
                Title = "Furiosa: A Mad Max Saga",
                ReleaseDate = new DateOnly(2024, 5, 24),
                Genre = "Sci-fi (Cyberpunk)",
                Price = 13.49M,
            });

        context.SaveChanges();
    }
}
```

A database context instance is obtained from the dependency injection (DI) container. If movies are present, `return` is called to avoid seeding the database. When the database is empty, the *Mad Max* franchise (©Warner Bros. Entertainment) movies are seeded.

To execute the seed initializer, add the following code to the `Program` file immediately after the line that builds the app (`var app = builder.Build();`). The using statement ensures that the database context is disposed after the seeding operation completes.

C#



```
using (var scope = app.Services.CreateScope())
{
    var services = scope.ServiceProvider;

    SeedData.Initialize(services);
}
```

If the database contains records from earlier testing, run the app and delete the entities that you created in the database. Stop the app by closing the browser's window.

When the database is empty, run the app.

Navigate to the movies `Index` page to see the seeded movies:

Bind a form to a model

Review the the `Edit` component (`Components/Pages/MoviePages/Edit.razor`).

When an HTTP GET request is made for the `Edit` component page (for example at the relative URL: `/movies/edit?id=6`):

- The OnInitializedAsync method fetches the movie with an `Id` of `6` from the database and assigns it to the `Movie` property.
- The EditForm.Model parameter specifies the top-level model object for the form. An edit context is constructed for the form using the assigned model.
- The form is displayed with the values from the movie.

When the `Edit` page is posted to the server, the form values on the page are bound to the `Movie` property because the [SupplyParameterFromForm] attribute is annotated on the `Movie` property:

C#

```
[SupplyParameterFromForm]
private Movie? Movie { get; set; }
```

If the model state has errors when the form is posted, for example if `ReleaseDate` can't be converted into a date, the form is redisplayed with the submitted values. If no model errors exist, the movie is saved using the form's posted values.

Concurrency exception handling

Review the `UpdateMovie` method of the `Edit` component (`Components/Pages/MoviePages/Edit.razor`):

C#

```
private async Task UpdateMovie()
{
    using var context = DbFactory.CreateDbContext();
    context.Attach(Movie!).State = EntityState.Modified;

    try
    {
        await context.SaveChangesAsync();
    }
    catch (DbUpdateConcurrencyException)
    {
        if (!MovieExists(Movie!.Id))
```

```
            {
                NavigationManager.NavigateTo("notfound");
            }
            else
            {
                throw;
            }
        }

        NavigationManager.NavigateTo("/movies");
    }
```

Concurrency exceptions are detected when one client deletes the movie and a different client posts changes to the movie.

To test how concurrency is handled by the preceding code:

1. Select **Edit** for a movie, make changes, but don't select **Save**.
2. In a different browser window, open the app to the movie `Index` page and select the **Delete** link for the same movie to delete the movie.
3. In the previous browser window, post changes to the movie by selecting the **Save** button.
4. The browser is navigated to the `notfound` endpoint, which doesn't exist and yields a 404 (Not Found) result.

Additional guidance on handling concurrency with EF Core in Blazor apps is available in the Blazor documentation.

Stop the app

If the app is running, shut the app down by closing the browser's window.

Troubleshoot with the completed sample

If you run into a problem while following the tutorial that you can't resolve from the text, compare your code to the completed project in the Blazor samples repository:

Blazor samples GitHub repository (dotnet/blazor-samples)

Select the latest version folder. The sample folder for this tutorial's project is named `BlazorWebAppMovies`.

Previous: Learn about Razor components | Next: Add Validation

Build a Blazor movie database app (Part 5 - Add validation)

Article • 08/26/2024

This article is the fifth part of the Blazor movie database app tutorial that teaches you the basics of building an ASP.NET Core Blazor Web App with features to manage a movie database.

This part of the tutorial series explains how metadata of the `Movie` model is used to validate user input in the forms that create and edit movies.

Validation using data annotations

Validation rules are specified on a model class using *data annotations*. The following list shows some of the System.ComponentModel.DataAnnotations attributes for user input validation of public properties in a form's model:

- [Required]: Require that the user provide a value.
- [StringLength]: Specifies the minimum and maximum length of characters. Note that a `MinimumLength` passed to the attribute doesn't make the string required (apply the [Required] attribute).
- [RegularExpression]: Specify a pattern to match for the user's input.
- [Range]: Specify the minimum and maximum values.

Value types, such as `decimal`, `int`, `float`, `DateOnly`, `TimeOnly`, and `DateTime`, are inherently required. Placing a [Required] attribute on value types isn't necessary.

Additional data annotations that you can use in your forms are covered by the Blazor reference documentation.

Add validation to the `Movie` model

Add the following data annotations to the `Movie` class properties. To update all of the properties at once, you can copy and paste the entire `Models/Movie.cs` file, which appears after the following code example.

diff

```
+ [Required]
+ [StringLength(60, MinimumLength = 3)]
```

```
  public string? Title { get; set; }

+ [Required]
* [StringLength(30)]
+ [RegularExpression(@"^[A-Z]+[a-zA-Z()\s-]*$")]
  public string? Genre { get; set; }

+ [Range(0, 100)]
  [DataType(DataType.Currency)]
  [Column(TypeName = "decimal(18, 2)")]
  public decimal Price { get; set; }
```

`Models/Movie.cs` file after the preceding data annotations are applied to the properties:

C#

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace BlazorWebAppMovies.Models;

public class Movie
{
    public int Id { get; set; }

    [Required]
    [StringLength(60, MinimumLength = 3)]
    public string? Title { get; set; }

    public DateOnly ReleaseDate { get; set; }

    [Required]
    [StringLength(30)]
    [RegularExpression(@"^[A-Z]+[a-zA-Z()\s-]*$")]
    public string? Genre { get; set; }

    [Range(0, 100)]
    [DataType(DataType.Currency)]
    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }
}
```

The preceding validation rules are merely for demonstration and aren't optimal for a production system. For example, the preceding validation prevents entering a movie with only one or two characters and doesn't allow additional special characters for a movie's genre.

Create an EF Core migration and update the database

A data model schema defines how data is organized and connected within a relational database.

Adding the data annotations to the `Movie` class in the preceding section doesn't automatically result in matching changes to the database's schema.

Review the annotations applied to the `Title` property:

C#

```
[Required]
[StringLength(60, MinimumLength = 3)]
public string? Title { get; set; }
```

The difference between the model property and the database's schema are summarized in the following table. Neither constraint matches after the data annotation is applied to the `Movie` model.

Expand table

Constraint	Model `Title` property	Database `Title` column
Maximum length	60 characters	Byte pairs up to ~2 GB† NVARCHAR (MAX)
Required	✔ [Required]	✘ `NULL` is permitted in the column.

†Database character columns are defined by *size* (byte pairs). One byte-pair per character is used for characters defined in the Unicode range 0 to 65,535. However, individual characters outside of that Unicode range take multiple byte-pairs to store, so the actual number of characters that a column can store is arbitrary. The important concept for our purposes in comparing the `Title` property of the `Movie` model and the database schema for the `Title` column is that ~2 GB of stored byte-pairs in the database far exceeds the 60 character limit set for the property. The database schema *should be adjusted downward* to match the app's constraint.

To match the `Movie` model's `Title` property length in the app, the database should indicate `NVARCHAR (60)` for the size of the `Title` column. The schema difference doesn't cause EF Core to throw an exception when the app is used because a user posting a 60

character movie title fits within the database's ~2 GB byte-pair limit for a movie title. However, consider the reverse situation where a model property is given a constraint larger than what the database permits and the user posts a string too long for a database character column: An exception is thrown by the database or data is truncated when the user posts the value. You should always keep the app's models aligned with the database's schema because a misaligned schema can cause exceptions and the storage of incorrect data.

Although the `Title` property is a nullable reference type (NRT), as indicated by the `?` on the `string` type (`string?`), the database shouldn't store a `NULL` value in its `Title` column due to the model's `Required` constraint. When the database's schema is updated in the next step, the database's `Title` column should reflect `NOT NULL` for the `Title` column to match the property. The important concept is that just because a model property is an NRT and can hold a `null` value in code doesn't mean that the database column's schema should be nullable (`NULL` permitted). These are independent conditions used for different purposes: NRTs are used to prevent coding errors with nullable types, while the database schema reflects the exact type and size of stored data.

To align the model and the database schema, create and apply an EF Core *database migration* with a migration name that identifies the migration changes. The migration name is similar to a commit message in a version control system. In the following command examples, the migration name "`NewMovieDataAnnotations`" reflects that new data annotations are added to the `Movie` model.

> **ⓘ Important**
>
> Make sure that the app isn't running for the next steps.
>
> Stopping the app when using Visual Studio only requires you to close the browser's window.
>
> When using VS Code, close the browser's window and stop the app in VS Code with **Run** > **Stop Debugging** or by pressing `Shift`+`F5` on the keyboard.
>
> When using the .NET CLI, close the browser's window and stop the app in the command shell with `Ctrl`+`C` (Windows) or `⌘`+`C` (macOS).

In Visual Studio **Solution Explorer**, double-click **Connected Services**. In the **Service Dependencies** area, select the ellipsis (`...`) followed by **Add migration** in the **SQL Server Express LocalDB** area.

Give the migration a **Migration name** of `NewMovieDataAnnotations` to describe the migration. Wait for the database context to load in the **DbContext class names** field. Select **Finish** to create the migration. Select the **Close** button when the operation completes.

Select the ellipsis (`...`) again followed by the **Update database** command.

The **Update database with the latest migration** dialog opens. Wait for the **DbContext class names** field to update and for prior migrations to load. Select the **Finish** button. Select the **Close** button when the operation completes.

After applying the migration, the model property and the database's schema match, as summarized in the following table.

Expand table

Constraint	**Model `Title` property**	**Database `Title` column**
Maximum length	60 characters	Sixty (60) byte pairs are permitted†. NVARCHAR (60)
Required	✔ [Required]	✔ `NOT NULL` is indicated for the column.

†Sixty (60) byte pairs is 60 characters if one byte-pair per character is used to store the movie title, which is true when using characters defined in the Unicode range 0 to 65,535.

Troubleshoot with the completed sample

If you run into a problem while following the tutorial that you can't resolve from the text, compare your code to the completed project in the Blazor samples repository:

Blazor samples GitHub repository (dotnet/blazor-samples)

Select the latest version folder. The sample folder for this tutorial's project is named `BlazorWebAppMovies`.

Build a Blazor movie database app (Part 6 - Add search)

Article • 08/26/2024

This article is the sixth part of the Blazor movie database app tutorial that teaches you the basics of building an ASP.NET Core Blazor Web App with features to manage a movie database.

This part of the tutorial series covers adding a search feature to the movies `Index` component to filter movies by title.

Implement a filter feature for the `QuickGrid` component

The QuickGrid component is used by the movie `Index` component (`Components/MoviePages/Index.razor`) to display movies from the database:

razor

```
<QuickGrid Class="table" Items="context.Movie">
    ...
</QuickGrid>
```

The Items parameter receives an `IQueryable<TGridItem>`, where `TGridItem` is the type of data represented by each row in the grid (`Movie`). Items is assigned a collection of movie entities (`DbSet<Movie>`) obtained from the created database context (CreateDbContext) of the injected database context factory (`DbFactory`).

To make the `QuickGrid` component filter on the movie title, the `Index` component should:

- Set a filter string as a *component parameter* from the query string.
- If the parameter has a value, filter the movies returned from the database.
- Provide an input for the user to provide the filter string and a button to trigger a reload using the filter.

Start by adding the following code to the `@code` block of the `Index` component (`MoviePages/Index.razor`):

C#

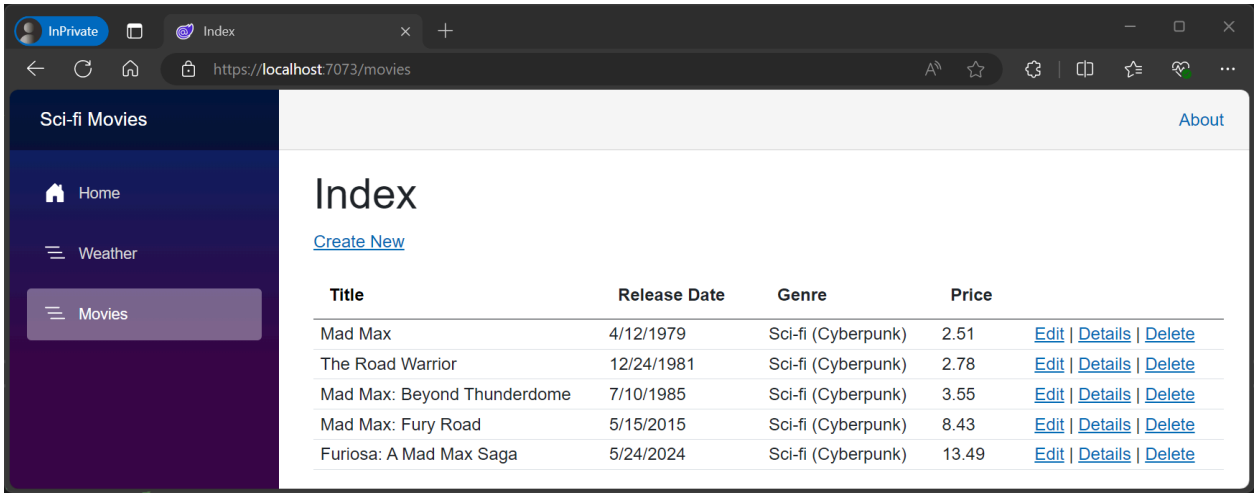
```
[SupplyParameterFromQuery]
private string? TitleFilter { get; set; }

private IQueryable<Movie> FilteredMovies =>
    context.Movie.Where(m => m.Title!.Contains(TitleFilter ??
string.Empty));
```

`TitleFilter` is the filter string. The property is provided the [SupplyParameterFromQuery] attribute, which lets Blazor know that the value of `TitleFilter` should be assigned from the query string when the query string contains a field of the same name (for example, `?titleFilter=road+warrior` yields a `TitleFilter` value of `road warrior`). Note that query string field names, such as `titleFilter`, aren't case sensitive.

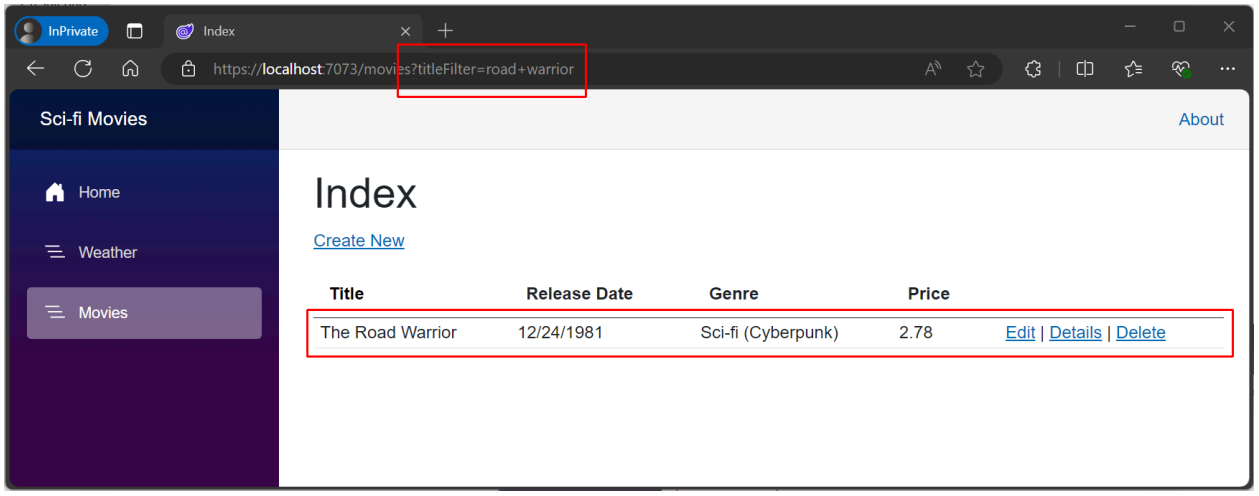
The `FilteredMovies` property is an `IQueryable<Movie>`, which is the type for assignment to the `QuickGrid`'s Items parameter. The property filters the list of movies based on the supplied `TitleFilter`. If a `TitleFilter` isn't assigned a value from the query string (`TitleFilter` is `null`), an empty string (`string.Empty`) is used for the Contains clause. Therefore, no movies are filtered for display.

Change the `QuickGrid` component's Items parameter to use the `movies` collection:



diff

```
- <QuickGrid Class="table" Items="context.Movie">
+ <QuickGrid Class="table" Items="FilteredMovies">
```



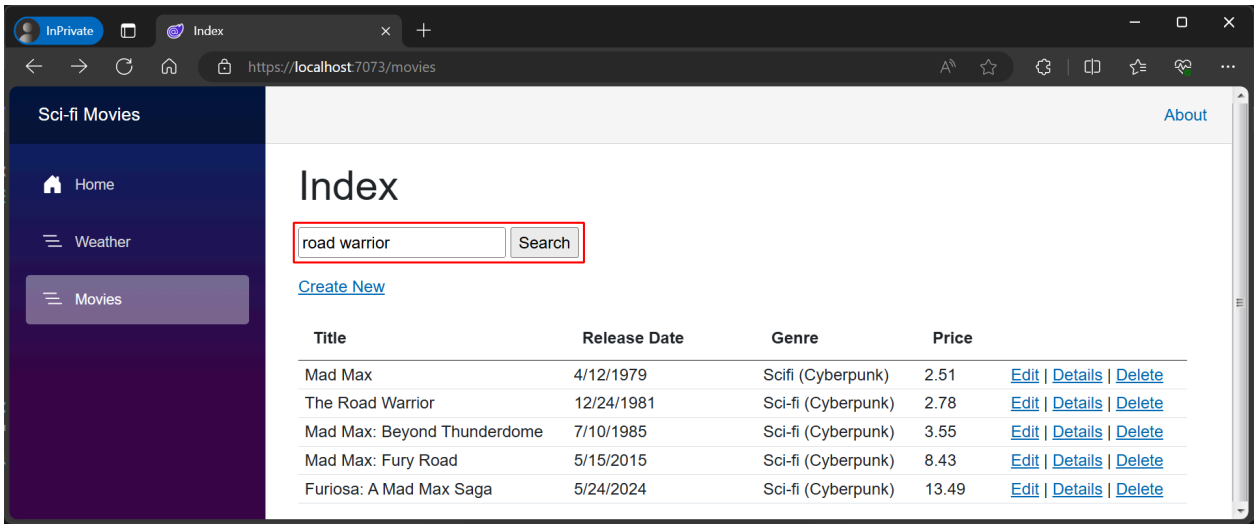
The `movie => movie.Title!.Contains(...)` code is a *lambda expression*. Lambdas are used in method-based LINQ queries as arguments to standard query operator methods such as the Where or Contains methods. LINQ queries aren't executed when they're defined or when they're modified by calling a method, such as Where, Contains, or OrderBy. Rather, query execution is deferred. The evaluation of an expression is delayed until its realized value is iterated.

The Contains method is run on the database, not in the C# code. The case sensitivity of the query depends on the database and the collation. For SQL Server, Contains maps to SQL LIKE, which is case insensitive. SQLite with default collation provides a mixture of case sensitive and case insensitive filtering, depending on the query. For information on making case insensitive SQLite queries, see the Additional resources section of this article.

Run the app and navigate to the movies `Index` page at `/movies`. The movies in the database load:

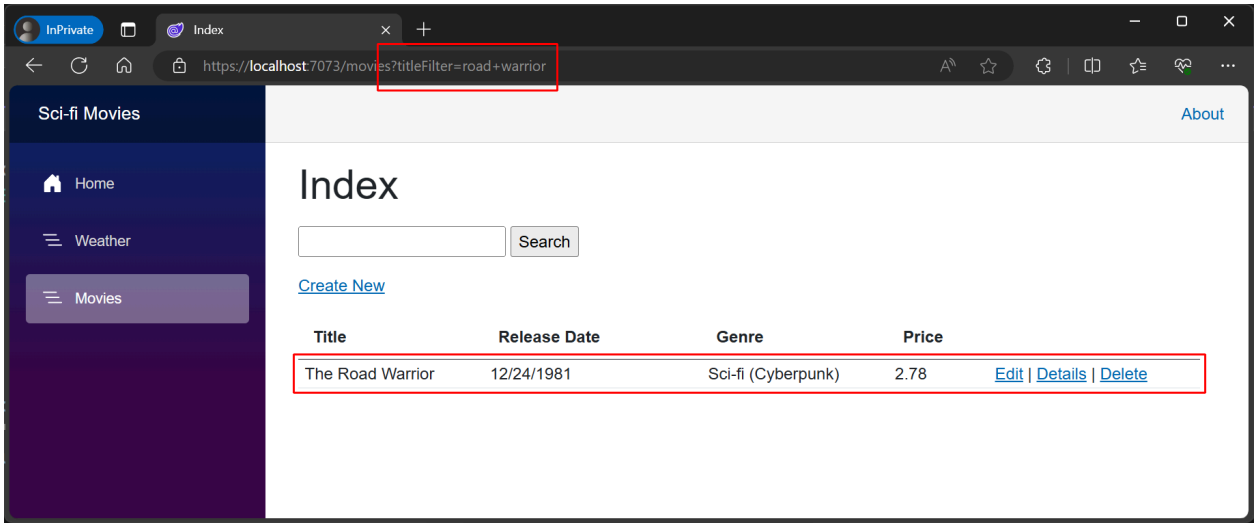
Append a query string to the URL in the address bar: `?titleFilter=road+warrior`. For example, the full URL appears as `https://localhost:7073/movies?titleFilter=road+warrior`, assuming the port number is `7073`. The filtered movie is displayed:

Next, give users a way to provide the `titleFilter` filter string via the component's UI. Add the following HTML under the H1 heading (`<h1>Index</h1>`). The following HTML reloads the page with the contents of the textbox as a query string value:



HTML

```
<p>
    <form action="/movies" data-enhance>
        <input type="search" name="titleFilter" />
        <input type="submit" value="Search" />
    </form>
</p>
```



The `data-enhance` attribute applies *enhanced navigation* to the component, where Blazor intercepts the GET request and performs a fetch request instead. Blazor then patches the response content into the page, which avoids a full-page reload and preserves more of the page state. The page loads faster, usually without losing the user's scroll position.

Save the file that you're working on. Apply the change by either restarting the app or using Hot Reload to apply the change to the running app.

Type "`road warrior`" into the search box and select the **Search** button to filter the movies:

The result after searching on `road warrior`:

Notice that the search box loses the search value ("`road warrior`") when the movies are filtered. If you want to preserve the searched value, add the `data-permanent` attribute:

diff

```
- <form action="/movies" data-enhance>
```

```
+ <form action="/movies" data-enhance data-permanent>
```

Stop the app

Stop the app by closing the browser's window.

Troubleshoot with the completed sample

If you run into a problem while following the tutorial that you can't resolve from the text, compare your code to the completed project in the Blazor samples repository:

Blazor samples GitHub repository (dotnet/blazor-samples)

Select the latest version folder. The sample folder for this tutorial's project is named `BlazorWebAppMovies`.

Previous: Add validation | Next: Add a new field

Build a Blazor movie database app (Part 7 - Add a new field)

Article • 08/26/2024

This article is the seventh part of the Blazor movie database app tutorial that teaches you the basics of building an ASP.NET Core Blazor Web App with features to manage a movie database.

This part of the tutorial series covers adding a new field to the movie class, CRUD pages, and database.

The database update is handled by EF Core migrations. EF Core transparently tracks changes to the database in a migration history table and automatically throws an exception if the app's model classes aren't synchronized with the database's tables and columns. EF Core migrations make it possible to quickly troubleshoot database consistency problems.

> **ⓘ Important**
>
> Confirm that the app isn't running for the next steps.

Add a movie rating to the app's model

Open the `Models/Movie.cs` file and add a `Rating` property with a regular expression that limits the value of `Rating` to the exact Motion Picture Association film rating designations:

C#

```
[Required]
[RegularExpression(@"^(G|PG|PG-13|R|NC-17)$")]
public string? Rating { get; set; }
```

Add the movie rating to the app's CRUD components

Open the `Create` component definition file (`Components/Pages/MoviePages/Create.razor`).

Add the following `<div>` block between the `<div>` block for `Price` and the create button (`<button>`):

razor

```
<div class="mb-3">
    <label for="rating" class="form-label">Rating:</label>
    <InputText id="rating" @bind-Value="Movie.Rating" class="form-control"
/>
    <ValidationMessage For="() => Movie.Rating" class="text-danger" />
</div>
```

Open the `Delete` component definition file (`Components/Pages/MoviePages/Delete.razor`).

Add the following description list (`<dl>`) block between the description list block for `Price` and the `EditForm` component:

razor

```
<dl class="row">
    <dt class="col-sm-2">Rating</dt>
    <dd class="col-sm-10">@movie.Rating</dd>
</dl>
```

Open the `Details` component definition file (`Components/Pages/MoviePages/Details.razor`).

Add the following description list term (`<dt>`) and description list element (`<dl>`) after the term and element for `Price` just inside the closing `</dl>` tag:

razor

```
<dt class="col-sm-2">Rating</dt>
<dd class="col-sm-10">@movie.Rating</dd>
```

Open the `Edit` component definition file (`Components/Pages/MoviePages/Edit.razor`).

Add the following `<div>` block between the `<div>` block for `Price` and the save button (`<button>`):

razor

```
<div class="mb-3">
    <label for="rating" class="form-label">Rating:</label>
```

```
    <InputText id="rating" @bind-Value="Movie.Rating" class="form-control"
/>
    <ValidationMessage For="() => Movie.Rating" class="text-danger" />
</div>
```

Open the `Index` component definition file (`Components/Pages/MoviePages/Index.razor`).

Update the `QuickGrid` component to include the movie rating. Add the following PropertyColumn<TGridItem,TProp> immediately after the column for `Price`:

razor

```
<PropertyColumn Property="movie => movie.Rating" />
```

Update the `SeedData` class (`Data/SeedData.cs`) to provide a default value for the new `Rating` property for reseeding operations.

The following change is for the *Mad Max* `new Movie` block. `Rating = "R",` is added to the block:

diff

```
new Movie
{
    Title = "Mad Max",
    ReleaseDate = DateOnly.Parse("1979-4-12"),
    Genre = "Sci-fi (Cyberpunk)",
    Price = 2.51M,
+   Rating = "R",
},
```

Add the `Rating` property to each of the other `new Movie` blocks in the same fashion. Here are the ratings of the remaining *Mad Max* movies when you add the new `Rating` lines:

- *The Road Warrior*: R
- *Mad Max: Beyond Thunderdome*: PG-13
- *Mad Max: Fury Road*: R
- *Furiosa: A Mad Max Saga*: R

Save all of the updated files.

Don't run the app yet. Build the app to confirm that there are no errors.

Select **Build** > **Rebuild Solution** from the menu bar.

Fix any errors in the app that were introduced by pasting the preceding markup and code before proceeding to the next step.

Update the database

If you were to try and run the app at this point, the app would fail with a SQL exception because the database doesn't include a `Rating` column in its `Movie` table. There are three approaches that you can take to resolve the discrepancy between the database's schema and the model's schema:

- Modify the schema of the database so that it matches the model class. The advantage of this approach is that it maintains the database's data. Adopt this approach using either database tooling or by creating a database change script, which are approaches not covered by this tutorial but can be learned using other articles. The downside to this approach is that it requires more time and is more prone to errors due to its increased complexity. *This tutorial doesn't adopt this approach.*
- Use EF Core to automatically drop and recreate the database using the new model class schema, losing the data stored in the database in the process. The database is reseeded with fresh data when the app is run. This approach allows you to quickly evolve the model and database schema together. Don't use this approach on a production database with data that must be preserved. *This tutorial doesn't adopt this approach.*
- Use an EF Core migration to update the database schema after the model is changed in the app. This approach is efficient and preserves the database's data. ***This tutorial adopts this approach.***

Create a migration to update the database's schema. The movie rating, as a `Rating` column, is added to the database's `Movie` table.

In Visual Studio **Solution Explorer**, double-click **Connected Services**. In the **SQL Server Express LocalDB** area of **Service Dependencies**, select the ellipsis (`...`) followed by **Add migration**.

Give the migration a **Migration name** of `AddRatingField` to describe the migration. Wait for the database context to load in the **DbContext class names** field. Select **Finish** to create the migration. Select **Close** when the operation is complete.

The migration:

- Compares the `Movie` model with the `Movie` database table schema.
- Creates code to migrate the database schema to match the model.

Creating the migration doesn't automatically provision a default value for the rating when the database is updated. However, you can manually make a change to the migration file to apply a default movie rating value, which can be helpful when there are many records that require a default value. In this case, all but one of the *Mad Max* movies is rated *R*, so a default value of "`R`" for the `Rating` column is an appropriate choice. The one movie that doesn't have an *R* rating can be updated later in the running app.

Examine the files in the `Migrations` folder of the project in Visual Studio's **Solution Explorer**. Open the migration file that adds the movie rating field, which has a file name of `{TIME STAMP}_AddRatingField.cs`, where the `{TIME STAMP}` placeholder is a time stamp (for example, `20240530123755_AddRatingField.cs`).

Find the `AddColumn` block that adds the rating column to the `Movie` table in the database. Modify the last line that applies a default value (`defaultValue`). Change it from an empty string (`""`) to an *R* movie rating (`"R"`):

diff

```
migrationBuilder.AddColumn<string>(
    name: "Rating",
    table: "Movie",
    type: "nvarchar(max)",
    nullable: false,
-   defaultValue: "");
+   defaultValue: "R");
```

Save the migration file.

In the **SQL Server Express LocalDB** area of **Service Dependencies**, select the ellipsis (`...`) again followed by the **Update database** command.

The **Update database with the latest migration** dialog opens. Wait for the **DbContext class names** field to update and for prior migrations to load. Select the **Finish** button. Select the **Close** button when the operation completes.

Modify the one movie that isn't rated *R*:

1. Run the app.
2. Edit the *Mad Max: Beyond Thunderdome* movie.
3. Update the movie rating from `R` to `PG-13`. Save the change.

> ⓘ **Note**

An alternative to modifying the migration file is to delete the records in the database and rerun the app to reseed the database. The seeding code was modified earlier to supply default values. This approach is useful in cases where the assignment of default values to fields is better controlled or faster for you to implement with C# code during seeding. For more information see the Delete all database records and reseed the database section at the end of this article.

Run the app and verify you can create, edit, and display movies with the new movie rating field.

Troubleshoot

In the event that the database becomes corrupted, delete the database and use migrations to recreate the database:

1. Select the database in **SQL Server Object Explorer** (SSOX).
2. Right-click on the database, and select **Delete**. *Make sure that you select the correct database in the list.*
3. Check **Close existing connections**.
4. Select **OK**.
5. In **Solution Explorer**, double-click **Connected Services**. In the **Service Dependencies** area, select the ellipsis (`...`) followed by **Update database** in the **SQL Server Express LocalDB** area. Updating the database executes the existing migrations that recreate the database.

Delete all database records and reseed the database

This section describes an alternative process for updating the database with a default value for a new model property without modifying the migration file. Following the guidance in this section isn't necessary if you followed all of the steps in the Update the database section earlier in this article.

To delete all of the records in the database, use one of the following approaches:

- Run the app and use the delete links in the browser. This approach is reasonably fast when there are only a few records to delete.
- In Visual Studio from **SQL Server Object Explorer** (SSOX), delete the database records. With the database table visible, right-click the table and select **View Data**. When the table opens to show the movie records, select the first record. Hold the

`Shift` key and select the last record to select all of the records in the table. With all of the records selected, press the `Delete` key to delete the records. This approach is reasonably fast when there are many records to delete.

- In Visual Studio from SSOX, right-click the database and select **New Query**. A blank SQL file (`.sql`) opens. Paste the following command into the file: `DELETE FROM dbo.Movie;`. Select the green **Execute** triangle to execute the query or press `Ctrl`+`Shift`+`E` on the keyboard. In the **Message** tab, SSOX reports the number of rows affected, deleted in this case, by the query. You can save the query for later use if you wish. Otherwise, close the file without saving it. This approach is especially useful when the table is large and contains hundreds to thousands of records.

> **⊗ Caution**
>
> Use extreme caution when deleting records from a database. Deleting records is permanent without taking additional data loss mitigation steps. Production databases often provision automatic backup copies of data, either instantaneously as the database is modified or periodically, including with off-site copies and permanent physical storage of data.

After deleting all of the records, run the app. The initializer reseeds the database and includes the correct movie ratings for the `Rating` field based on the seeding code.

Troubleshoot with the completed sample

If you run into a problem while following the tutorial that you can't resolve from the text, compare your code to the completed project in the Blazor samples repository:

Blazor samples GitHub repository (dotnet/blazor-samples)

Select the latest version folder. The sample folder for this tutorial's project is named `BlazorWebAppMovies`.

Previous: Add Search | Next: Add interactivity

Build a Blazor movie database app (Part 8 - Add interactivity)

Article • 08/26/2024

This article is the eighth part of the Blazor movie database app tutorial that teaches you the basics of building an ASP.NET Core Blazor Web App with features to manage a movie database.

Up to this point in the tutorial, the entire app has been *enabled* for interactivity, but the app has only *adopted* interactivity in its `Counter` sample component. This part of the tutorial series explains how to adopt interactivity in the movie `Index` component.

> **ⓘ Important**
>
> Confirm that the app isn't running for the next steps.

Adopt interactivity

Interactivity means that a component has the capacity to process UI events via C# code, such as a button click. The events are either processed on the server by the ASP.NET Core runtime or in the browser on the client by the WebAssembly-based Blazor runtime. This tutorial adopts interactive server-side rendering (interactive SSR), also known generally as Interactive Server (`InteractiveServer`) rendering. Client-side rendering (CSR), which is inherently interactive, is covered in the Blazor reference documentation.

Interactive SSR enables a rich user experience like one would expect from a client app but without the need to create API endpoints to access server resources. UI interactions are handled by the server over a real-time SignalR connection with the browser. Page content for interactive pages is prerendered, where content on the server is initially generated and sent to the client without enabling event handlers for rendered controls. With prerendering, the server outputs the HTML UI of the page as soon as possible in response to the initial request, which makes the app feel more responsive to users.

Review the API in the `Program` file (`Program.cs`) that enables interactive SSR. Razor component services are added to the app to enable Razor components to render statically from the server (AddRazorComponents) and execute code with interactive SSR (AddInteractiveServerComponents):

```
C#
```

```
builder.Services.AddRazorComponents()
    .AddInteractiveServerComponents();
```

MapRazorComponents maps components defined in the root `App` component to the given .NET assembly and renders routable components, and AddInteractiveServerRenderMode configures the app's SignalR hub to support interactive SSR:

C#

```
app.MapRazorComponents<App>()
    .AddInteractiveServerRenderMode();
```

Up to this point in the tutorial series, the calls to AddInteractiveServerComponents and AddInteractiveServerRenderMode weren't required for the movie pages because the app only adopted static SSR features for the movie components. This article explains how to adopt interactive features in the movie `Index` component.

When Blazor sets the type of rendering for a component, the rendering is referred to as the component's *render mode*. The following table shows the available render modes for rendering Razor components in a Blazor Web App.

Expand table

Name	Description	Render location	Interactive
Static Server	Static server-side rendering (static SSR)	Server	✗
Interactive Server	Interactive server-side rendering (interactive SSR) using Blazor Server.	Server	✓
Interactive WebAssembly	Client-side rendering (CSR) using Blazor WebAssembly.	Client	✓
Interactive Auto	Interactive SSR using Blazor Server initially and then CSR on subsequent visits after the Blazor bundle is downloaded.	Server, then client	✓

To apply a render mode to a component, the developer either uses the `@rendermode` directive or directive attribute on the component instance or on the component definition:

- The following example shows how to set the render mode on a component instance with the `@rendermode` directive attribute. The following example uses a hypothetical dialog (`Dialog`) component in a parent chat (`Chat`) component.

  Within the `Components/Pages/Chat.razor` file:

  ```razor
  <Dialog @rendermode="InteractiveServer" />
  ```

- The following example shows how to set the render mode on a component definition with the `@rendermode` directive. The following example shows setting the render mode in a hypothetical sales forecast (`SalesForecast`) component definition file (`.razor`).

  At the top of `Components/Pages/SalesForecast.razor` file:

  ```razor
  @page "/sales-forecast"
  @rendermode InteractiveServer
  ```

Using the preceding approaches, you can apply a render mode on a per-page/component basis. However, an entire app can adopt a single render mode via a root component that then by inheritance sets the render mode of every other component loaded. This is termed *global interactivity*, as opposed to *per-page/component interactivity*. Global interactivity is useful if most of the app requires interactive features. Global interactivity is usually applied via the `App` component, which is the root component of an app created from the Blazor Web App project template.

> **Note**
>
> More information on render modes and global interactivity is provided by Blazor's reference documentation. For the purposes of this tutorial, the app only adopts interactive SSR on a per-page/component basis. After the tutorial, you're free to use this app to study the other component render modes and the global interactivity location.

Open the movie `Index` component file (`Components/Pages/MoviePages/Index.razor`), and add the following `@rendermode` directive immediately after the `@page` directive to make the component interactive:

diff

```
@rendermode InteractiveServer
```

To see how making a component interactive enhances the user experience, let's provide three enhancements to the app in the following sections:

- Add pagination to the movie `QuickGrid` component.
- Make the `QuickGrid` component *sortable*.
- Replace the HTML form for filtering movies by title with C# code that:
  - Runs on the server.
  - Renders content interactively over the underlying SignalR connection.

Add pagination to the `QuickGrid`

The `QuickGrid` component can page data from the database.

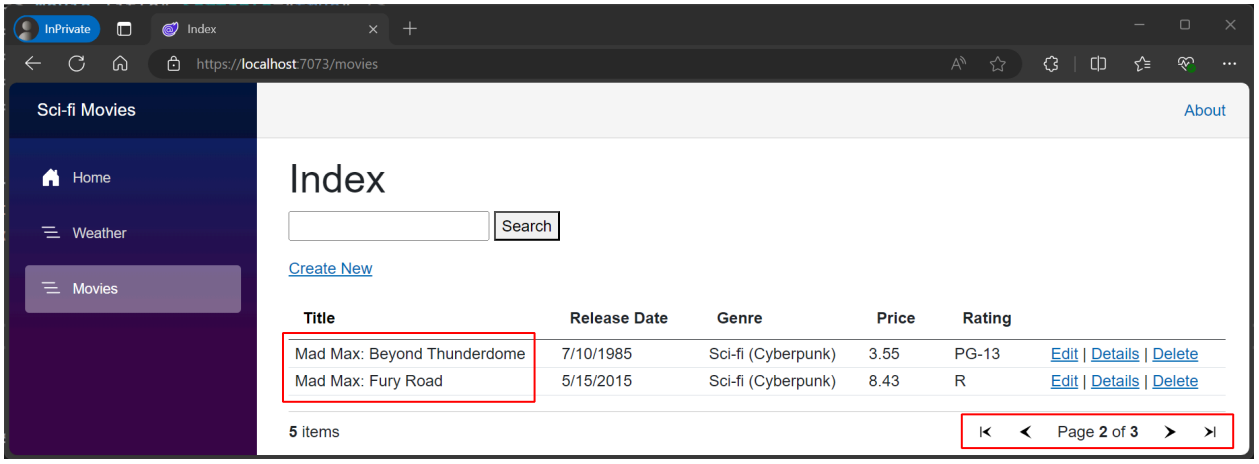
Open the `Index` component (`Components/Pages/Movies/Index.razor`). Add a PaginationState instance to the `@code` block. Because the tutorial only uses five movie records for demonstration, set the ItemsPerPage to `2` items in order to demonstrate pagination. Normally, the number of items to display would be set to a higher value or set dynamically via a dropdown list.

C#

```
private PaginationState pagination = new PaginationState { ItemsPerPage = 2
};
```

Set the `QuickGrid` component's Pagination property to `pagination`:

diff



```
- <QuickGrid Class="table" Items="FilteredMovies">
+ <QuickGrid Class="table" Items="FilteredMovies" Pagination="pagination">
```

To provide a UI for pagination below the `QuickGrid` component, add a Paginator component below the `QuickGrid` component. Set the Paginator.State to `pagination`:

razor

```
<Paginator State="pagination" />
```

Run the app and navigate to the movies `Index` page. You can page through the movie items at two movies per page:

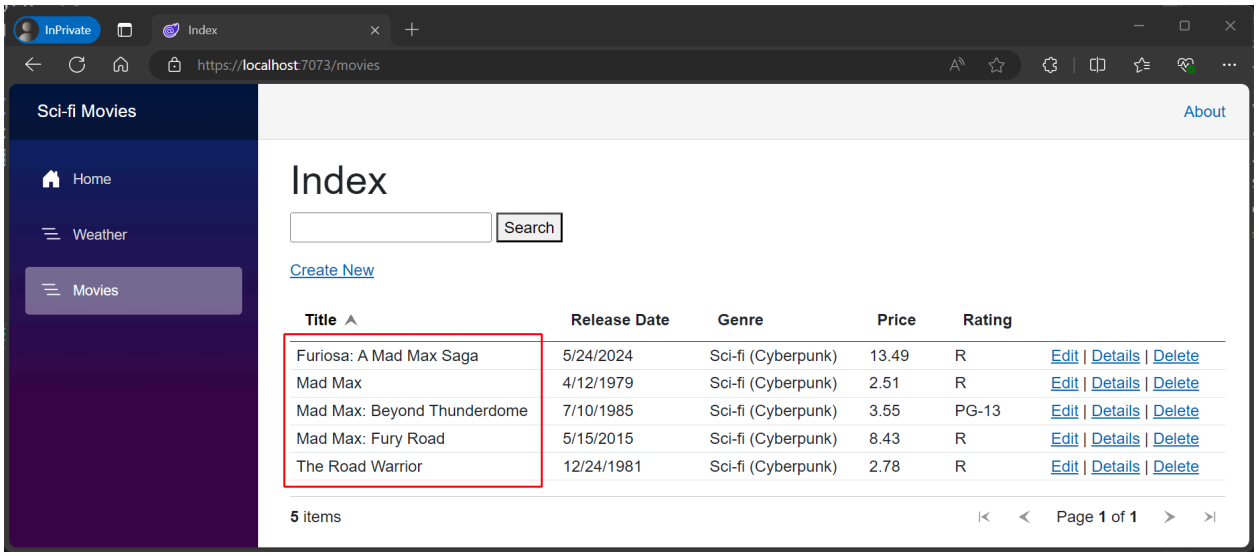
The component is *interactive*. The page doesn't reload for paging to occur. The paging is performed live over the SignalR connection between the browser and the server, where the paging operation is performed on the server with the rendered result sent back to the client for the browser to display.

Change ItemsPerPage to a more reasonable value, such as 10 items per page:

diff

```
- private PaginationState pagination = new PaginationState { ItemsPerPage =
2 };
+ private PaginationState pagination = new PaginationState { ItemsPerPage =
10 };
```

Sortable `QuickGrid`



Open the `Index` component (`Components/Pages/Movies/Index.razor`).

Add `Sortable="true"` (Sortable) to the title PropertyColumn<TGridItem,TProp>:

diff

```
- <PropertyColumn Property="movie => movie.Title" />
+ <PropertyColumn Property="movie => movie.Title" Sortable="true" />
```

You can sort the `QuickGrid` by movie title by selecting the **Title** column. The page doesn't reload for sorting to occur. The sorting is performed live over the SignalR connection, where the sorting operation is performed on the server with the rendered result sent back to the client:

Use C# code and interactivity to search by title

In an earlier part of the tutorial series, the `Index` component was modified to allow the user to filter movies by title. This was accomplished by:

- Adding an HTML form that issues a GET request to the server with the user's title search string as a query string field-value pair (for example, `?titleFilter=road+warrior` if the user searches for "`road warrior`").
- Adding code to the component that obtains the title search string from the query string and uses it to filter the database's records.

The preceding approach is effective for a component that adopts static SSR, where the only interaction between the client and server is via HTTP requests. There was no live SignalR connection between the client and the server, and there was no way for the app on the server to process C# code *interactively* based on the user's actions in the component's UI and return content.

Now that the component is interactive, it can provide an improved user experience with Blazor features for binding and event handling.

Add a delegate event handler that the user can trigger to filter the database's movie records. The method uses the value of the `TitleFilter` property to perform the operation. If the user clears `TitleFilter` and searches, the method loads the entire movie list for display.

Delete the following lines from the `@code` block:

diff

```
- [SupplyParameterFromQuery]
- private string? TitleFilter { get; set; }
```

```
- private IQueryable<Movie> FilteredMovies =>
-     context.Movie.Where(m => m.Title!.Contains(TitleFilter ??
string.Empty));
```

Replace the deleted code with the following code:

C#

```
private string titleFilter = string.Empty;

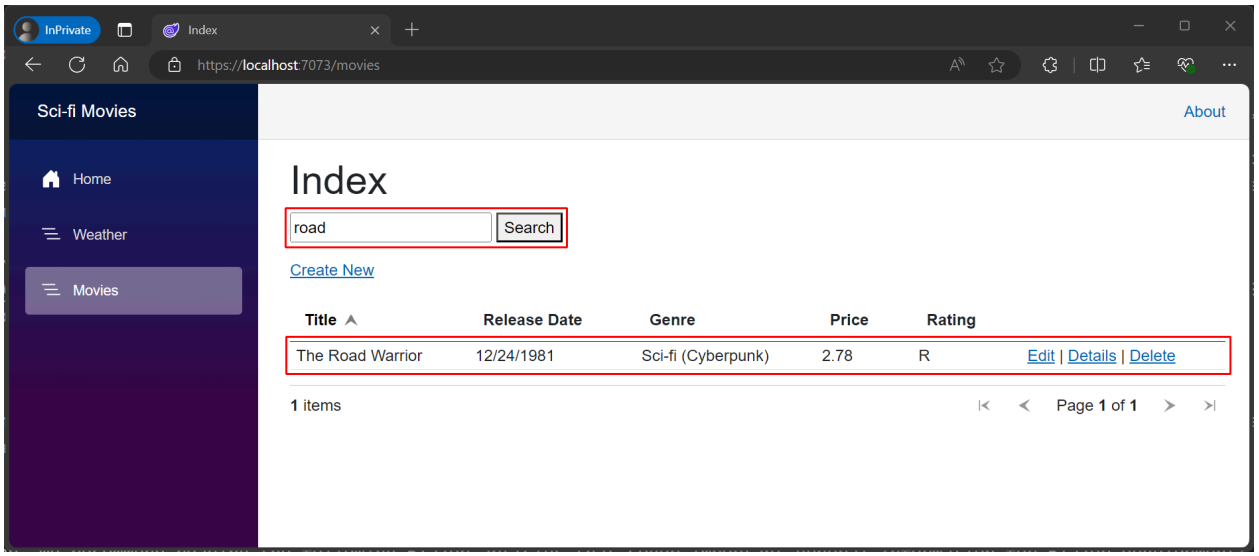
private IQueryable<Movie> FilteredMovies =>
    context.Movie.Where(m => m.Title!.Contains(titleFilter));
```

Next, the component should bind the `titleFilter` field to an `<input>` element, so user input is stored in the `titleFilter` variable. Binding is achieved in Blazor with the `@bind` directive attribute.

Remove the HTML form from the component:

diff

```
- <form action="/movies" data-enhance>
-     <input type="search" name="titleFilter" />
-     <input type="submit" value="Search" />
- </form>
```



In its place, add the following Razor markup:

razor

```
<input type="search" @bind="titleFilter" @bind:event="oninput" />
```

`@bind:event="oninput"` performs binding for the HTML's `oninput` event, which fires when the `<input>` element's value is changed as a direct result of a user typing in the search box. The `QuickGrid` is bound to `FilteredMovies`. As `titleFilter` changes with the value of the search box, rerendering the `QuickGrid` bound to the `FilteredMovies` method filters movie entities based on the updated value of `titleFilter`.

Run the app, type "`road warrior`" into the search field and notice how the `QuickGrid` is filtered for each character entered until *The Road Warrior* movie is left when the search field reaches "`road `" ("road" followed by a space).

Filtering database records is performed on the server, and the server interactively sends back the HTML to display over the same SignalR connection. The page doesn't reload. The user feels like their interactions with the page are running code on the client. Actually, the code is running the server.

Instead of an HTML form, submitting a GET request in this scenario could've also used JavaScript to submit the request to the server, either using the Fetch API ` or XMLHttpRequest API . In most cases, JavaScript can be replaced by using Blazor and C# in an interactive component.

Clean up

When you're finished with the tutorial and delete the sample app from your local system, you can also delete the `BlazorWebAppMovies` database in Visual Studio's SQL Server Object Explorer (SSOX):

1. Access SSOX by selecting **View** > **SQL Server Object Explorer** from the menu bar.
2. Display the database list by selecting the triangles next to `SQL Server` > `(localdb)\MSSQLLocalDB` > `Databases`.
3. Right-click the `BlazorWebAppMovies` database in the list and select **Delete**.
4. Select the checkbox to close existing collections before selecting **OK**.

When deleting the database in SSOX, the database's physical files are removed from your Windows user folder.

Congratulations!

Congratulations on completing the tutorial series! We hope you enjoyed this tutorial on Blazor. Blazor offers many more features than we were able to cover in this series, and

we invite you to explore the Blazor documentation, examples, and sample apps to learn more. *Happy coding with Blazor!*

Next steps

If you're new to Blazor, we recommend reading the following Blazor articles that cover important general information for Blazor development:

- ASP.NET Core Blazor
- ASP.NET Core Blazor supported platforms
- Tooling for ASP.NET Core Blazor
- ASP.NET Core Blazor hosting models
- ASP.NET Core Blazor project structure
- ASP.NET Core Blazor fundamentals and the other *Fundamentals* node articles.
- ASP.NET Core Razor components and the other *Components* node articles.
- ASP.NET Core Blazor forms overview
- ASP.NET Core Blazor JavaScript interoperability (JS interop) and the other *JavaScript interop* articles.
- ASP.NET Core Blazor authentication and authorization
- Host and deploy ASP.NET Core Blazor
- ASP.NET Core Blazor with Entity Framework Core (EF Core) covers concurrency with EF Core in Blazor apps.

In the documentation website's sidebar navigation, articles are organized by subject matter and laid out in roughly in a general-to-specific or basic-to-complex order. The best approach when starting to learn about Blazor is to read down the table of contents from top to bottom.

Troubleshoot with the completed sample

If you run into a problem while following the tutorial that you can't resolve from the text, compare your code to the completed project in the Blazor samples repository:

Blazor samples GitHub repository (dotnet/blazor-samples)

Select the latest version folder. The sample folder for this tutorial's project is named `BlazorWebAppMovies`.

Previous: Add a new field

Use ASP.NET Core SignalR with Blazor

Article • 06/19/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This tutorial provides a basic working experience for building a real-time app using SignalR with Blazor. This article is useful for developers who are already familiar with SignalR and are seeking to understand how to use SignalR in a Blazor app. For detailed guidance on the SignalR and Blazor frameworks, see the following reference documentation sets and the API documentation:

- Overview of ASP.NET Core SignalR
- ASP.NET Core Blazor
- .NET API browser

Learn how to:

- ✓ Create a Blazor app
- ✓ Add the SignalR client library
- ✓ Add a SignalR hub
- ✓ Add SignalR services and an endpoint for the SignalR hub
- ✓ Add a Razor component code for chat

At the end of this tutorial, you'll have a working chat app.

Prerequisites

Visual Studio

Visual Studio (latest release) with the **ASP.NET and web development** workload

Sample app

Downloading the tutorial's sample chat app isn't required for this tutorial. The sample app is the final, working app produced by following the steps of this tutorial. When you open the samples repository, open the version folder that you plan to target and find the sample named `BlazorSignalRApp`.

View or download sample code (how to download)

Create a Blazor Web App

Follow the guidance for your choice of tooling:

Visual Studio

> **Note**
>
> Visual Studio 2022 or later and .NET Core SDK 8.0.0 or later are required.

In Visual Studio:

- Select **Create a new project** from the **Start Window** or select **File** > **New** > **Project** from the menu bar.
- In the **Create a new project** dialog, select **Blazor Web App** from the list of project templates. Select the **Next** button.
- In the **Configure your new project** dialog, name the project `BlazorSignalRApp` in the **Project name** field, including matching the capitalization. Using this exact project name is important to ensure that the namespaces match for code that you copy from the tutorial into the app that you're building.
- Confirm that the **Location** for the app is suitable. Leave the **Place solution and project in the same directory** checkbox selected. Select the **Next** button.
- In the **Additional information** dialog, use the following settings:
  - **Framework**: Confirm that the latest framework is selected. If Visual Studio's **Framework** dropdown list doesn't include the latest available .NET framework, update Visual Studio and restart the tutorial.
  - **Authentication type**: **None**
  - **Configure for HTTPS**: Selected
  - **Interactive render mode**: **WebAssembly**
  - **Interactivity location**: **Per page/component**
  - **Include sample pages**: Selected
  - **Do not use top-level statements**: Not selected

- Select **Create**.

The guidance in this article uses a WebAssembly component for the SignalR client because it doesn't make sense to use SignalR to connect to a hub from an Interactive Server component in the same app, as that can lead to server port exhaustion.

Add the SignalR client library

Visual Studio

In **Solution Explorer**, right-click the `BlazorSignalRApp.Client` project and select **Manage NuGet Packages**.

In the **Manage NuGet Packages** dialog, confirm that the **Package source** is set to `nuget.org`.

With **Browse** selected, type `Microsoft.AspNetCore.SignalR.Client` in the search box.

In the search results, select the latest release of the Microsoft.AspNetCore.SignalR.Client package. Select **Install**.

If the **Preview Changes** dialog appears, select **OK**.

If the **License Acceptance** dialog appears, select **I Accept** if you agree with the license terms.

Add a SignalR hub

In the server `BlazorSignalRApp` project, create a `Hubs` (plural) folder and add the following `ChatHub` class (`Hubs/ChatHub.cs`):

C#

```
using Microsoft.AspNetCore.SignalR;

namespace BlazorSignalRApp.Hubs;

public class ChatHub : Hub
{
    public async Task SendMessage(string user, string message)
    {
        await Clients.All.SendAsync("ReceiveMessage", user, message);
```

```
    }
}
```

Add services and an endpoint for the SignalR hub

Open the `Program` file of the server `BlazorSignalRApp` project.

Add the namespaces for Microsoft.AspNetCore.ResponseCompression and the `ChatHub` class to the top of the file:

C#

```
using Microsoft.AspNetCore.ResponseCompression;
using BlazorSignalRApp.Hubs;
```

Add SignalR and Response Compression Middleware services:

C#

```
builder.Services.AddSignalR();

builder.Services.AddResponseCompression(opts =>
{
   opts.MimeTypes = ResponseCompressionDefaults.MimeTypes.Concat(
       ["application/octet-stream"]);
});
```

Use Response Compression Middleware at the top of the processing pipeline's configuration. Place the following line of code immediately after the line that builds the app (`var app = builder.Build();`):

C#

```
app.UseResponseCompression();
```

Add an endpoint for the hub immediately before the line that runs the app (`app.Run();`):

C#

```
app.MapHub<ChatHub>("/chathub");
```

Add Razor component code for chat

Add the following `Pages/Chat.razor` file to the `BlazorSignalRApp.Client` project:

razor

```razor
@page "/chat"
@rendermode InteractiveWebAssembly
@using Microsoft.AspNetCore.SignalR.Client
@inject NavigationManager Navigation
@implements IAsyncDisposable

<PageTitle>Chat</PageTitle>

<div class="form-group">
    <label>
        User:
        <input @bind="userInput" />
    </label>
</div>
<div class="form-group">
    <label>
        Message:
        <input @bind="messageInput" size="50" />
    </label>
</div>
<button @onclick="Send" disabled="@(!IsConnected)">Send</button>

<hr>

<ul id="messagesList">
    @foreach (var message in messages)
    {
        <li>@message</li>
    }
</ul>

@code {
    private HubConnection? hubConnection;
    private List<string> messages = new List<string>();
    private string? userInput;
    private string? messageInput;

    protected override async Task OnInitializedAsync()
    {
        hubConnection = new HubConnectionBuilder()
            .WithUrl(Navigation.ToAbsoluteUri("/chathub"))
            .Build();

        hubConnection.On<string, string>("ReceiveMessage", (user, message)
=>
        {
            var encodedMsg = $"{user}: {message}";
```

```
            messages.Add(encodedMsg);
            InvokeAsync(StateHasChanged);
        });

        await hubConnection.StartAsync();
    }

    private async Task Send()
    {
        if (hubConnection is not null)
        {
            await hubConnection.SendAsync("SendMessage", userInput,
messageInput);
        }
    }

    public bool IsConnected =>
        hubConnection?.State == HubConnectionState.Connected;

    public async ValueTask DisposeAsync()
    {
        if (hubConnection is not null)
        {
            await hubConnection.DisposeAsync();
        }
    }
}
```

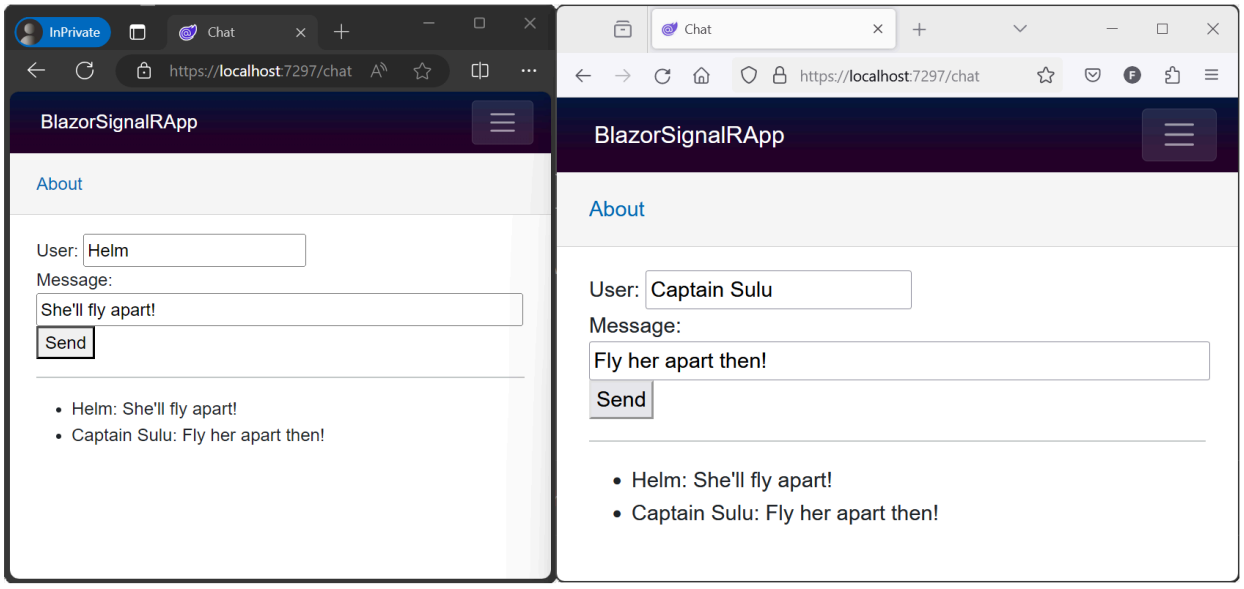
Add an entry to the `NavMenu` component to reach the chat page. In `Components/Layout/NavMenu.razor` immediately after the `<div>` block for the `Weather` component, add the following `<div>` block:

razor

```
<div class="nav-item px-3">
    <NavLink class="nav-link" href="chat">
        <span class="bi bi-list-nested-nav-menu" aria-hidden="true"></span>
Chat
    </NavLink>
</div>
```

> ⓘ Note
>
> Disable Response Compression Middleware in the `Development` environment when using Hot Reload. For more information, see ASP.NET Core Blazor SignalR guidance.

Run the app



Follow the guidance for your tooling:

Visual Studio

With the server `BlazorSignalRApp` project selected in **Solution Explorer**, press `F5` to run the app with debugging or `Ctrl`+`F5` (Windows)/`⌘`+`F5` (macOS) to run the app without debugging.

Copy the URL from the address bar, open another browser instance or tab, and paste the URL in the address bar.

Choose either browser, enter a name and message, and select the button to send the message. The name and message are displayed on both pages instantly:

Quotes: *Star Trek VI: The Undiscovered Country* ©1991 Paramount

Next steps

In this tutorial, you learned how to:

- ✓ Create a Blazor app
- ✓ Add the SignalR client library
- ✓ Add a SignalR hub
- ✓ Add SignalR services and an endpoint for the SignalR hub
- ✓ Add a Razor component code for chat

For detailed guidance on the SignalR and Blazor frameworks, see the following reference documentation sets:

Overview of ASP.NET Core SignalR | ASP.NET Core Blazor

Additional resources

- Bearer token authentication with Identity Server, WebSockets, and Server-Sent Events
- Secure a SignalR hub in Blazor WebAssembly apps
- SignalR cross-origin negotiation for authentication
- SignalR configuration
- Debug ASP.NET Core Blazor apps
- Blazor samples GitHub repository (dotnet/blazor-samples) (how to download)

ASP.NET Core Blazor Hybrid

Article • 02/09/2024

This article explains ASP.NET Core Blazor Hybrid, a way to build interactive client-side web UI with .NET in an ASP.NET Core app.

Use *Blazor Hybrid* to blend desktop and mobile native client frameworks with .NET and Blazor.

In a Blazor Hybrid app, Razor components run natively on the device. Components render to an embedded Web View control through a local interop channel. Components don't run in the browser, and WebAssembly isn't involved. Razor components load and execute code quickly, and components have full access to the native capabilities of the device through the .NET platform. Component styles rendered in a Web View are platform dependent and may require you to account for rendering differences across platforms using custom stylesheets.

Blazor Hybrid articles cover subjects pertaining to integrating Razor components into native client frameworks.

Blazor Hybrid apps with .NET MAUI

Blazor Hybrid support is built into the .NET Multi-platform App UI (.NET MAUI) framework. .NET MAUI includes the BlazorWebView control that permits rendering Razor components into an embedded Web View. By using .NET MAUI and Blazor together, you can reuse one set of web UI components across mobile, desktop, and web.

Blazor Hybrid apps with WPF and Windows Forms

Blazor Hybrid apps can be built with Windows Presentation Foundation (WPF) and Windows Forms. Blazor provides `BlazorWebView` controls for both of these frameworks (WPF BlazorWebView, Windows Forms BlazorWebView). Razor components run natively in the Windows desktop and render to an embedded Web View. Using Blazor in WPF and Windows Forms enables you to add new UI to your existing Windows desktop apps that can be reused across platforms with .NET MAUI or on the web.

Web View configuration

Blazor Hybrid exposes the underlying Web View configuration for different platforms through events of the `BlazorWebView` control:

- `BlazorWebViewInitializing` provides access to the settings used to create the Web View on each platform, if settings are available.
- `BlazorWebViewInitialized` provides access to the Web View to allow further configuration of the settings.

Use the preferred patterns on each platform to attach event handlers to the events to execute your custom code.

API documentation:

- .NET MAUI
  - BlazorWebViewInitializing
  - BlazorWebViewInitialized
- WPF
  - BlazorWebViewInitializing
  - BlazorWebViewInitialized
- Windows Forms
  - BlazorWebViewInitializing
  - BlazorWebViewInitialized

Unhandled exceptions in Windows Forms and WPF apps

This section only applies to Windows Forms and WPF Blazor Hybrid apps.

Create a callback for `UnhandledException` on the System.AppDomain.CurrentDomain property. The following example uses a compiler directive to display a MessageBox that either alerts the user that an error has occurred or shows the error information to the developer. Log the error information in `error.ExceptionObject`.

C#

```
AppDomain.CurrentDomain.UnhandledException += (sender, error) =>
{
#if DEBUG
    MessageBox.Show(text: error.ExceptionObject.ToString(), caption:
"Error");
#else
    MessageBox.Show(text: "An error has occurred.", caption: "Error");
#endif
```

```
    // Log the error information (error.ExceptionObject)
};
```

Globalization and localization

This section only applies to .NET MAUI Blazor Hybrid apps.

.NET MAUI configures the CurrentCulture and CurrentUICulture based on the device's ambient information.

IStringLocalizer and other API in the Microsoft.Extensions.Localization namespace generally work as expected, along with globalization formatting, parsing, and binding that relies on the user's culture.

When dynamically changing the app culture at runtime, the app must be reloaded to reflect the change in culture, which takes care of rerendering the root component and passing the new culture to rerendered child components.

.NET's resource system supports embedding localized images (as blobs) into an app, but Blazor Hybrid can't display the embedded images in Razor components at this time. Even if a user reads an image's bytes into a Stream using ResourceManager, the framework doesn't currently support rendering the retrieved image in a Razor component.

A platform-specific approach to include localized images is a feature of .NET's resource system, but a Razor component's browser elements in a .NET MAUI Blazor Hybrid app aren't able to interact with such images.

For more information, see the following resources:

- Xamarin.Forms String and Image Localization: The guidance generally applies to Blazor Hybrid apps. Not every scenario is supported at this time.
- Blazor Image component to display images that are not accessible through HTTP endpoints (dotnet/aspnetcore #25274)

Access scoped services from native UI

BlazorWebView has a TryDispatchAsync method that calls a specified `Action<ServiceProvider>` asynchronously and passes in the scoped services available in Razor components. This enables code from the native UI to access scoped services such as NavigationManager:

```
```

C#

```
private async void MyMauiButtonHandler(object sender, EventArgs e)
{
    var wasDispatchCalled = await _blazorWebView.TryDispatchAsync(sp =>
    {
        var navMan = sp.GetRequiredService<NavigationManager>();
        navMan.CallSomeNavigationApi(...);
    });

    if (!wasDispatchCalled)
    {
        ...
    }
}
```

When `wasDispatchCalled` is `false`, consider what to do if the call wasn't dispatched. Generally, the dispatch shouldn't fail. If it fails, OS resources might be exhausted. If resources are exhausted, consider logging a message, throwing an exception, and perhaps alerting the user.

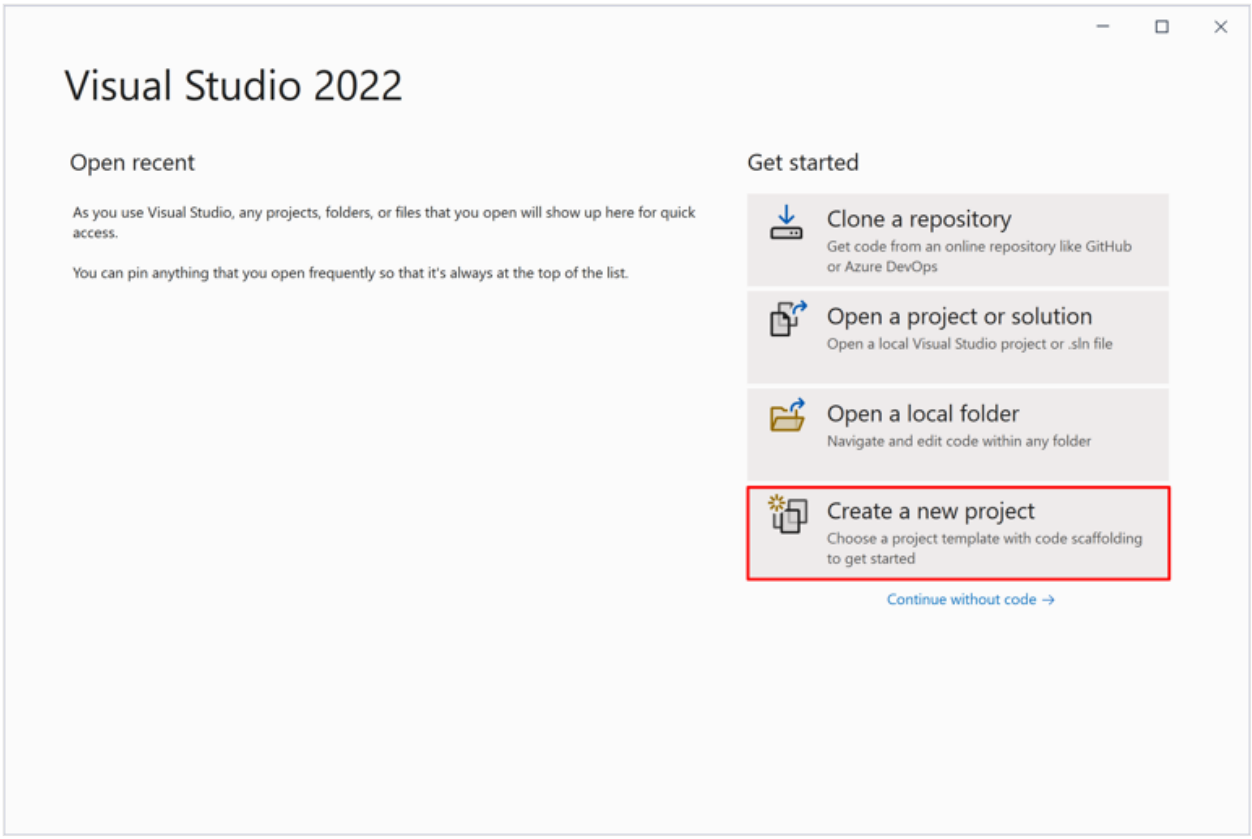
Build a .NET MAUI Blazor Hybrid app

Article • 02/09/2024

This tutorial shows you how to build and run a .NET MAUI Blazor Hybrid app. You learn how to:

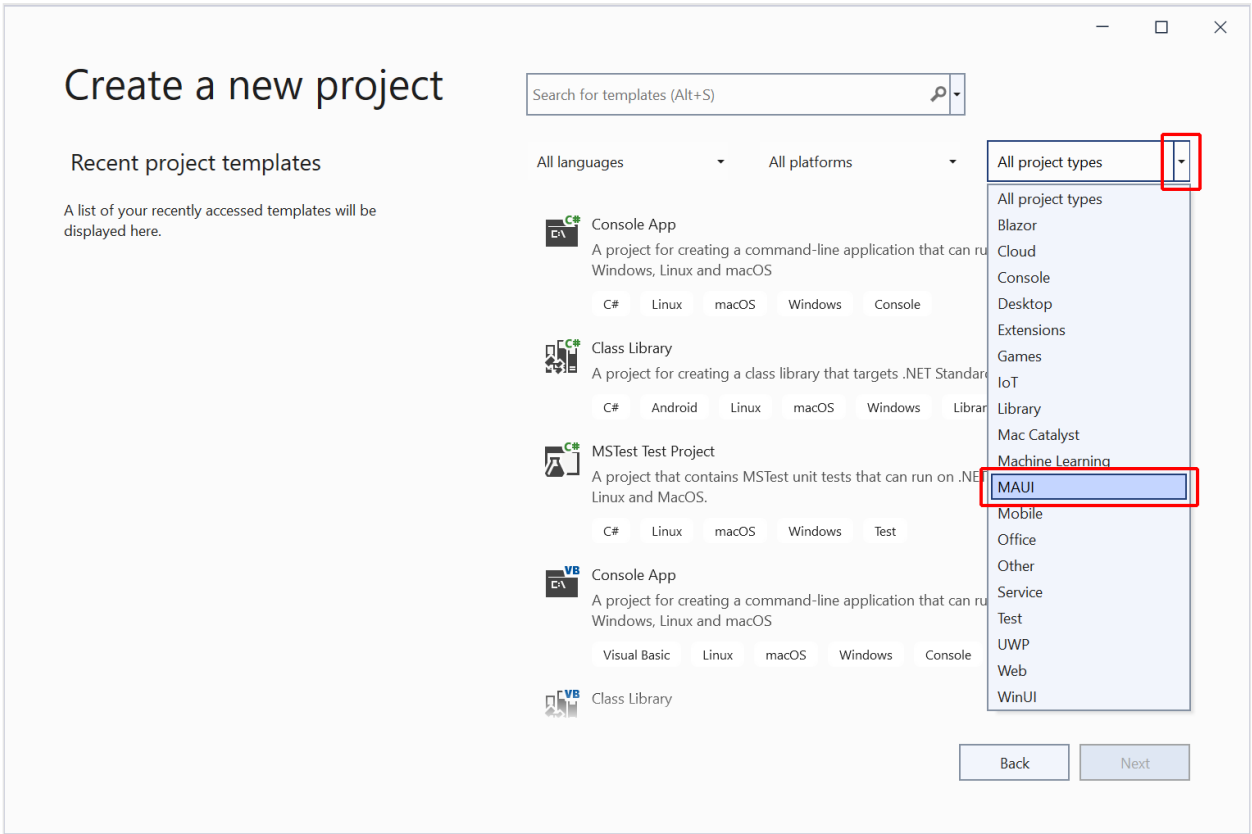
- ✓ Create a .NET MAUI Blazor Hybrid app project in Visual Studio
- ✓ Run the app on Windows
- ✓ Run the app on an emulated mobile device in the Android Emulator

Prerequisites



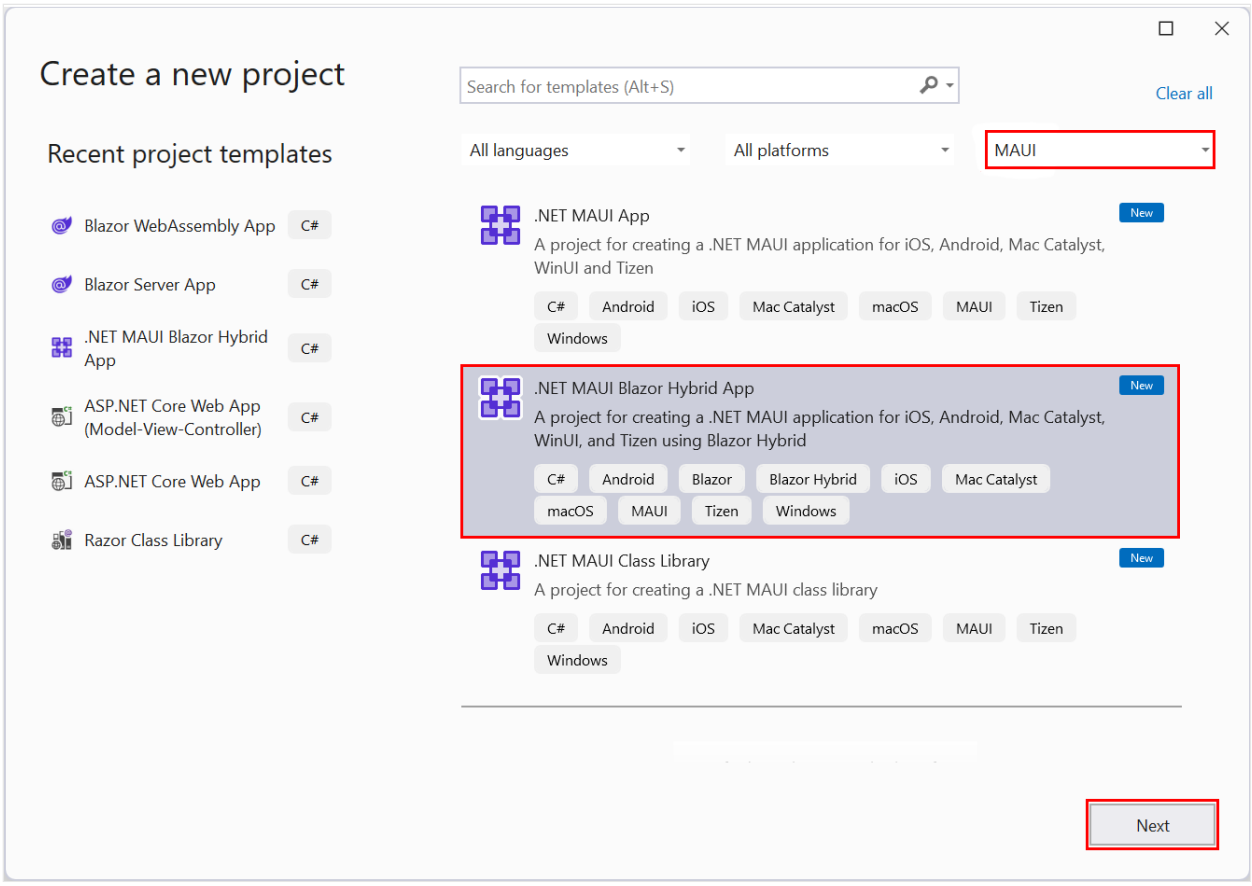
- Supported platforms (.NET MAUI documentation)
- Visual Studio with the **.NET Multi-platform App UI development** workload.
- Microsoft Edge WebView2: WebView2 is required on Windows when running a native app. When developing .NET MAUI Blazor Hybrid apps and only running them in Visual Studio's emulators, WebView2 isn't required.
- Enable hardware acceleration to improve the performance of the Android emulator.

For more information on prerequisites and installing software for this tutorial, see the following resources in the .NET MAUI documentation:



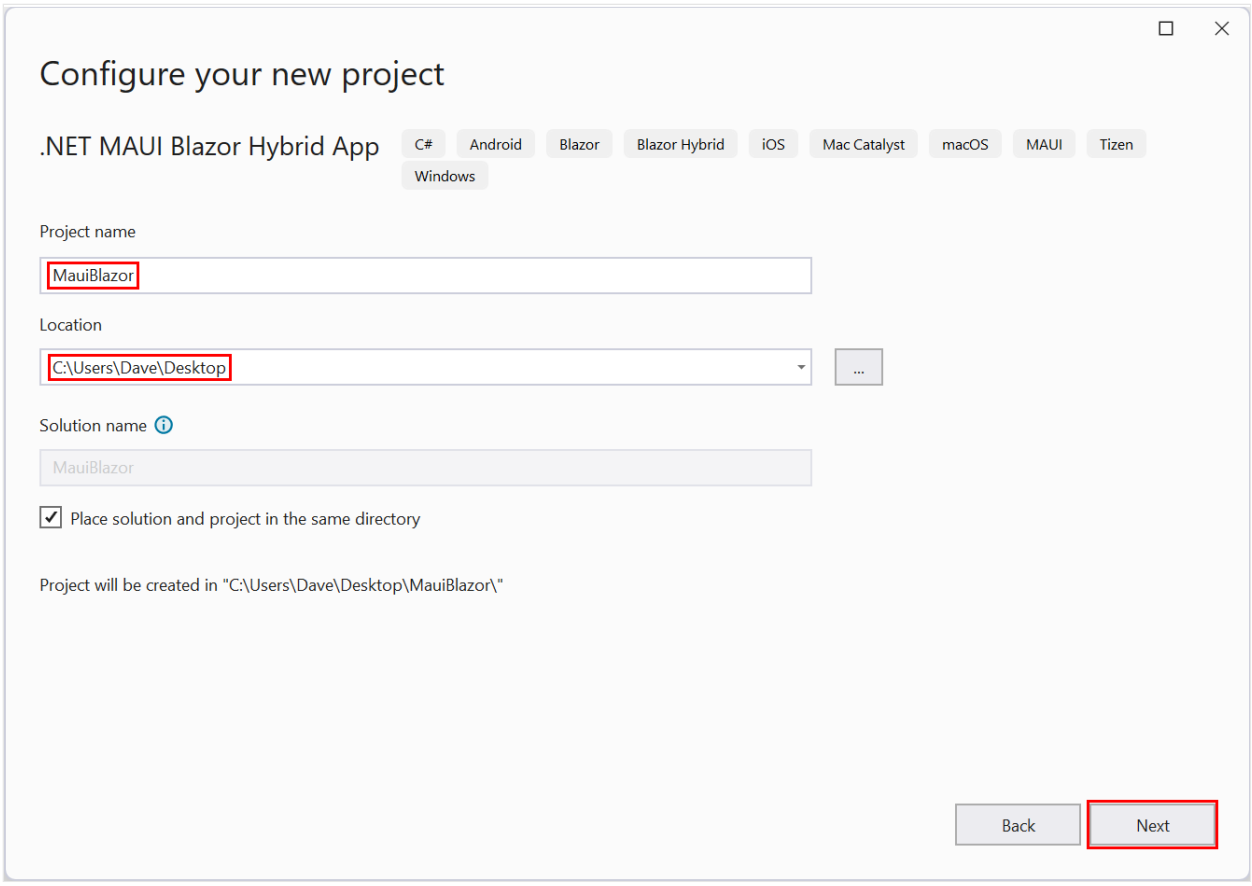
- Supported platforms for .NET MAUI apps
- Installation (Visual Studio)

Create a .NET MAUI Blazor Hybrid app

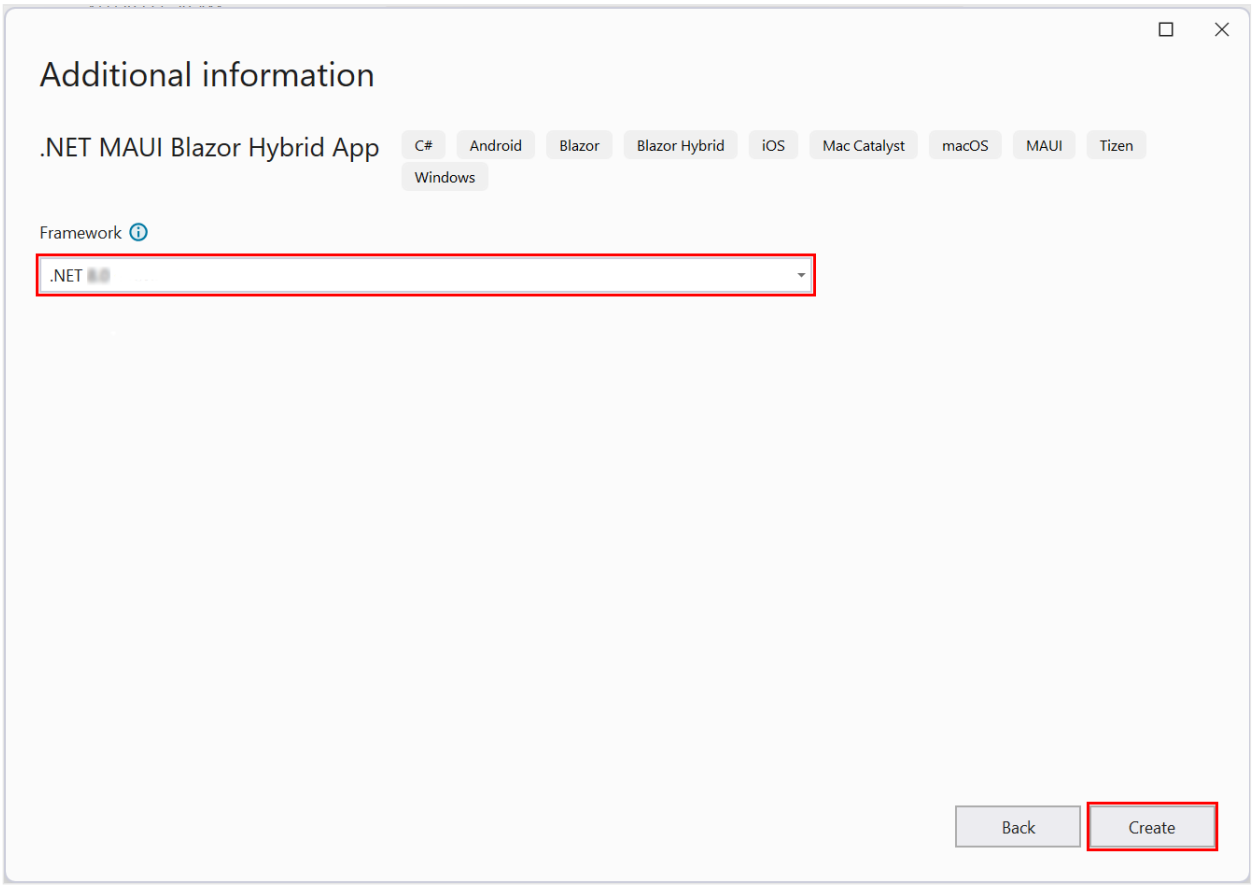


Launch Visual Studio. In the **Start Window**, select **Create a new project**:

In the **Create a new project** window, use the **Project type** dropdown to filter **MAUI** templates:



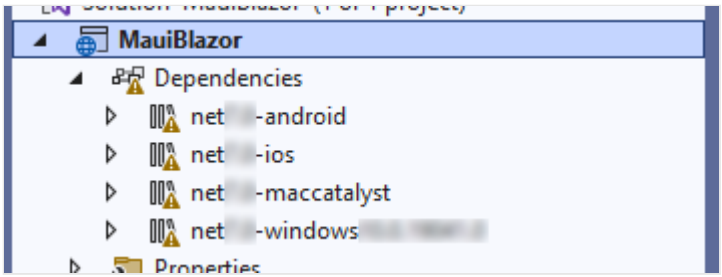
Select the **.NET MAUI Blazor Hybrid App** template and then select the **Next** button:



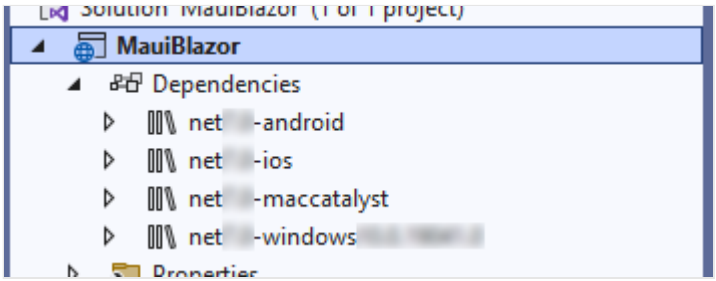
> **Note**
>
> In .NET 7 or earlier, the template is named **.NET MAUI Blazor App**.

In the **Configure your new project** dialog:

- Set the **Project name** to **MauiBlazor**.
- Choose a suitable location for the project.
- Select the **Next** button.



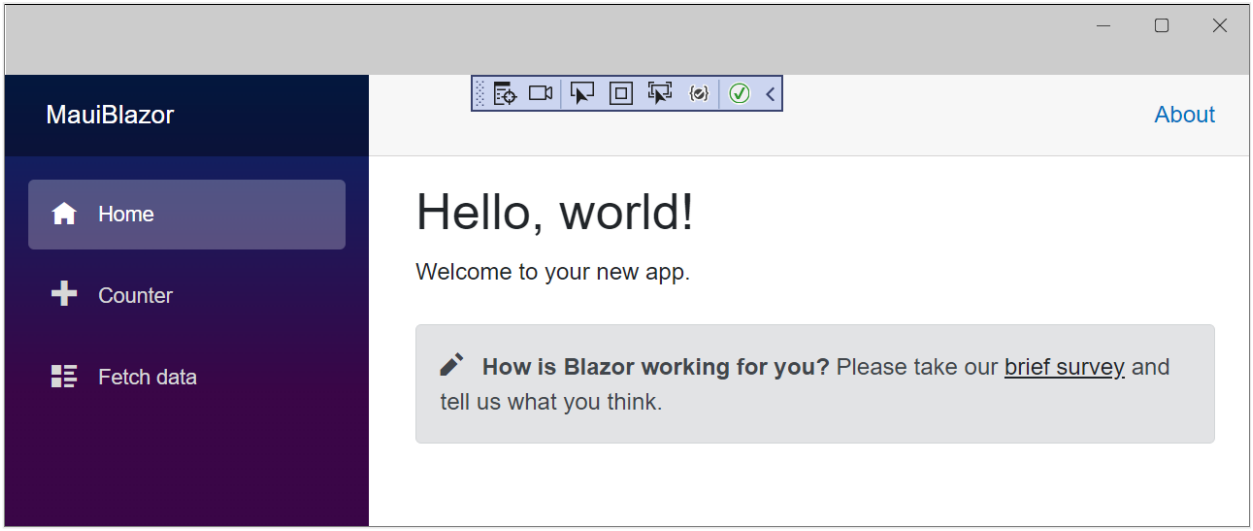
In the **Additional information** dialog, select the framework version with the **Framework** dropdown list. Select the **Create** button:



Wait for Visual Studio to create the project and restore the project's dependencies. Monitor the progress in **Solution Explorer** by opening the **Dependencies** entry.

Dependencies restoring:

Dependencies restored:

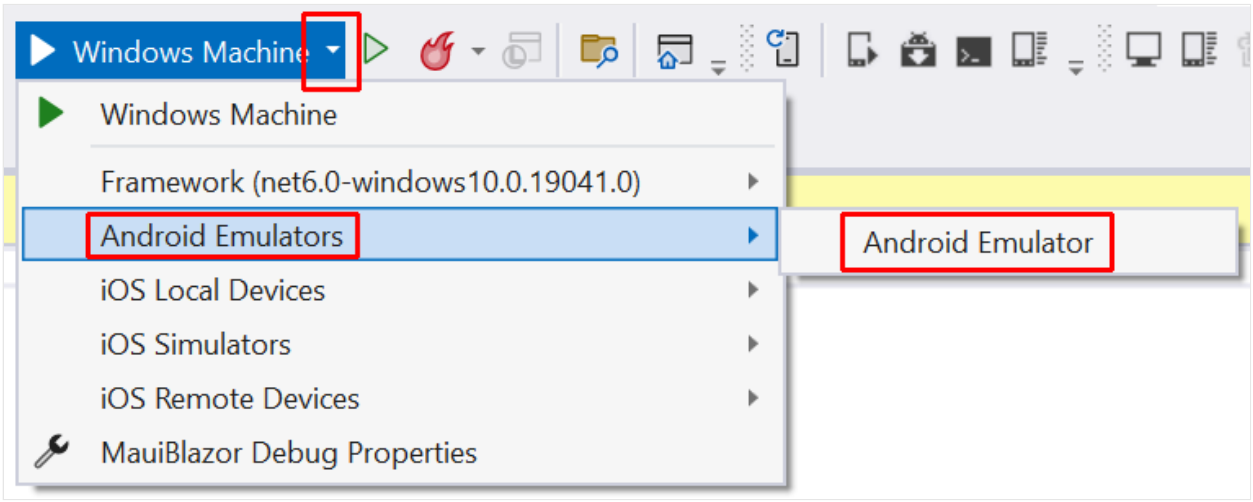


Run the app on Windows

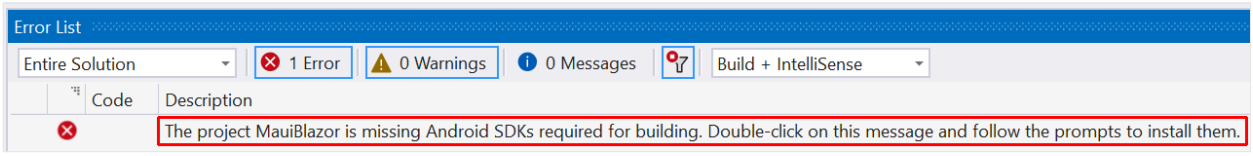
In the Visual Studio toolbar, select the **Windows Machine** button to build and start the project:

If Developer Mode isn't enabled, you're prompted to enable it in **Settings** > **For developers** > **Developer Mode** (Windows 10) or **Settings** > **Privacy & security** > **For developers** > **Developer Mode** (Windows 11). Set the switch to **On**.

The app running as a Windows desktop app:

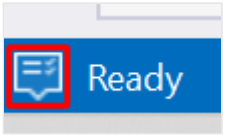


Run the app in the Android Emulator

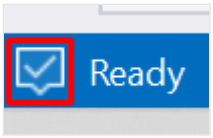


If you followed the guidance in the Run the app on Windows section, select the **Stop Debugging** button in the toolbar to stop the running Windows app:

In the Visual Studio toolbar, select the start configuration dropdown button. Select **Android Emulators** > **Android Emulator**:



Android SDKs are required to build apps for Android. In the **Error List** panel, a message appears asking you to double-click the message to install the required Android SDKs:



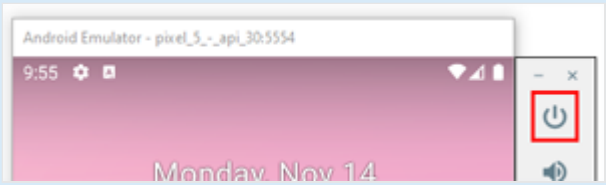
The **Android SDK License Acceptance** window appears, select the **Accept** button for each license that appears. An additional window appears for the **Android Emulator** and **SDK Patch Applier** licenses. Select the **Accept** button.

Wait for Visual Studio to download the Android SDK and Android Emulator. You can track the progress by selecting the background tasks indicator in the lower-left corner of the Visual Studio UI:

The indicator shows a checkmark when the background tasks are complete:

In the toolbar, select the **Android Emulator** button:

In the **Create a Default Android Device** window, select the **Create** button:



Wait for Visual Studio to download, unzip, and create an Android Emulator. When the Android phone emulator is ready, select the **Start** button.

> ⓘ **Note**
>
> Enable hardware acceleration to improve the performance of the Android emulator.

Close the **Android Device Manager** window. Wait until the emulated phone window appears, the Android OS loads, and the home screen appears.

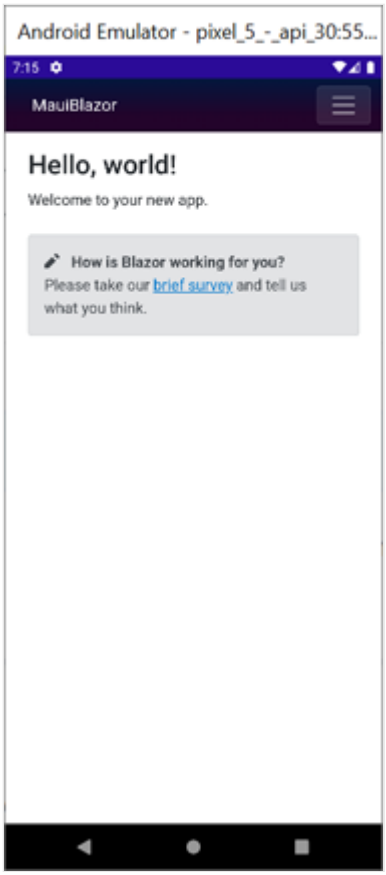
> ⓘ **Important**
>
> The emulated phone must be powered on with the Android OS loaded in order to load and run the app in the debugger. If the emulated phone isn't running, turn on

the phone using either the `Ctrl`+`P` keyboard shortcut or by selecting the **Power** button in the UI:

In the Visual Studio toolbar, select the **Pixel 5 - {VERSION}** button to build and run the project, where the `{VERSION}` placeholder is the Android version. In the following example, the Android version is **API 30 (Android 11.0 - API 30)**, and a later version appears depending on the Android SDK installed:

Visual Studio builds the project and deploys the app to the emulator.

Starting the emulator, loading the emulated phone and OS, and deploying and running the app can take several minutes depending on the speed of the system and whether or not hardware acceleration is enabled. You can monitor the progress of the deployment by inspecting Visual Studio's status bar at the bottom of the UI. The **Ready** indicator receives a checkmark and the emulator's deployment and app loading indicators disappear when the app is running:



During deployment:

During app startup:

The app running in the Android Emulator:

Next steps

In this tutorial, you learned how to:

- ✓ Create a .NET MAUI Blazor Hybrid app project in Visual Studio
- ✓ Run the app on Windows
- ✓ Run the app on an emulated mobile device in the Android Emulator

Build a .NET MAUI Blazor Hybrid app with a Blazor Web App

Article • 10/18/2024

This article shows you how to build a .NET MAUI Blazor Hybrid app with a Blazor Web App that uses a shared user interface via a Razor class library (RCL).

Prerequisites and preliminary steps

For prerequisites and preliminary steps, see Build a .NET MAUI Blazor Hybrid app. We recommend using the .NET MAUI Blazor Hybrid tutorial to set up your local system for .NET MAUI development before using the guidance in this article.

.NET MAUI Blazor Hybrid and Web App solution template

The .NET MAUI Blazor Hybrid and Web App solution template sets up a solution that targets Android, iOS, Mac, Windows and Web that reuses UI. You can choose a Blazor interactive render mode for the web app and it creates the appropriate projects for the app, including a Blazor Web App and a .NET MAUI Blazor Hybrid app. A shared Razor class library (RCL) maintains the Razor components for the app's UI. The template also provides sample code to show you how to use dependency injection to provide different interface implementations for the Blazor Hybrid and Blazor Web App, which is covered in the Using interfaces to support different device implementations section of this article.

If you haven't already installed the .NET MAUI workload, install it now. The .NET MAUI workload provides the project template:

.NET CLI

```
dotnet workload install maui
```

Create a solution from the project template with the following .NET CLI command:

.NET CLI

```
dotnet new maui-blazor-web -o MauiBlazorWeb -I Server
```

In the preceding command:

- The `-o|--output` option creates a new folder for the app named `MauiBlazorWeb`.
- The `-I|--InteractivityPlatform` option sets the interactivity render mode to Interactive Server (`InteractiveServer`). All three interactive Blazor render modes (`Server`, `WebAssembly`, and `Auto`) are supported by the project template. For more information, see the Use Blazor render modes section.

The app automatically adopts global interactivity, which is important because MAUI apps always run interactively and throw errors on Razor component pages that explicitly specify a render mode. For more information, see BlazorWebView needs a way to enable overriding ResolveComponentForRenderMode (dotnet/aspnetcore #51235).

Use Blazor render modes

Use the guidance in one of the following subsections that matches your app's specifications for applying Blazor render modes in the Blazor Web App but ignore the render mode assignments in the MAUI project.

Render mode specification subsections:

- Global Server interactivity
- Global Auto or WebAssembly interactivity

Global Server interactivity

- Interactive render mode: **Server**
- Interactivity location: **Global**
- Solution projects
  - MAUI (`MauiBlazorWeb`)
  - Blazor Web App (`MauiBlazorWeb.Web`)
  - RCL (`MauiBlazorWeb.Shared`): Contains the shared Razor components without setting render modes in each component.

Project references: `MauiBlazorWeb` and `MauiBlazorWeb.Web` have a project reference to `MauiBlazorWeb.Shared`.

Global Auto or WebAssembly interactivity

- Interactive render mode: **Auto** or **WebAssembly**
- Interactivity location: **Global**

- Solution projects
  - MAUI (`MauiBlazorWeb`)
  - Blazor Web App
    - Server project: `MauiBlazorWeb.Web`
    - Client project: `MauiBlazorWeb.Web.Client`
  - RCL (`MauiBlazorWeb.Shared`): Contains the shared Razor components without setting render modes in each component.

Project references:

- `MauiBlazorWeb`, `MauiBlazorWeb.Web`, and `MauiBlazorWeb.Web.Client` projects have a project reference to `MauiBlazorWeb.Shared`.
- `MauiBlazorWeb.Web` has a project reference to `MauiBlazorWeb.Web.Client`.

Per-page/component Server interactivity

- Interactive render mode: **Server**
- Interactivity location: **Per-page/component**
- Solution projects
  - MAUI (`MauiBlazorWeb`): Calls `InteractiveRenderSettings.ConfigureBlazorHybridRenderModes` in `MauiProgram.cs`.
  - Blazor Web App (`MauiBlazorWeb.Web`): Doesn't set an `@rendermode` directive attribute on the `HeadOutlet` and `Routes` components of the `App` component (`Components/App.razor`).
  - RCL (`MauiBlazorWeb.Shared`): Contains the shared Razor components that set the `InteractiveServer` render mode in each component.

`MauiBlazorWeb` and `MauiBlazorWeb.Web` have a project reference to `MauiBlazorWeb.Shared`.

Add the following `InteractiveRenderSettings` class to the RCL. The class properties are used to set component render modes.

The MAUI project is interactive by default, so no action is taken at the project level in the MAUI project other than calling `InteractiveRenderSettings.ConfigureBlazorHybridRenderModes`.

For the Blazor Web App on the web client, the property values are assigned from RenderMode. When the components are loaded into a BlazorWebView for the MAUI project's native client, the render modes are unassigned (`null`) because the MAUI

project explicitly sets the render mode properties to `null` when `ConfigureBlazorHybridRenderModes` is called.

`InteractiveRenderSettings.cs`:

```
C#

using Microsoft.AspNetCore.Components;
using Microsoft.AspNetCore.Components.Web;

namespace MauiBlazorWeb.Shared;

public static class InteractiveRenderSettings
{
    public static IComponentRenderMode? InteractiveServer { get; set; } =
        RenderMode.InteractiveServer;
    public static IComponentRenderMode? InteractiveAuto { get; set; } =
        RenderMode.InteractiveAuto;
    public static IComponentRenderMode? InteractiveWebAssembly { get; set; }
=
        RenderMode.InteractiveWebAssembly;

    public static void ConfigureBlazorHybridRenderModes()
    {
        InteractiveServer = null;
        InteractiveAuto = null;
        InteractiveWebAssembly = null;
    }
}
```

In `MauiProgram.CreateMauiApp` of `MauiProgram.cs`, call `ConfigureBlazorHybridRenderModes`:

```
C#

InteractiveRenderSettings.ConfigureBlazorHybridRenderModes();
```

In the `_Imports.razor` file of the `.Shared` RCL, replace the `@using` statement for Microsoft.AspNetCore.Components.Web.RenderMode with an `@using` statement for `InteractiveRenderSettings` to make the properties of the `InteractiveRenderSettings` class available to components:

```
diff

- @using static Microsoft.AspNetCore.Components.Web.RenderMode
+ @using static InteractiveRenderSettings
```

> **Note**
>
> The assignment of render modes via the RCL's `InteractiveRenderSettings` class properties differs from a typical standalone Blazor Web App. In a Blazor Web App, the render modes are normally provided by **RenderMode** in the Blazor Web App's `_Import` file.

Per-page/component Auto interactivity

- Interactive render mode: **Auto**
- Interactivity location: **Per-page/component**
- Solution projects
  - MAUI (`MauiBlazorWeb`): Calls `InteractiveRenderSettings.ConfigureBlazorHybridRenderModes` in `MauiProgram.cs`.
  - Blazor Web App
    - Server project: `MauiBlazorWeb.Web`: Doesn't set an `@rendermode` directive attribute on the `HeadOutlet` and `Routes` components of the `App` component (`Components/App.razor`).
    - Client project: `MauiBlazorWeb.Web.Client`
  - RCL (`MauiBlazorWeb.Shared`): Contains the shared Razor components that set the `InteractiveAuto` render mode in each component.

Project references:

- `MauiBlazorWeb`, `MauiBlazorWeb.Web`, and `MauiBlazorWeb.Web.Client` have a project reference to `MauiBlazorWeb.Shared`.
- `MauiBlazorWeb.Web` has a project reference to `MauiBlazorWeb.Web.Client`.

Add the following `InteractiveRenderSettings` class is added to the RCL. The class properties are used to set component render modes.

The MAUI project is interactive by default, so no action is taken at the project level in the MAUI project other than calling `InteractiveRenderSettings.ConfigureBlazorHybridRenderModes`.

For the Blazor Web App on the web client, the property values are assigned from RenderMode. When the components are loaded into a BlazorWebView for the MAUI project's native client, the render modes are unassigned (`null`) because the MAUI

project explicitly sets the render mode properties to `null` when `ConfigureBlazorHybridRenderModes` is called.

`InteractiveRenderSettings.cs`:

C#

```
using Microsoft.AspNetCore.Components;
using Microsoft.AspNetCore.Components.Web;

namespace MauiBlazorWeb.Shared;

public static class InteractiveRenderSettings
{
    public static IComponentRenderMode? InteractiveServer { get; set; } =
        RenderMode.InteractiveServer;
    public static IComponentRenderMode? InteractiveAuto { get; set; } =
        RenderMode.InteractiveAuto;
    public static IComponentRenderMode? InteractiveWebAssembly { get; set; }
=
        RenderMode.InteractiveWebAssembly;

    public static void ConfigureBlazorHybridRenderModes()
    {
        InteractiveServer = null;
        InteractiveAuto = null;
        InteractiveWebAssembly = null;
    }
}
```

In `MauiProgram.CreateMauiApp` of `MauiProgram.cs`, call `ConfigureBlazorHybridRenderModes`:

C#

```
InteractiveRenderSettings.ConfigureBlazorHybridRenderModes();
```

In the `_Imports.razor` file of the `.Shared.Client` RCL, replace the `@using` statement for Microsoft.AspNetCore.Components.Web.RenderMode with an `@using` statement for `InteractiveRenderSettings` to make the properties of the `InteractiveRenderSettings` class available to components:

diff

```
- @using static Microsoft.AspNetCore.Components.Web.RenderMode
+ @using static InteractiveRenderSettings
```

> **Note**
>
> The assignment of render modes via the RCL's `InteractiveRenderSettings` class properties differs from a typical standalone Blazor Web App. In a Blazor Web App, the render modes are normally provided by **RenderMode** in the Blazor Web App's `_Import` file.

Per-page/component WebAssembly interactivity

- Interactive render mode: **WebAssembly**
- Interactivity location: **Per-page/component**
- Solution projects
  - MAUI (`MauiBlazorWeb`)
  - Blazor Web App
    - Server project: `MauiBlazorWeb.Web`: Doesn't set an `@rendermode` directive attribute on the `HeadOutlet` and `Routes` components of the `App` component (`Components/App.razor`).
    - Client project: `MauiBlazorWeb.Web.Client`
  - RCLs
    - `MauiBlazorWeb.Shared`
    - `MauiBlazorWeb.Shared.Client`: Contains the shared Razor components that set the `InteractiveWebAssembly` render mode in each component. The `.Shared.Client` RCL is maintained separately from the `.Shared` RCL because the app should maintain the components that are required to run on WebAssembly separately from the components that run on server and that stay on the server.

Project references:

- `MauiBlazorWeb` and `MauiBlazorWeb.Web` have project references to `MauiBlazorWeb.Shared`.
- `MauiBlazorWeb.Web` has a project reference to `MauiBlazorWeb.Web.Client`.
- `MauiBlazorWeb.Web.Client` and `MauiBlazorWeb.Shared` have a project reference to `MauiBlazorWeb.Shared.Client`.

Add the following AdditionalAssemblies parameter to the `Router` component instance for the `MauiBlazorWeb.Shared.Client` project assembly (via its `_Imports` file) in the `MauiBlazorWeb.Shared` project's `Routes.razor` file:

```
```

razor

```
<Router AppAssembly="@typeof(Routes).Assembly"
        AdditionalAssemblies="new [] {
typeof(MauiBlazorWeb.Shared.Client._Imports).Assembly }">
    <Found Context="routeData">
        <RouteView RouteData="@routeData"
DefaultLayout="@typeof(Components.Layout.MainLayout)" />
        <FocusOnNavigate RouteData="@routeData" Selector="h1" />
    </Found>
</Router>
```

Add the `MauiBlazorWeb.Shared.Client` project assembly (via its `_Imports` file) with the following AddAdditionalAssemblies call in the `MauiBlazorWeb.Web` project's `Program.cs` file:

C#

```
app.MapRazorComponents<App>()
    .AddInteractiveWebAssemblyRenderMode()
    .AddAdditionalAssemblies(typeof(MauiBlazorWeb.Shared._Imports).Assembly)

.AddAdditionalAssemblies(typeof(MauiBlazorWeb.Shared.Client._Imports).Assemb
ly);
```

Add the following `InteractiveRenderSettings` class is added to the `.Shared.Client` RCL. The class properties are used to set component render modes for server-based components.

The MAUI project is interactive by default, so no action is taken at the project level in the MAUI project other than calling `InteractiveRenderSettings.ConfigureBlazorHybridRenderModes`.

For the Blazor Web App on the web client, the property values are assigned from RenderMode. When the components are loaded into a BlazorWebView for the MAUI project's native client, the render modes are unassigned (`null`) because the MAUI project explicitly sets the render mode properties to `null` when `ConfigureBlazorHybridRenderModes` is called.

`InteractiveRenderSettings.cs` (`.Shared.Client` RCL):

C#

```
using Microsoft.AspNetCore.Components;
using Microsoft.AspNetCore.Components.Web;
```

```
namespace MauiBlazorWeb.Shared;

public static class InteractiveRenderSettings
{
    public static IComponentRenderMode? InteractiveServer { get; set; } =
        RenderMode.InteractiveServer;
    public static IComponentRenderMode? InteractiveAuto { get; set; } =
        RenderMode.InteractiveAuto;
    public static IComponentRenderMode? InteractiveWebAssembly { get; set; }
=
        RenderMode.InteractiveWebAssembly;

    public static void ConfigureBlazorHybridRenderModes()
    {
        InteractiveServer = null;
        InteractiveAuto = null;
        InteractiveWebAssembly = null;
    }
}
```

A slightly different version of the `InteractiveRenderSettings` class is added to the `.Shared` RCL. In the class added to the `.Shared` RCL, `InteractiveRenderSettings.ConfigureBlazorHybridRenderModes` of the `.Shared.Client` RCL is called. This ensures that the render mode of WebAssembly components rendered on the MAUI client are unassigned (`null`) because they're interactive by default on the native client.

`InteractiveRenderSettings.cs` (`.Shared` RCL):

C#

```
using Microsoft.AspNetCore.Components;
using Microsoft.AspNetCore.Components.Web;

namespace MauiBlazorWeb.Shared
{
    public static class InteractiveRenderSettings
    {
        public static IComponentRenderMode? InteractiveServer { get; set; }
=
            RenderMode.InteractiveServer;
        public static IComponentRenderMode? InteractiveAuto { get; set; } =
            RenderMode.InteractiveAuto;
        public static IComponentRenderMode? InteractiveWebAssembly { get;
set; } =
            RenderMode.InteractiveWebAssembly;

        public static void ConfigureBlazorHybridRenderModes()
        {
            InteractiveServer = null;
            InteractiveAuto = null;
```

```
            InteractiveWebAssembly = null;
            MauiBlazorWeb.Shared.Client.InteractiveRenderSettings
                .ConfigureBlazorHybridRenderModes();
        }
    }
}
```

In `MauiProgram.CreateMauiApp` of `MauiProgram.cs`, call `ConfigureBlazorHybridRenderModes`:

C#

```
InteractiveRenderSettings.ConfigureBlazorHybridRenderModes();
```

In the `_Imports.razor` file of the `.Shared.Client` RCL, replace the `@using` statement for Microsoft.AspNetCore.Components.Web.RenderMode with an `@using` statement for `InteractiveRenderSettings` to make the properties of the `InteractiveRenderSettings` class available to components:

diff

```
- @using static Microsoft.AspNetCore.Components.Web.RenderMode
+ @using static InteractiveRenderSettings
```

> **Note**
>
> The assignment of render modes via the RCL's `InteractiveRenderSettings` class properties differs from a typical standalone Blazor Web App. In a Blazor Web App, the render modes are normally provided by RenderMode in the Blazor Web App's `_Import` file.

Using interfaces to support different device implementations

The following example demonstrates how to use an interface to call into different implementations across the web app and the native (MAUI) app. The following example creates a component that displays the device form factor. Use the MAUI abstraction layer for native apps and provide an implementation for the web app.

In the Razor class library (RCL), a `Services` folder contains an `IFormFactor` interface.

`Services/IFormFactor.cs`:

C#

```
namespace MauiBlazorWeb.Shared.Services
{
    public interface IFormFactor
    {
        public string GetFormFactor();
        public string GetPlatform();
    }
}
```

The `Home` component (`Components/Pages/Home.razor`) of the RCL displays the form factor and platform.

`Components/Pages/Home.razor`:

razor

```
@page "/"
@using MauiBlazorWeb.Shared.Services
@inject IFormFactor FormFactor

<PageTitle>Home</PageTitle>

<h1>Hello, world!</h1>

Welcome to your new app running on <em>@factor</em> using
<em>@platform</em>.

@code {
    private string factor => FormFactor.GetFormFactor();
    private string platform => FormFactor.GetPlatform();
}
```

The web and native apps contain the implementations for `IFormFactor`.

In the Blazor Web App, a folder named `Services` contains the following `FormFactor.cs` file with the `FormFactor` implementation for web app use.

`Services/FormFactor.cs` (`MauiBlazorWeb.Web` project):

C#

```
using MauiBlazorWeb.Shared.Services;

namespace MauiBlazorWeb.Web.Services
{
```

```
    public class FormFactor : IFormFactor
    {
        public string GetFormFactor()
        {
            return "Web";
        }

        public string GetPlatform()
        {
            return Environment.OSVersion.ToString();
        }
    }
}
```

In the MAUI project, a folder named `Services` contains the following `FormFactor.cs` file with the `FormFactor` implementation for native use. The MAUI abstractions layer is used to write code that works on all native device platforms.

`Services/FormFactor.cs` (`MauiBlazorWeb` project):

C#

```
using MauiBlazorWeb.Shared.Services;

namespace MauiBlazorWeb.Services
{
    public class FormFactor : IFormFactor
    {
        public string GetFormFactor()
        {
            return DeviceInfo.Idiom.ToString();
        }

        public string GetPlatform()
        {
            return DeviceInfo.Platform.ToString() + " - " +
DeviceInfo.VersionString;
        }
    }
}
```

Dependency injection is used to obtain the implementations of these services.

In the MAUI project, the `MauiProgram.cs` file has following `using` statements at the top of the file:

C#

```
using MauiBlazorWeb.Services;
```

```
using MauiBlazorWeb.Shared.Interfaces;
```

Immediately before the call to `builder.Build()`, `FormFactor` is registered to add device-specific services used by the RCL:

```
C#

builder.Services.AddSingleton<IFormFactor, FormFactor>();
```

In the Blazor Web App, the `Program` file has the following `using` statements at the top of the file:

```
C#

using MauiBlazorWeb.Shared.Interfaces;
using MauiBlazorWeb.Web.Services;
```

Immediately before the call to `builder.Build()`, `FormFactor` is registered to add device-specific services used by the Blazor Web App:

```
C#

builder.Services.AddScoped<IFormFactor, FormFactor>();
```

If the solution also targets WebAssembly via a `.Web.Client` project, an implementation of the preceding API is also required in the `.Web.Client` project.

You can also use compiler preprocessor directives in your RCL to implement different UI depending on the device the app is running on. For this scenario, the app must multi-target the RCL just like the MAUI app does. For an example, see the BethMassi/BethTimeUntil GitHub repository.

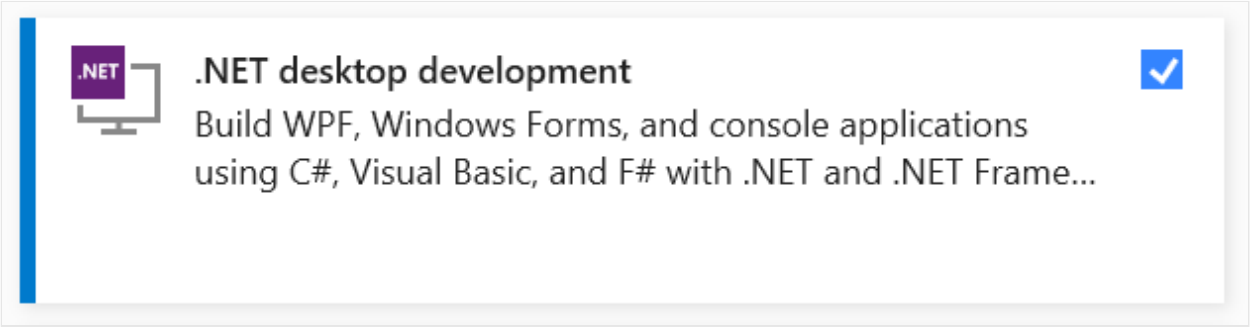
Build a Windows Forms Blazor app

Article • 09/12/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

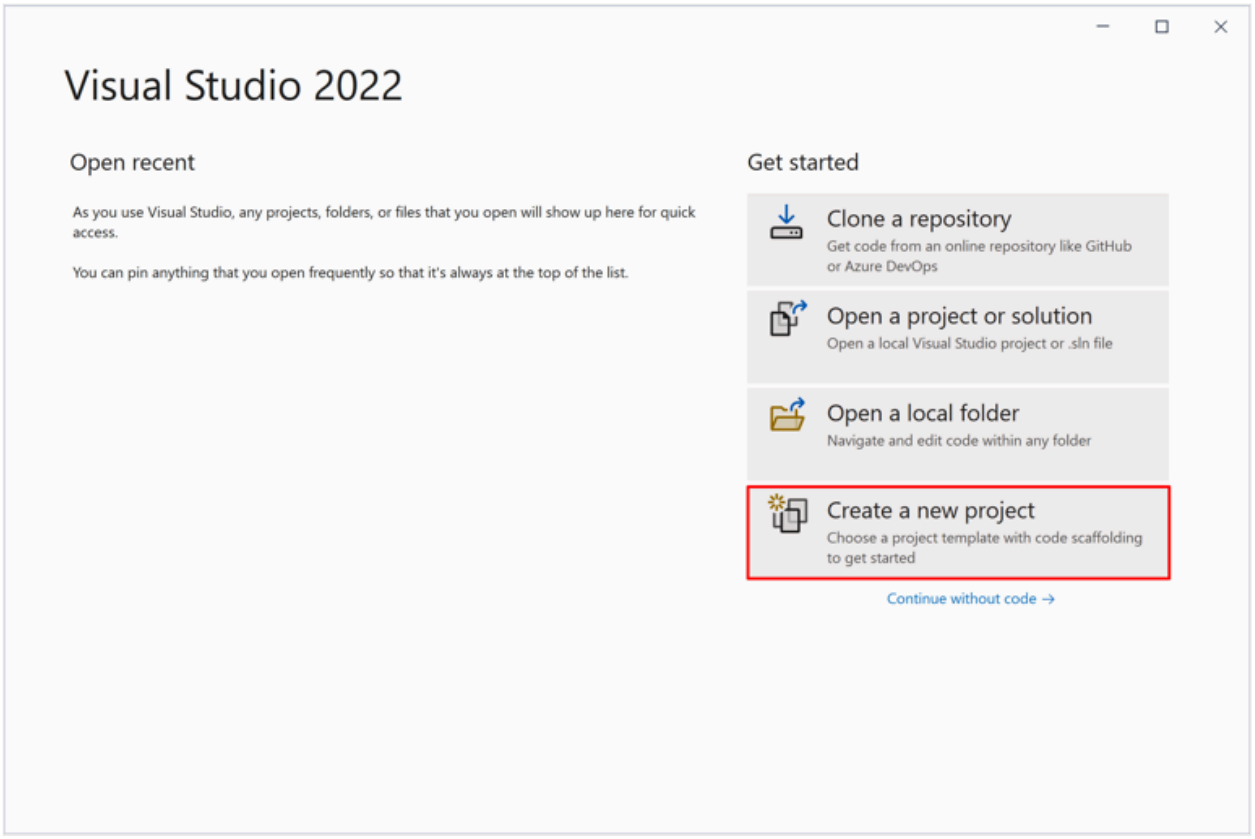
This tutorial shows you how to build and run a Windows Forms Blazor app. You learn how to:



- ✓ Create a Windows Forms Blazor app project
- ✓ Run the app on Windows

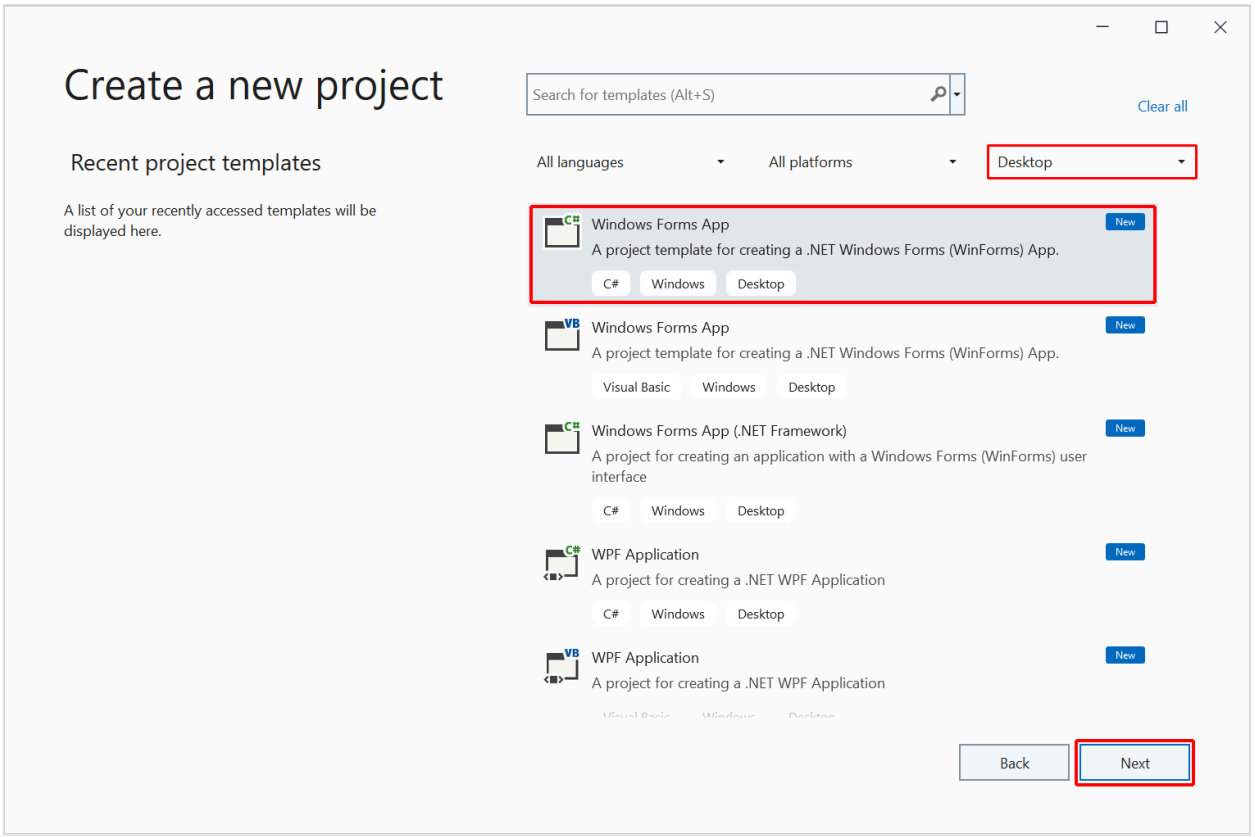
Prerequisites

- Supported platforms (Windows Forms documentation)
- Visual Studio 2022 with the **.NET desktop development** workload



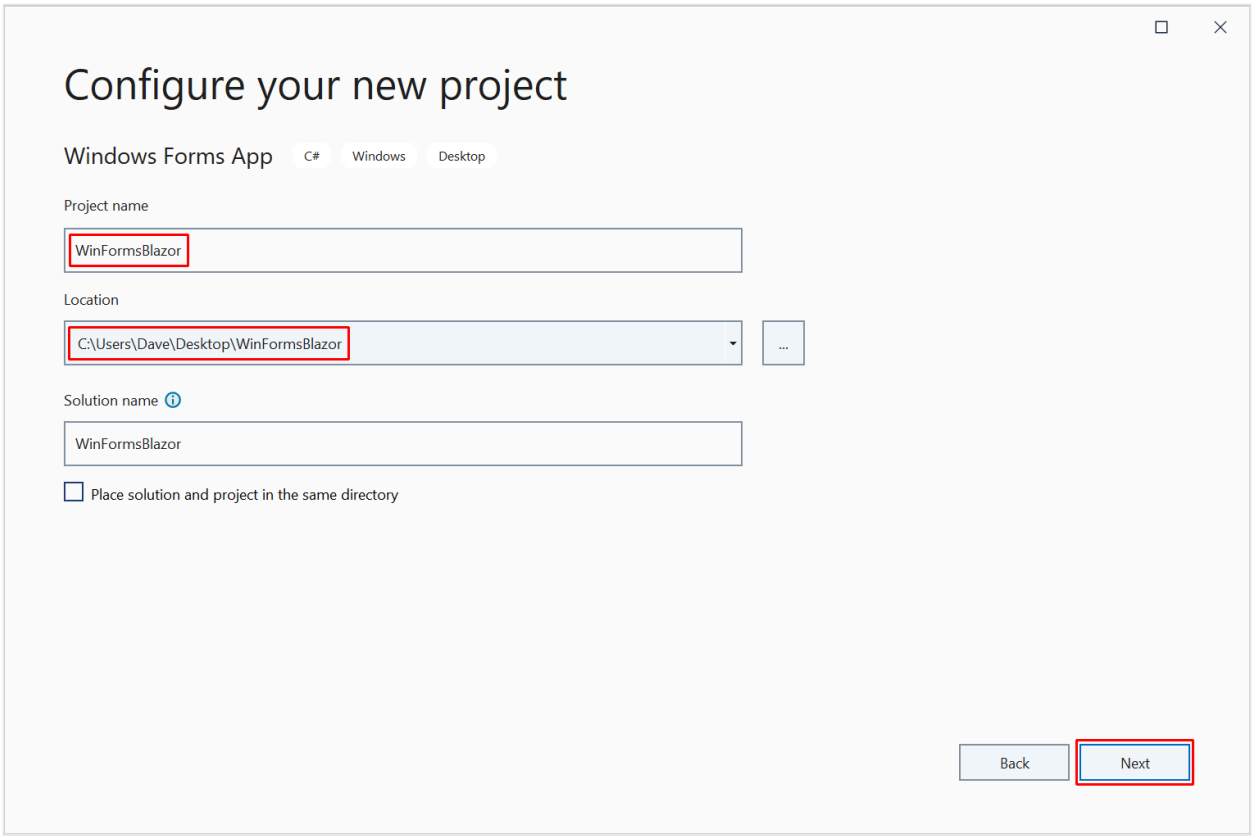
Visual Studio workload

If the **.NET desktop development** workload isn't installed, use the Visual Studio installer to install the workload. For more information, see Modify Visual Studio workloads, components, and language packs.

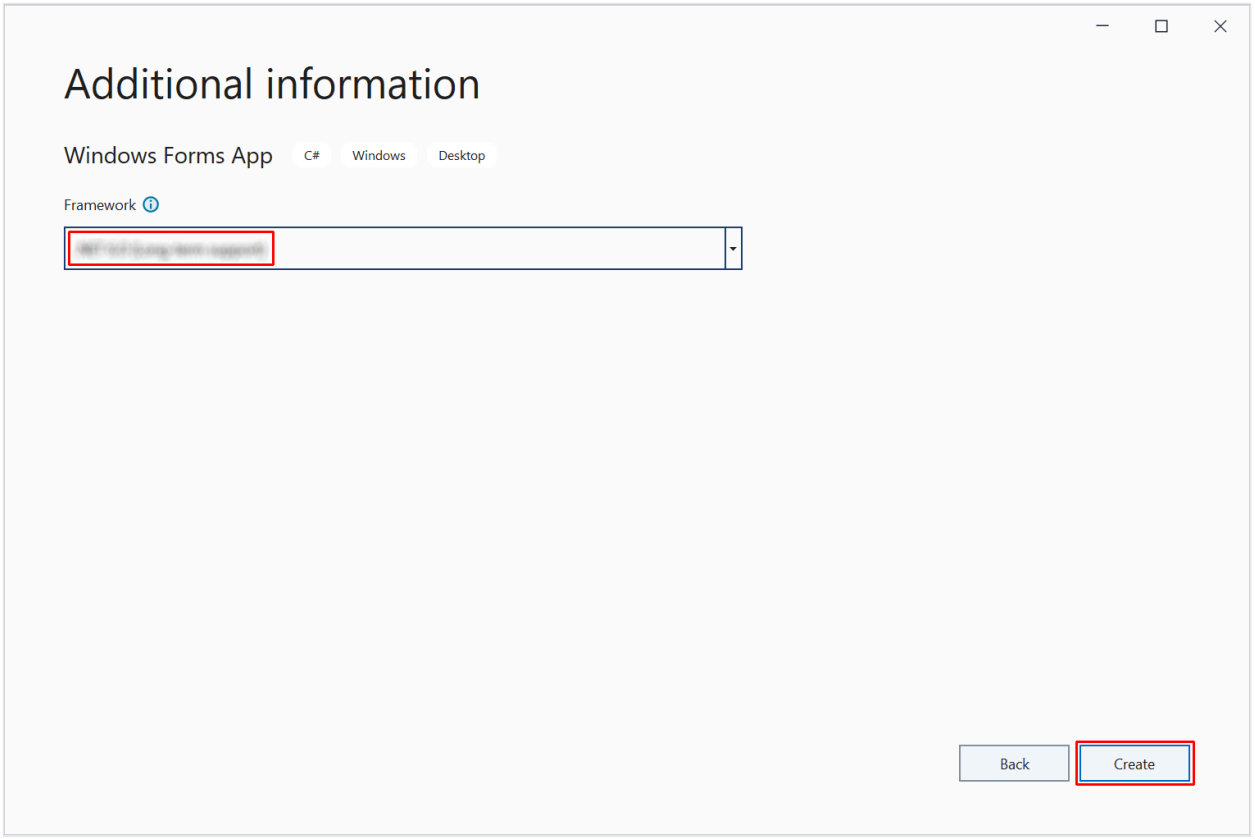


Create a Windows Forms Blazor project

Launch Visual Studio. In the **Start Window**, select **Create a new project**:

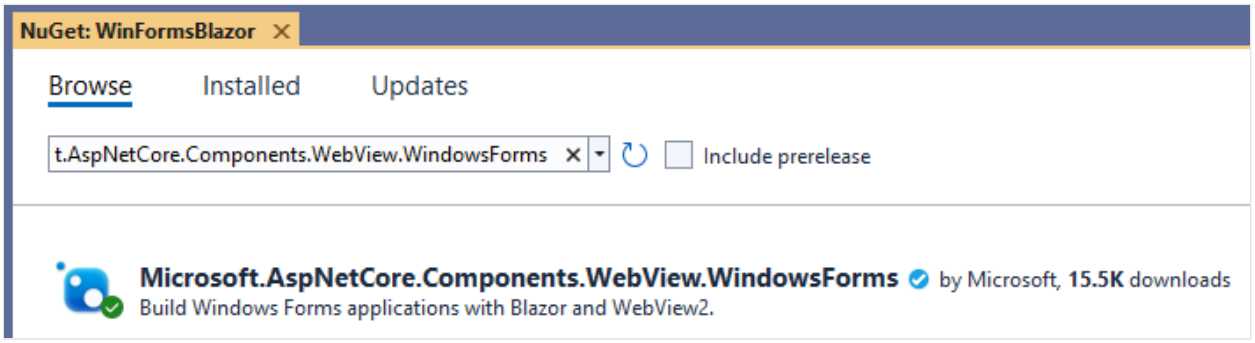


In the **Create a new project** dialog, filter the **Project type** dropdown to **Desktop**. Select the C# project template for **Windows Forms App** and select the **Next** button:



In the **Configure your new project** dialog:

- Set the **Project name** to **WinFormsBlazor**.
- Choose a suitable location for the project.



- Select the **Next** button.

In the **Additional information** dialog, select the framework version with the **Framework** dropdown list. Select the **Create** button:

Use NuGet Package Manager to install the Microsoft.AspNetCore.Components.WebView.WindowsForms NuGet package:

In **Solution Explorer**, right-click the project's name, **WinFormsBlazor**, and select **Edit Project File** to open the project file (`WinFormsBlazor.csproj`).

At the top of the project file, change the SDK to `Microsoft.NET.Sdk.Razor`:

XML

```xml
<Project Sdk="Microsoft.NET.Sdk.Razor">
```

Save the changes to the project file (`WinFormsBlazor.csproj`).

Add an `_Imports.razor` file to the root of the project with an @using directive for Microsoft.AspNetCore.Components.Web.

`_Imports.razor`:

razor

```razor
@using Microsoft.AspNetCore.Components.Web
```

Save the `_Imports.razor` file.

Add a `wwwroot` folder to the project.

Add an `index.html` file to the `wwwroot` folder with the following markup.

`wwwroot/index.html`:

HTML

```html
<!DOCTYPE html>
<html lang="en">
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>WinFormsBlazor</title>
    <base href="/" />
    <link href="css/bootstrap/bootstrap.min.css" rel="stylesheet" />
```

```
    <link href="css/app.css" rel="stylesheet" />
    <link href="WinFormsBlazor.styles.css" rel="stylesheet" />
</head>

<body>

    <div id="app">Loading...</div>

    <div id="blazor-error-ui" data-nosnippet>
        An unhandled error has occurred.
        <a href="" class="reload">Reload</a>
        <a class="dismiss">✕</a>
    </div>

    <script src="_framework/blazor.webview.js"></script>

</body>

</html>
```

Inside the `wwwroot` folder, create a `css` folder to hold stylesheets.

Add an `app.css` stylesheet to the `wwwroot/css` folder with the following content.

`wwwroot/css/app.css`:

```css
html, body {
    font-family: 'Helvetica Neue', Helvetica, Arial, sans-serif;
}

h1:focus {
    outline: none;
}

a, .btn-link {
    color: #0071c1;
}

.btn-primary {
    color: #fff;
    background-color: #1b6ec2;
    border-color: #1861ac;
}

.valid.modified:not([type=checkbox]) {
    outline: 1px solid #26b050;
}

.invalid {
    outline: 1px solid red;
}
```

```
.validation-message {
    color: red;
}

#blazor-error-ui {
    background: lightyellow;
    bottom: 0;
    box-shadow: 0 -1px 2px rgba(0, 0, 0, 0.2);
    display: none;
    left: 0;
    padding: 0.6rem 1.25rem 0.7rem 1.25rem;
    position: fixed;
    width: 100%;
    z-index: 1000;
}

    #blazor-error-ui .dismiss {
        cursor: pointer;
        position: absolute;
        right: 0.75rem;
        top: 0.5rem;
    }
```

Inside the `wwwroot/css` folder, create a `bootstrap` folder. Inside the `bootstrap` folder, place a copy of `bootstrap.min.css`. You can obtain the latest version of `bootstrap.min.css` from the Bootstrap website. Because all of the content at the site is versioned in the URL, a direct link can't be provided here. Therefore, follow navigation bar links to **Docs** > **Download** to obtain `bootstrap.min.css`.

Add the following `Counter` component to the root of the project, which is the default `Counter` component found in Blazor project templates.

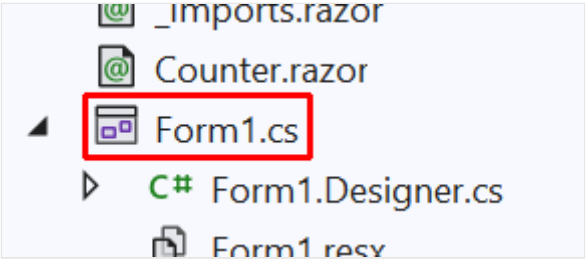
`Counter.razor`:

razor

```
<h1>Counter</h1>

<p>Current count: @currentCount</p>

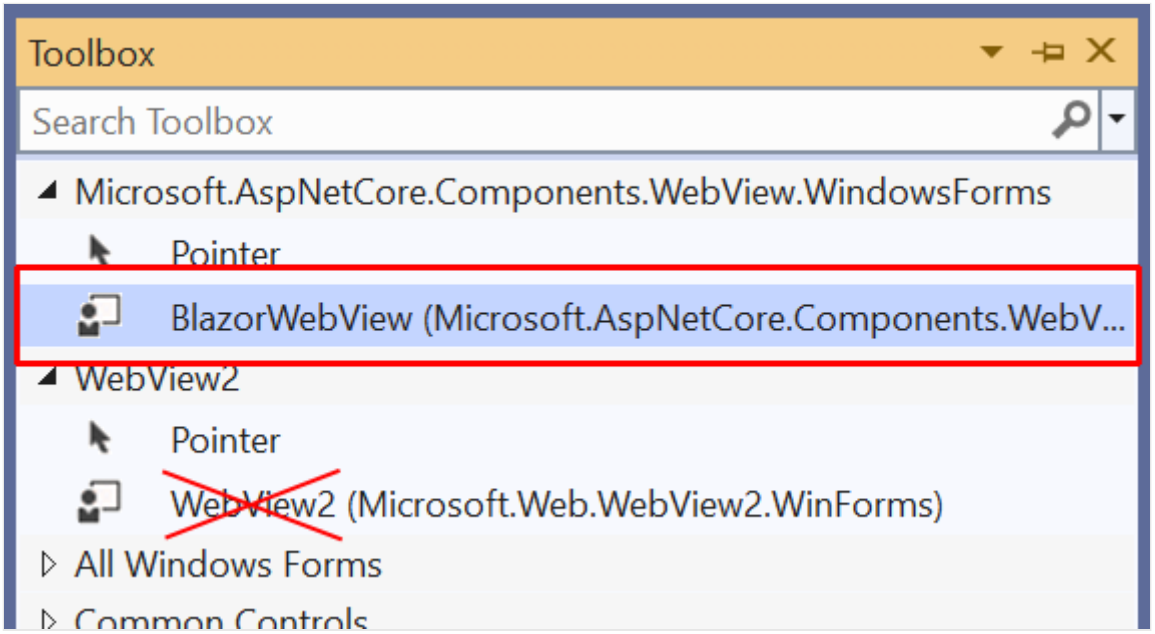
<button class="btn btn-primary" @onclick="IncrementCount">Click me</button>



@code {
    private int currentCount = 0;

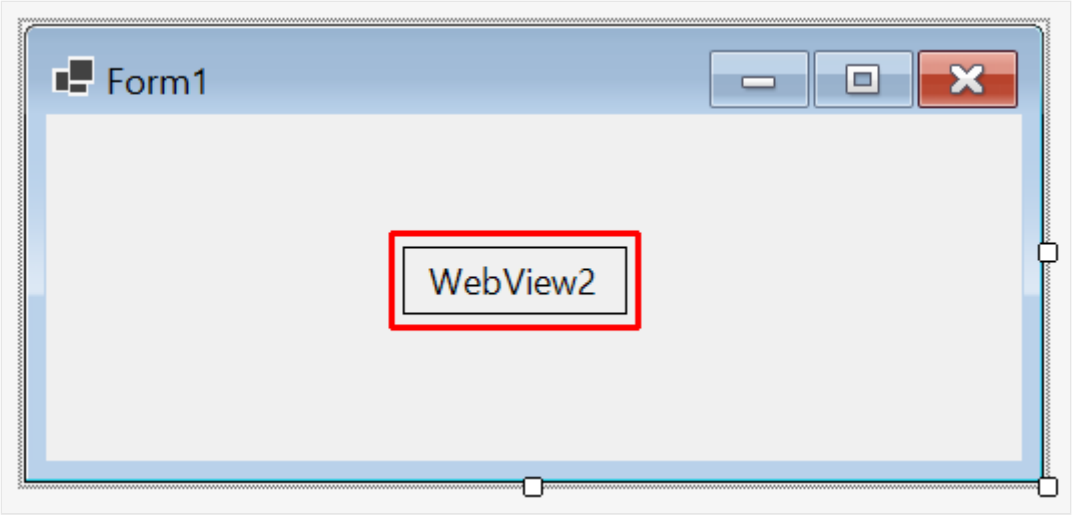
    private void IncrementCount()
    {
        currentCount++;
```

```
    }
}
```



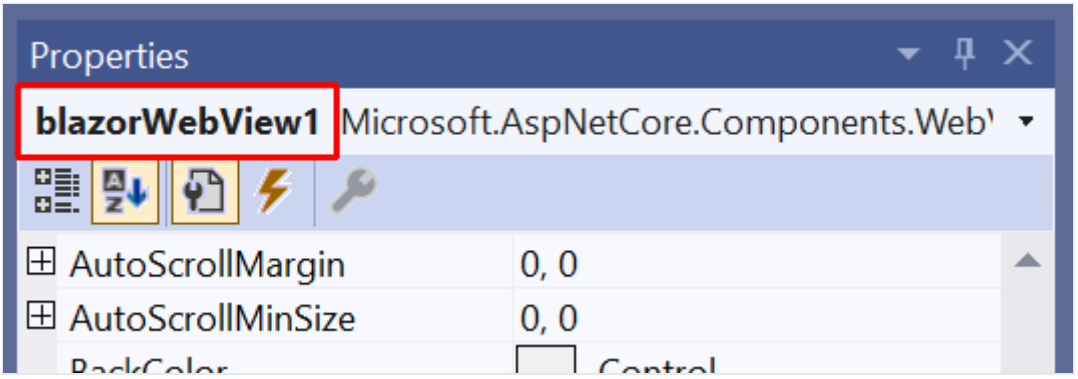
Save the `Counter` component (`Counter.razor`).

In **Solution Explorer**, double-click on the `Form1.cs` file to open the designer:

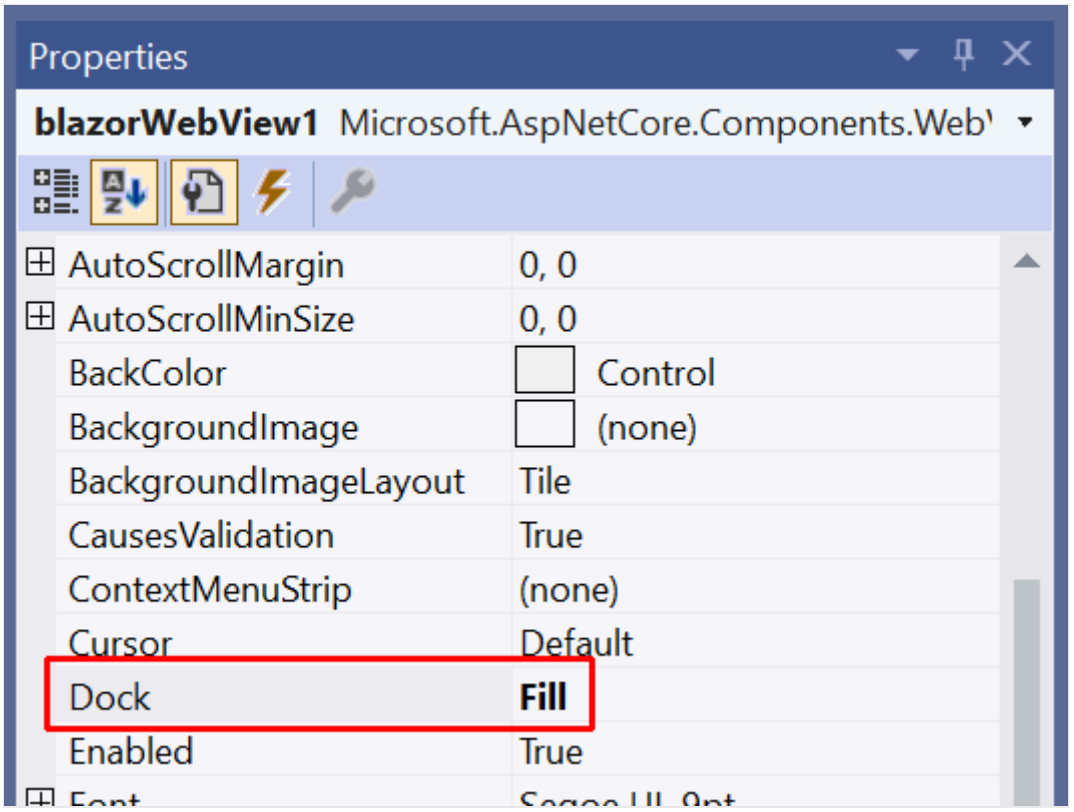


Open the **Toolbox** by either selecting the **Toolbox** button along the left edge of the Visual Studio window or selecting the **View** > **Toolbox** menu command.

Locate the **`BlazorWebView`** control under **`Microsoft.AspNetCore.Components.WebView.WindowsForms`**. Drag the BlazorWebView from the **Toolbox** into the `Form1` designer. Be careful not to accidentally drag a **`WebView2`** control into the form.



Visual Studio shows the BlazorWebView control in the form designer as `WebView2` and automatically names the control `blazorWebView1`:



In `Form1`, select the BlazorWebView (`WebView2`) with a single click.

In the BlazorWebView's **Properties**, confirm that the control is named `blazorWebView1`. If the name isn't `blazorWebView1`, the wrong control was dragged from the **Toolbox**. Delete the `WebView2` control in `Form1` and drag the **`BlazorWebView` control** into the form.

In the control's properties, change the BlazorWebView's **Dock** value to **Fill**:

In the `Form1` designer, right-click `Form1` and select **View Code**.

Add namespaces for Microsoft.AspNetCore.Components.WebView.WindowsForms and Microsoft.Extensions.DependencyInjection to the top of the `Form1.cs` file:

C#

```
using Microsoft.AspNetCore.Components.WebView.WindowsForms;
using Microsoft.Extensions.DependencyInjection;
```

Inside the `Form1` constructor, after the `InitializeComponent` method call, add the following code:

C#

```
var services = new ServiceCollection();
services.AddWindowsFormsBlazorWebView();
blazorWebView1.HostPage = "wwwroot\\index.html";
blazorWebView1.Services = services.BuildServiceProvider();
blazorWebView1.RootComponents.Add<Counter>("#app");
```

> ⓘ Note
>
> The `InitializeComponent` method is automatically generated at app build time and added to the compilation object for the calling class.

The final, complete C# code of `Form1.cs` with a file-scoped namespace:

```C#
using Microsoft.AspNetCore.Components.WebView.WindowsForms;
using Microsoft.Extensions.DependencyInjection;

namespace WinFormsBlazor;

public partial class Form1 : Form
{
    public Form1()
    {
        InitializeComponent();

        var services = new ServiceCollection();
        services.AddWindowsFormsBlazorWebView();
        blazorWebView1.HostPage = "wwwroot\\index.html";
        blazorWebView1.Services = services.BuildServiceProvider();
        blazorWebView1.RootComponents.Add<Counter>("#app");
    }
}
```

Run the app

Select the start button in the Visual Studio toolbar:

The app running on Windows:

Next steps

In this tutorial, you learned how to:

- ✓ Create a Windows Forms Blazor app project
- ✓ Run the app on Windows

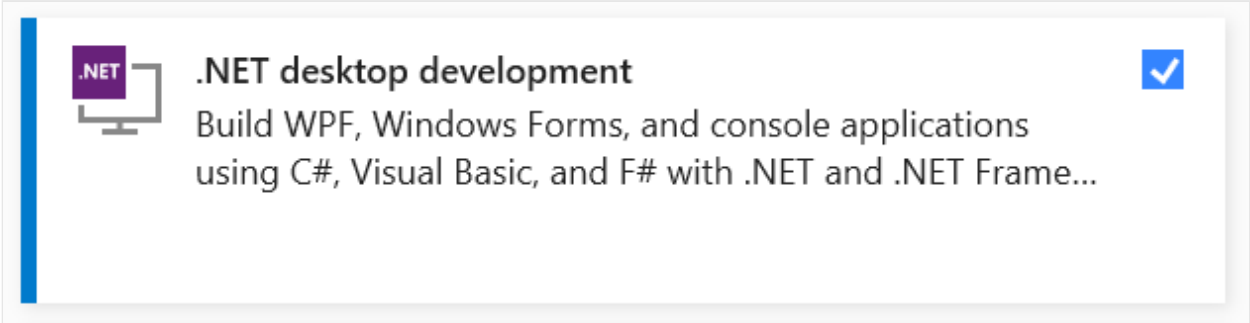
Learn more about Blazor Hybrid apps:

ASP.NET Core Blazor Hybrid

Build a Windows Presentation Foundation (WPF) Blazor app

Article • 03/08/2024

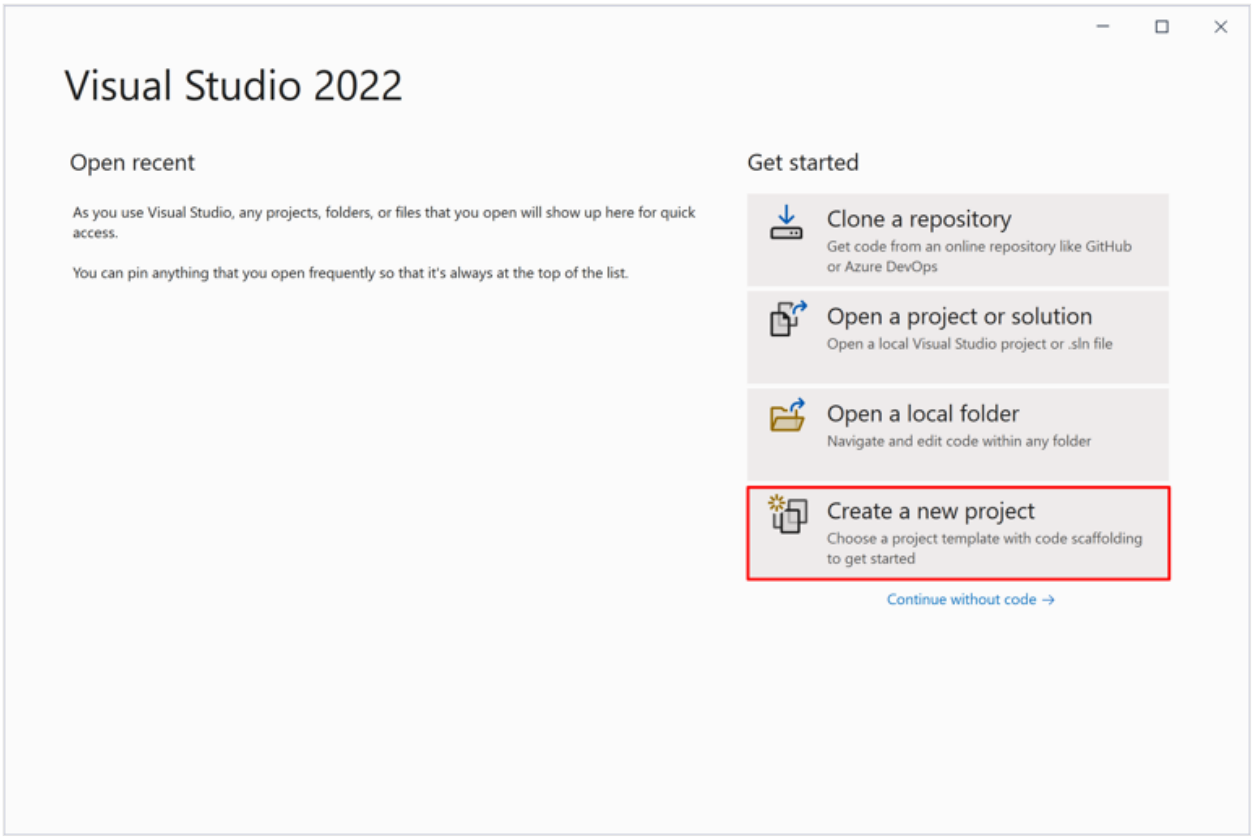
This tutorial shows you how to build and run a WPF Blazor app. You learn how to:



- ✓ Create a WPF Blazor app project
- ✓ Add a Razor component to the project
- ✓ Run the app on Windows

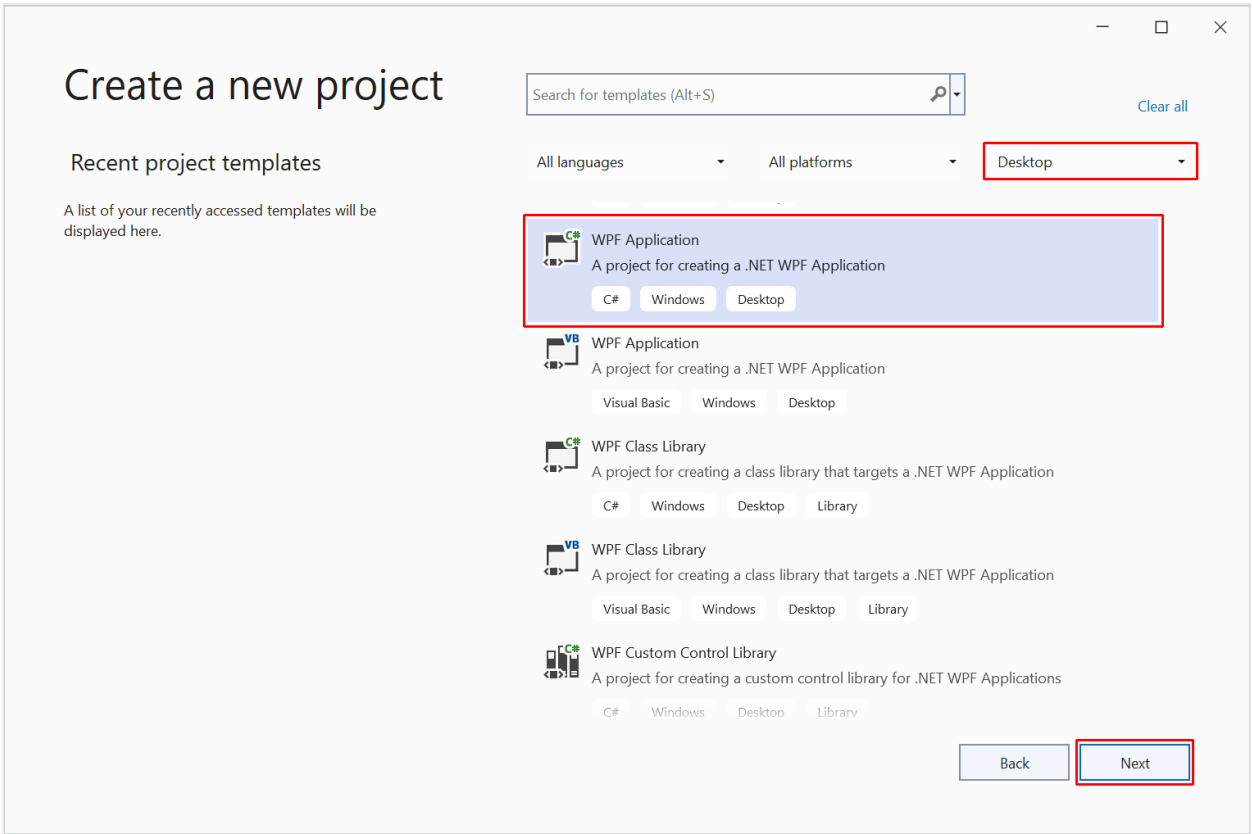
Prerequisites

- Supported platforms (WPF documentation)
- Visual Studio 2022 with the **.NET desktop development** workload



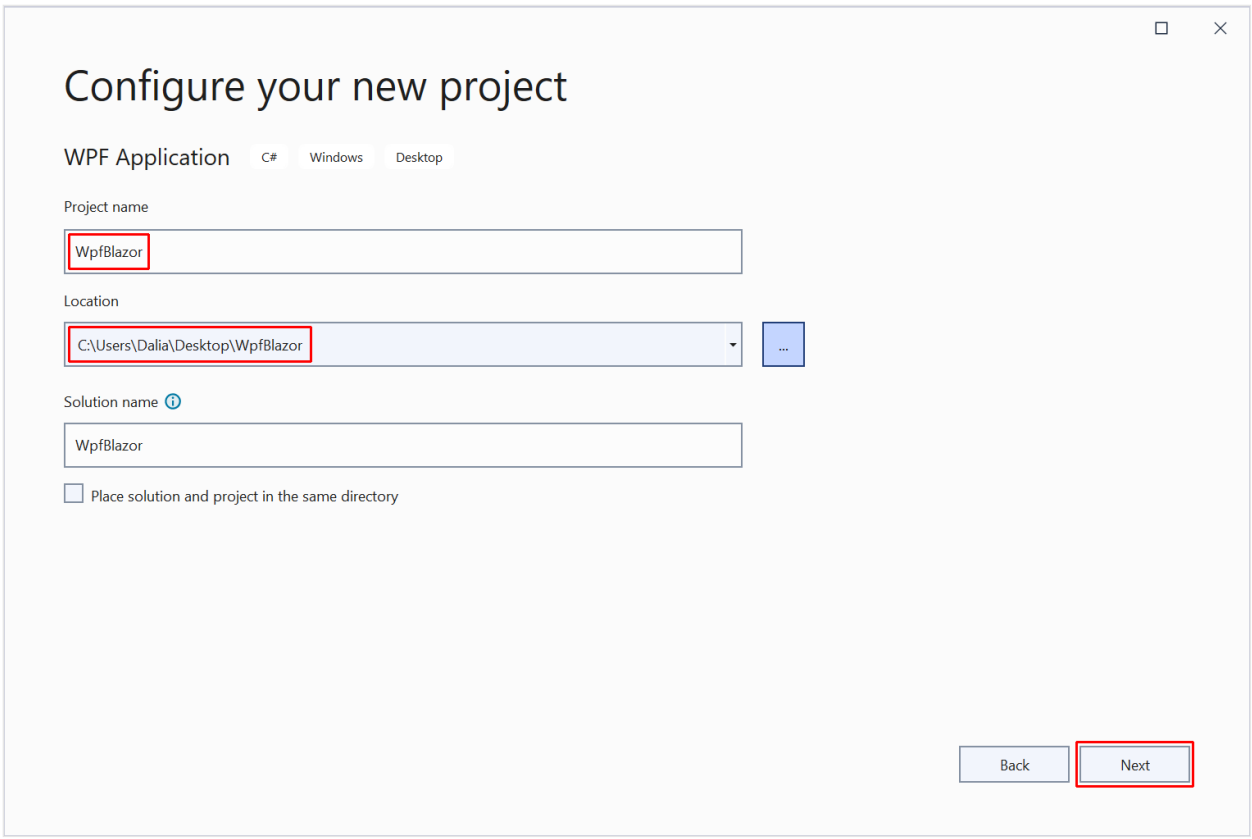
Visual Studio workload

If the **.NET desktop development** workload isn't installed, use the Visual Studio installer to install the workload. For more information, see Modify Visual Studio workloads, components, and language packs.

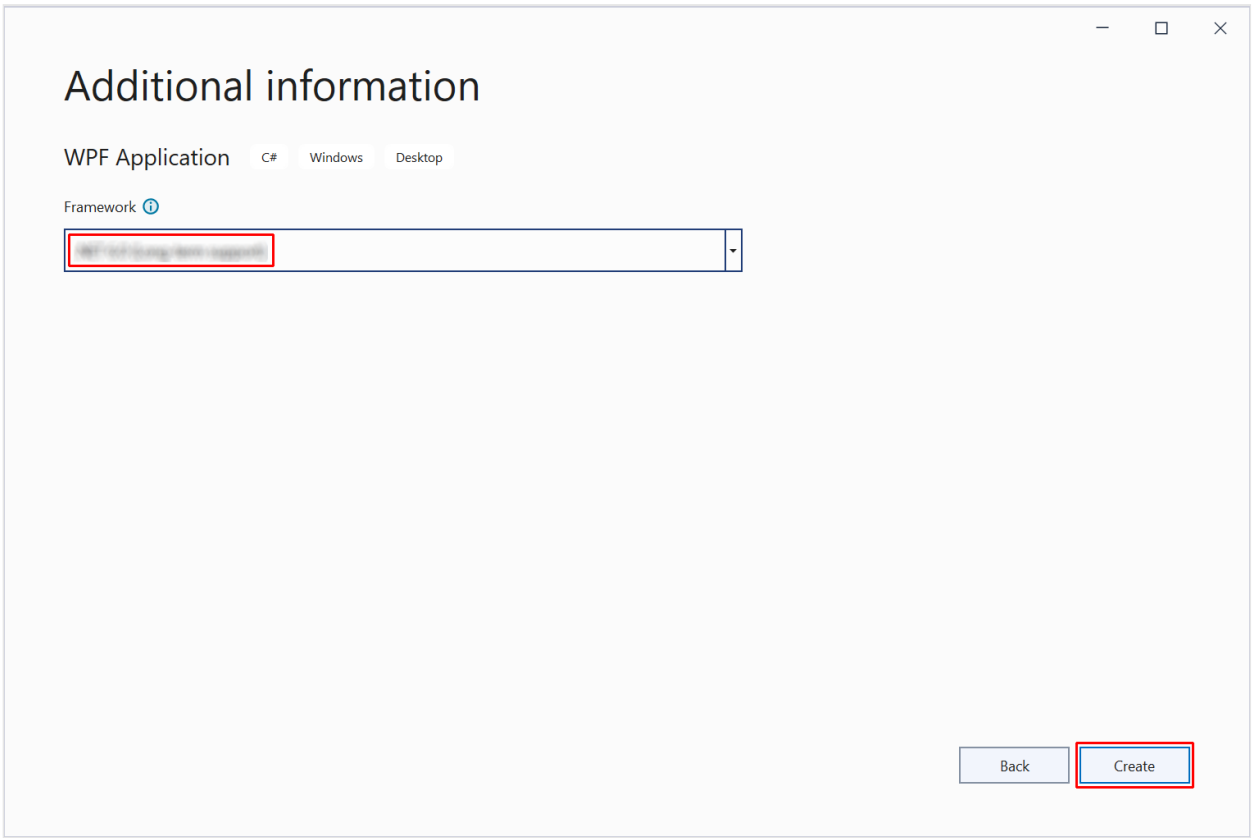


Create a WPF Blazor project

Launch Visual Studio. In the **Start Window**, select **Create a new project**:

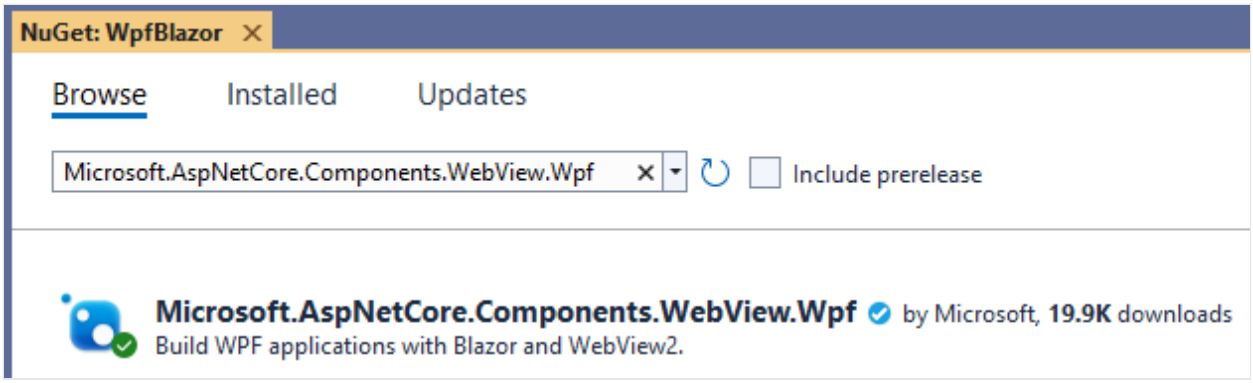


In the **Create a new project** dialog, filter the **Project type** dropdown to **Desktop**. Select the C# project template for **WPF Application** and select the **Next** button:



In the **Configure your new project** dialog:

- Set the **Project name** to **WpfBlazor**.
- Choose a suitable location for the project.



- Select the **Next** button.

In the **Additional information** dialog, select the framework version with the **Framework** dropdown list. Select the **Create** button:

Use NuGet Package Manager to install the Microsoft.AspNetCore.Components.WebView.Wpf NuGet package:

In **Solution Explorer**, right-click the project's name, **WpfBlazor**, and select **Edit Project File** to open the project file (`WpfBlazor.csproj`).

At the top of the project file, change the SDK to `Microsoft.NET.Sdk.Razor`:

XML

```xml
<Project Sdk="Microsoft.NET.Sdk.Razor">
```

In the project file's existing `<PropertyGroup>` add the following markup to set the app's root namespace, which is `WpfBlazor` in this tutorial:

XML

```xml
<RootNamespace>WpfBlazor</RootNamespace>
```

> **Note**
>
> The preceding guidance on setting the project's root namespace is a temporary workaround. For more information, see [Blazor][Wpf] Root namespace related issue (dotnet/maui #5861).

Save the changes to the project file (`WpfBlazor.csproj`).

Add an `_Imports.razor` file to the root of the project with an `@using` directive for `Microsoft.AspNetCore.Components.Web`.

`_Imports.razor`:

razor

```razor
@using Microsoft.AspNetCore.Components.Web
```

Save the `_Imports.razor` file.

Add a `wwwroot` folder to the project.

Add an `index.html` file to the `wwwroot` folder with the following markup.

`wwwroot/index.html`:

HTML

```
<!DOCTYPE html>
<html lang="en">

<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>WpfBlazor</title>
    <base href="/" />
    <link href="css/bootstrap/bootstrap.min.css" rel="stylesheet" />
    <link href="css/app.css" rel="stylesheet" />
    <link href="WpfBlazor.styles.css" rel="stylesheet" />
</head>

<body>
    <div id="app">Loading...</div>

    <div id="blazor-error-ui" data-nosnippet>
        An unhandled error has occurred.
        <a href="" class="reload">Reload</a>
        <a class="dismiss">✕</a>
    </div>
    <script src="_framework/blazor.webview.js"></script>
</body>

</html>
```

Inside the `wwwroot` folder, create a `css` folder.

Add an `app.css` stylesheet to the `wwwroot/css` folder with the following content.

`wwwroot/css/app.css`:

css

```
html, body {
    font-family: 'Helvetica Neue', Helvetica, Arial, sans-serif;
}

h1:focus {
    outline: none;
}
```

```
a, .btn-link {
    color: #0071c1;
}

.btn-primary {
    color: #fff;
    background-color: #1b6ec2;
    border-color: #1861ac;
}

.valid.modified:not([type=checkbox]) {
    outline: 1px solid #26b050;
}

.invalid {
    outline: 1px solid red;
}

.validation-message {
    color: red;
}

#blazor-error-ui {
    background: lightyellow;
    bottom: 0;
    box-shadow: 0 -1px 2px rgba(0, 0, 0, 0.2);
    display: none;
    left: 0;
    padding: 0.6rem 1.25rem 0.7rem 1.25rem;
    position: fixed;
    width: 100%;
    z-index: 1000;
}

    #blazor-error-ui .dismiss {
        cursor: pointer;
        position: absolute;
        right: 0.75rem;
        top: 0.5rem;
    }
```

Inside the `wwwroot/css` folder, create a `bootstrap` folder. Inside the `bootstrap` folder, place a copy of `bootstrap.min.css`. You can obtain the latest version of `bootstrap.min.css` from the Bootstrap website. Follow navigation bar links to **Docs** > **Download**. A direct link can't be provided here because all of the content at the site is versioned in the URL.

Add the following `Counter` component to the root of the project, which is the default `Counter` component found in Blazor project templates.

`Counter.razor`:

razor

```razor
<h1>Counter</h1>

<p>Current count: @currentCount</p>

<button class="btn btn-primary" @onclick="IncrementCount">Click me</button>

@code {
    private int currentCount = 0;

    private void IncrementCount()
    {
        currentCount++;
    }
}
```

Save the `Counter` component (`Counter.razor`).

If the `MainWindow` designer isn't open, open it by double-clicking the `MainWindow.xaml` file in **Solution Explorer**. In the `MainWindow` designer, replace the XAML code with the following:

XAML

```xaml
<Window x:Class="WpfBlazor.MainWindow"
        xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        xmlns:d="http://schemas.microsoft.com/expression/blend/2008"
        xmlns:mc="http://schemas.openxmlformats.org/markup-
compatibility/2006"
        xmlns:blazor="clr-
namespace:Microsoft.AspNetCore.Components.WebView.Wpf;assembly=Microsoft.Asp
NetCore.Components.WebView.Wpf"
        xmlns:local="clr-namespace:WpfBlazor"
        mc:Ignorable="d"
        Title="MainWindow" Height="450" Width="800">
    <Grid>
        <blazor:BlazorWebView HostPage="wwwroot\index.html" Services="
{DynamicResource services}">
            <blazor:BlazorWebView.RootComponents>
                <blazor:RootComponent Selector="#app" ComponentType="{x:Type
local:Counter}" />
            </blazor:BlazorWebView.RootComponents>
        </blazor:BlazorWebView>
    </Grid>
</Window>
```

In **Solution Explorer**, right-click `MainWindow.xaml` and select **View Code**:

Add the namespace Microsoft.Extensions.DependencyInjection to the top of the `MainWindow.xaml.cs` file:

C#

```
using Microsoft.Extensions.DependencyInjection;
```

Inside the `MainWindow` constructor, after the `InitializeComponent` method call, add the following code:

C#

```
var serviceCollection = new ServiceCollection();
serviceCollection.AddWpfBlazorWebView();
Resources.Add("services", serviceCollection.BuildServiceProvider());
```

> **Note**
>
> The `InitializeComponent` method is automatically generated at app build time and added to the compilation object for the calling class.

The final, complete C# code of `MainWindow.xaml.cs` with a file-scoped namespace and comments removed:

C#

```
using System;
using System.Collections.Generic;
using System.Linq;
```

```
using System.Text;
using System.Threading.Tasks;
using System.Windows;
using System.Windows.Controls;
using System.Windows.Data;
using System.Windows.Documents;
using System.Windows.Input;
using System.Windows.Media;
using System.Windows.Media.Imaging;
using System.Windows.Navigation;
using System.Windows.Shapes;
using Microsoft.Extensions.DependencyInjection;

namespace WpfBlazor;

public partial class MainWindow : Window
{
    public MainWindow()
    {
        InitializeComponent();

        var serviceCollection = new ServiceCollection();
        serviceCollection.AddWpfBlazorWebView();
        Resources.Add("services", serviceCollection.BuildServiceProvider());
    }
}
```

Run the app

Select the start button in the Visual Studio toolbar:

The app running on Windows:

Next steps

In this tutorial, you learned how to:

- ✓ Create a WPF Blazor app project
- ✓ Add a Razor component to the project
- ✓ Run the app on Windows

ASP.NET Core Blazor Hybrid routing and navigation

Article • 09/12/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article explains how to manage request routing and navigation in Blazor Hybrid apps.

URI request routing behavior

Default URI request routing behavior:

- A link is *internal* if the host name and scheme match between the app's origin URI and the request URI. When the host names and schemes don't match or if the link sets `target="_blank"`, the link is considered *external*.
- If the link is internal, the link is opened in the `BlazorWebView` by the app.
- If the link is external, the link is opened by an app determined by the device based on the device's registered handler for the link's scheme.
- For internal links that appear to request a file because the last segment of the URI uses dot notation (for example, `/file.x`, `/Maryia.Melnyk`, `/image.gif`) but don't point to any static content:
  - WPF and Windows Forms: The host page content is returned.
  - .NET MAUI: A 404 response is returned.

To change the link handling behavior for links that don't set `target="_blank"`, register the `UrlLoading` event and set the UrlLoadingEventArgs.UrlLoadingStrategy property. The UrlLoadingStrategy enumeration allows setting link handling behavior to any of the following values:

- OpenExternally: Load the URL using an app determined by the device. This is the default strategy for URIs with an external host.

- OpenInWebView: Load the URL within the `BlazorWebView`. This is the default strategy for URLs with a host matching the app origin. ***Don't use this strategy for external links unless you can ensure the destination URI is fully trusted.***
- CancelLoad: Cancels the current URL loading attempt.

The UrlLoadingEventArgs.Url property is used to get or dynamically set the URL.

> ⚠ **Warning**
>
> External links are opened in an app determined by the device. Opening external links within a `BlazorWebView` can introduce security vulnerabilities and shouldn't be enabled unless you can ensure that the external links are fully trusted.

API documentation:

- .NET MAUI: BlazorWebView.UrlLoading
- WPF: BlazorWebView.UrlLoading
- Windows Forms: BlazorWebView.UrlLoading

The Microsoft.AspNetCore.Components.WebView namespace is required for the following examples:

C#

```
using Microsoft.AspNetCore.Components.WebView;
```

Add the following event handler to the constructor of the `Page` where the `BlazorWebView` is created, which is `MainPage.xaml.cs` in an app created from the .NET MAUI project template.

C#

```
blazorWebView.UrlLoading +=
    (sender, urlLoadingEventArgs) =>
    {
        if (urlLoadingEventArgs.Url.Host != "0.0.0.0")
        {
            urlLoadingEventArgs.UrlLoadingStrategy =
                UrlLoadingStrategy.OpenInWebView;
        }
    };
```

Get or set a path for initial navigation

Use the `BlazorWebView.StartPath` property to get or set the path for initial navigation within the Blazor navigation context when the Razor component is finished loading. The default start path is the relative root URL path (`/`).

In the `MainPage` XAML markup (`MainPage.xaml`), specify the start path. The following example sets the path to a welcome page at `/welcome`:

XAML

```
<BlazorWebView ... StartPath="/welcome" ...>
    ...
<BlazorWebView>
```

Alternatively, the start path can be set in the `MainPage` constructor (`MainPage.xaml.cs`):

C#

```
blazorWebView.StartPath = "/welcome";
```

Navigation among pages and Razor components

This section explains how to navigate among .NET MAUI content pages and Razor components.

The .NET MAUI Blazor hybrid project template isn't a Shell-based app, so the URI-based navigation for Shell-based apps isn't suitable for a project based on the project template. The examples in this section use a NavigationPage to perform modeless or modal navigation.

In the following example:

- The namespace of the app is `MauiBlazor`, which matches the suggested project name of the Build a .NET MAUI Blazor Hybrid app tutorial.
- A ContentPage is placed in a new folder added to the app named `Views`.

In `App.xaml.cs`, create the `MainPage` as a NavigationPage by making the following change:

diff

```
- MainPage = new MainPage();
```

```
+ MainPage = new NavigationPage(new MainPage());
```

`Views/NavigationExample.xaml`:

XAML

```
<ContentPage xmlns="http://schemas.microsoft.com/dotnet/2021/maui"
             xmlns:x="http://schemas.microsoft.com/winfx/2009/xaml"
             xmlns:local="clr-namespace:MauiBlazor"
             x:Class="MauiBlazor.Views.NavigationExample"
             Title="Navigation Example"
             BackgroundColor="{DynamicResource PageBackgroundColor}">
    <StackLayout>
        <Label Text="Navigation Example"
               VerticalOptions="Center"
               HorizontalOptions="Center"
               FontSize="24" />
        <Button x:Name="CloseButton"
                Clicked="CloseButton_Clicked"
                Text="Close" />
    </StackLayout>
</ContentPage>
```

In the following `NavigationExample` code file, the `CloseButton_Clicked` event handler for the close button calls PopAsync to pop the ContentPage off of the navigation stack.

`Views/NavigationExample.xaml.cs`:

C#

```
namespace MauiBlazor.Views;

public partial class NavigationExample : ContentPage
{
    public NavigationExample()
    {
        InitializeComponent();
    }

    private async void CloseButton_Clicked(object sender, EventArgs e)
    {
        await Navigation.PopAsync();
    }
}
```

In a Razor component:

- Add the namespace for the app's content pages. In the following example, the namespace is `MauiBlazor.Views`.

- Add an HTML `button` element with an @onclick event handler to open the content page. The event handler method is named `OpenPage`.
- In the event handler, call PushAsync to push the ContentPage, `NavigationExample`, onto the navigation stack.

The following example is based on the `Index` component in the .NET MAUI Blazor project template.

`Pages/Index.razor`:

razor

```
@page "/"
@using MauiBlazor.Views

<h1>Hello, world!</h1>

Welcome to your new app.

<SurveyPrompt Title="How is Blazor working for you?" />

<button class="btn btn-primary" @onclick="OpenPage">Open</button>

@code {
    private async void OpenPage()
    {
        await App.Current.MainPage.Navigation.PushAsync(new
NavigationExample());
    }
}
```

To change the preceding example to modal navigation:

- In the `CloseButton_Clicked` method (`Views/NavigationExample.xaml.cs`), change PopAsync to PopModalAsync:

  diff

  ```
  - await Navigation.PopAsync();
  + await Navigation.PopModalAsync();
  ```

- In the `OpenPage` method (`Pages/Index.razor`), change PushAsync to PushModalAsync:

  diff

  ```
  - await App.Current.MainPage.Navigation.PushAsync(new
  NavigationExample());
  ```

```
+ await App.Current.MainPage.Navigation.PushModalAsync(new
NavigationExample());
```

For more information, see the following resources:

- NavigationPage article (.NET MAUI documentation)
- NavigationPage (API documentation)

App linking (deep linking)

It's often desirable to connect a website and a mobile app so that links on a website launch the mobile app and display content in the mobile app. App linking, also known as *deep linking*, is a technique that enables a mobile device to respond to a URI and launch content in a mobile app that's represented by the URI.

For more information, see the following articles in the .NET MAUI documentation:

- Android app links
- Apple universal links

ASP.NET Core Blazor Hybrid static files

Article • 09/12/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article describes how to consume static asset files in Blazor Hybrid apps.

In a Blazor Hybrid app, static files are *app resources*, accessed by Razor components using the following approaches:

- .NET MAUI: .NET MAUI file system helpers
- WPF and Windows Forms: ResourceManager

When static assets are only used in the Razor components, static assets can be consumed from the web root (`wwwroot` folder) in a similar way to Blazor WebAssembly and Blazor Server apps. For more information, see the Static assets limited to Razor components section.

.NET MAUI

In .NET MAUI apps, *raw assets* using the `MauiAsset` build action and .NET MAUI file system helpers are used for static assets.

> **Note**
>
> Interfaces, classes, and supporting types to work with storage on devices across all supported platforms for features such as choosing a file, saving preferences, and using secure storage are in the **Microsoft.Maui.Storage** namespace. The namespace is available throughout a MAUI Blazor Hybrid app, so there's no need to specify a `using` statement in a class file or an `@using` Razor directive in a Razor component for the namespace.

Place raw assets into the `Resources/Raw` folder of the app. The example in this section uses a static text file.

`Resources/Raw/Data.txt`:

```text
This is text from a static text file resource.
```

The following Razor component:

- Calls OpenAppPackageFileAsync to obtain a Stream for the resource.
- Reads the Stream with a StreamReader.
- Calls StreamReader.ReadToEndAsync to read the file.

`Pages/StaticAssetExample.razor`:

```razor
@page "/static-asset-example"
@using System.IO
@using Microsoft.Extensions.Logging
@inject ILogger<StaticAssetExample> Logger

<h1>Static Asset Example</h1>

<p>@dataResourceText</p>

@code {
    public string dataResourceText = "Loading resource ...";

    protected override async Task OnInitializedAsync()
    {
        try
        {
            using var stream =
                await FileSystem.OpenAppPackageFileAsync("Data.txt");
            using var reader = new StreamReader(stream);

            dataResourceText = await reader.ReadToEndAsync();
        }
        catch (FileNotFoundException ex)
        {
            dataResourceText = "Data file not found.";
            Logger.LogError(ex, "'Resource/Raw/Data.txt' not found.");
        }
    }
}
```

For more information, see the following resources:

- Target multiple platforms from .NET MAUI single project (.NET MAUI documentation)

- Improve consistency with resizetizer (dotnet/maui #4367)

WPF

Place the asset into a folder of the app, typically at the project's root, such as a `Resources` folder. The example in this section uses a static text file.

`Resources/Data.txt`:

```text
This is text from a static text file resource.
```

If a `Properties` folder doesn't exist in the app, create a `Properties` folder in the root of the app.

If the `Properties` folder doesn't contain a resources file (`Resources.resx`), create the file in **Solution Explorer** with the **Add** > **New Item** contextual menu command.

Double-click the `Resource.resx` file.

Select **Strings** > **Files** from the dropdown list.

Select **Add Resource** > **Add Existing File**. If prompted by Visual Studio to confirm editing the file, select **Yes**. Navigate to the `Resources` folder, select the `Data.txt` file, and select **Open**.

In the following example component, ResourceManager.GetString obtains the string resource's text for display.

> ⚠ **Warning**
>
> Never use ResourceManager methods with untrusted data.

`StaticAssetExample.razor`:

```razor
@page "/static-asset-example"
@using System.Resources

<h1>Static Asset Example</h1>

<p>@dataResourceText</p>
```

```
@code {
    public string dataResourceText = "Loading resource ...";

    protected override void OnInitialized()
    {
        var resources =
            new ResourceManager(typeof(WpfBlazor.Properties.Resources));

        dataResourceText = resources.GetString("Data") ?? "'Data' not
found.";
    }
}
```

Windows Forms

Place the asset into a folder of the app, typically at the project's root, such as a `Resources` folder. The example in this section uses a static text file.

`Resources/Data.txt`:

```
text
```

```
This is text from a static text file resource.
```

Examine the files associated with `Form1` in **Solution Explorer**. If `Form1` doesn't have a resource file (`.resx`), add a `Form1.resx` file with the **Add** > **New Item** contextual menu command.

Double-click the `Form1.resx` file.

Select **Strings** > **Files** from the dropdown list.

Select **Add Resource** > **Add Existing File**. If prompted by Visual Studio to confirm editing the file, select **Yes**. Navigate to the `Resources` folder, select the `Data.txt` file, and select **Open**.

In the following example component:

- The app's assembly name is `WinFormsBlazor`. The ResourceManager's base name is set to the assembly name of `Form1` (`WinFormsBlazor.Form1`).
- ResourceManager.GetString obtains the string resource's text for display.

> ⚠ **Warning**

Never use ResourceManager methods with untrusted data.

`StaticAssetExample.razor`:

razor

```razor
@page "/static-asset-example"
@using System.Resources

<h1>Static Asset Example</h1>

<p>@dataResourceText</p>

@code {
    public string dataResourceText = "Loading resource ...";

    protected override async Task OnInitializedAsync()
    {
        var resources =
            new ResourceManager("WinFormsBlazor.Form1",
this.GetType().Assembly);

        dataResourceText = resources.GetString("Data") ?? "'Data' not
found.";
    }
}
```

Static assets limited to Razor components

A `BlazorWebView` control has a configured host file (HostPage), typically `wwwroot/index.html`. The HostPage path is relative to the project. All static web assets (scripts, CSS files, images, and other files) that are referenced from a `BlazorWebView` are relative to its configured HostPage.

Static web assets from a Razor class library (RCL) use special paths: `_content/{PACKAGE ID}/{PATH AND FILE NAME}`. The `{PACKAGE ID}` placeholder is the library's package ID. The package ID defaults to the project's assembly name if `<PackageId>` isn't specified in the project file. The `{PATH AND FILE NAME}` placeholder is path and file name under `wwwroot`. These paths are logically subpaths of the app's `wwwroot` folder, although they're actually coming from other packages or projects. Component-specific CSS style bundles are also built at the root of the `wwwroot` folder.

The web root of the HostPage determines which subset of static assets are available:

- `wwwroot/index.html` (*recommended*): All assets in the app's `wwwroot` folder are available (for example: `wwwroot/image.png` is available from `/image.png`), including subfolders (for example: `wwwroot/subfolder/image.png` is available from `/subfolder/image.png`). RCL static assets in the RCL's `wwwroot` folder are available (for example: `wwwroot/image.png` is available from the path `_content/{PACKAGE ID}/image.png`), including subfolders (for example: `wwwroot/subfolder/image.png` is available from the path `_content/{PACKAGE ID}/subfolder/image.png`).
- `wwwroot/{PATH}/index.html`: All assets in the app's `wwwroot/{PATH}` folder are available using app web root relative paths. RCL static assets in `wwwroot/{PATH}` aren't because they would be in a non-existent theoretical location, such as `../../_content/{PACKAGE ID}/{PATH}`, which isn't a supported relative path.
- `wwwroot/_content/{PACKAGE ID}/index.html`: All assets in the RCL's `wwwroot/{PATH}` folder are available using RCL web root relative paths. The app's static assets in `wwwroot/{PATH}` are aren't because they would be in a non-existent theoretical location, such as `../../{PATH}`, which isn't a supported relative path.

For most apps, we recommend placing the HostPage at the root of the `wwwroot` folder of the app, which provides the greatest flexibility for supplying static assets from the app, RCLs, and via subfolders of the app and RCLs.

The following examples demonstrate referencing static assets from the app's web root (`wwwroot` folder) with a HostPage rooted in the `wwwroot` folder.

`wwwroot/data.txt`:

text

```
This is text from a static text file resource.
```

`wwwroot/scripts.js`:

JavaScript

```
export function showPrompt(message) {
  return prompt(message, 'Type anything here');
}
```

The following Jeep® image is also used in this section's example. You can right-click the following image to save it locally for use in a local test app.

`wwwroot/jeep-yj.png`:

In a Razor component:

- The static text file contents can be read using the following techniques:
  - .NET MAUI: .NET MAUI file system helpers (OpenAppPackageFileAsync)
  - WPF and Windows Forms: StreamReader.ReadToEndAsync
- JavaScript files are available at logical subpaths of `wwwroot` using `./` paths.
- The image can be the source attribute (`src`) of an image tag (`<img>`).

`StaticAssetExample2.razor`:

razor

```
@page "/static-asset-example-2"
@using Microsoft.Extensions.Logging
@implements IAsyncDisposable
@inject IJSRuntime JS
@inject ILogger<StaticAssetExample2> Logger

<h1>Static Asset Example 2</h1>

<h2>Read a file</h2>

<p>@dataResourceText</p>

<h2>Call JavaScript</h2>

<p>
    <button @onclick="TriggerPrompt">Trigger browser window prompt</button>
</p>

<p>@result</p>

<h2>Show an image</h2>

<p><img alt="1991 Jeep YJ" src="/jeep-yj.png" /></p>

<p>
    <em>Jeep</em> and <em>Jeep YJ</em> are registered trademarks of
```

```
    <a href="https://www.stellantis.com">FCA US LLC (Stellantis NV)</a>.
</p>

@code {
    private string dataResourceText = "Loading resource ...";
    private IJSObjectReference? module;
    private string result;

    protected override async Task OnInitializedAsync()
    {
        try
        {
            dataResourceText = await ReadData();
        }
        catch (FileNotFoundException ex)
        {
            dataResourceText = "Data file not found.";
            Logger.LogError(ex, "'wwwroot/data.txt' not found.");
        }
    }

    protected override async Task OnAfterRenderAsync(bool firstRender)
    {
        if (firstRender)
        {
            module = await JS.InvokeAsync<IJSObjectReference>("import",
                "./scripts.js");
        }
    }

    private async Task TriggerPrompt()
    {
        result = await Prompt("Provide some text");
    }

    public async ValueTask<string> Prompt(string message) =>
        module is not null ?
            await module.InvokeAsync<string>("showPrompt", message) : null;

    async ValueTask IAsyncDisposable.DisposeAsync()
    {
        if (module is not null)
        {
            await module.DisposeAsync();
        }
    }
}
```

In .NET MAUI apps, add the following `ReadData` method to the `@code` block of the preceding component:

```
C#
```

```
private async Task<string> ReadData()
{
    using var stream = await
FileSystem.OpenAppPackageFileAsync("wwwroot/data.txt");
    using var reader = new StreamReader(stream);

    return await reader.ReadToEndAsync();
}
```

In WPF and Windows Forms apps, add the following `ReadData` method to the `@code` block of the preceding component:

C#

```
private async Task<string> ReadData()
{
    using var reader = new StreamReader("wwwroot/data.txt");

    return await reader.ReadToEndAsync();
}
```

Collocated JavaScript files are also accessible at logical subpaths of `wwwroot`. Instead of using the script described earlier for the `showPrompt` function in `wwwroot/scripts.js`, the following collocated JavaScript file for the `StaticAssetExample2` component also makes the function available.

`Pages/StaticAssetExample2.razor.js`:

JavaScript

```
export function showPrompt(message) {
  return prompt(message, 'Type anything here');
}
```

Modify the module object reference in the `StaticAssetExample2` component to use the collocated JavaScript file path (`./Pages/StaticAssetExample2.razor.js`):

C#

```
module = await JS.InvokeAsync<IJSObjectReference>("import",
    "./Pages/StaticAssetExample2.razor.js");
```

Trademarks

Use browser developer tools with ASP.NET Core Blazor Hybrid

Article • 02/09/2024

This article explains how to use browser developer tools with Blazor Hybrid apps.

Browser developer tools with .NET MAUI Blazor

Ensure the Blazor Hybrid project is configured to support browser developer tools. You can confirm developer tools support by searching the app for `AddBlazorWebViewDeveloperTools`.

If the project isn't already configured for browser developer tools, add support by:

1. Locating where the call to AddMauiBlazorWebView is made, likely within the app's `MauiProgram.cs` file.
2. At the top of the `MauiProgram.cs` file, confirm the presence of a `using` statement for Microsoft.Extensions.Logging. If the `using` statement isn't present, add it to the top of the file:

   C#

   ```
   using Microsoft.Extensions.Logging;
   ```

3. After the call to AddMauiBlazorWebView, add the following code:

   C#

   ```
   #if DEBUG
       builder.Services.AddBlazorWebViewDeveloperTools();
       builder.Logging.AddDebug();
   #endif
   ```

To use browser developer tools with a Windows app:

1. Run the .NET MAUI Blazor Hybrid app for Windows and navigate to an app page that uses a BlazorWebView. The developer tools console is unavailable from ContentPages without a Blazor Web View.
2. Use the keyboard shortcut `Ctrl`+`Shift`+`I` to open browser developer tools.

3. Developer tools provide a variety of features for working with apps, including which assets the page requested, how long assets took to load, and the content of loaded assets. The following example shows the **Console** tab to see the console messages, which includes any exception messages generated by the framework or developer code:

Reuse Razor components in ASP.NET Core Blazor Hybrid

Article • 05/21/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

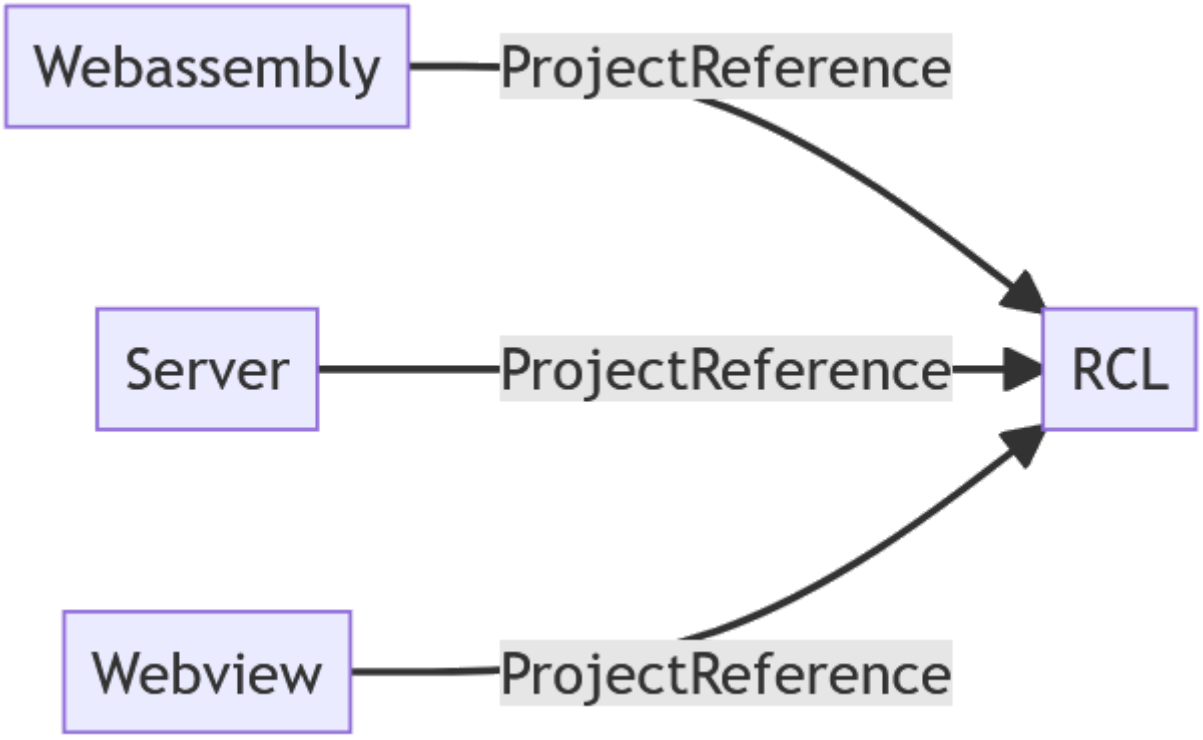
This article explains how to author and organize Razor components for the web and Web Views in Blazor Hybrid apps.

Razor components work across hosting models (Blazor WebAssembly, Blazor Server, and in the Web View of Blazor Hybrid) and across platforms (Android, iOS, and Windows). Hosting models and platforms have unique capabilities that components can leverage, but components executing across hosting models and platforms must leverage unique capabilities separately, which the following examples demonstrate:

- Blazor WebAssembly supports synchronous JavaScript (JS) interop, which isn't supported by the strictly asynchronous JS interop communication channel in Blazor Server and Web Views of Blazor Hybrid apps.
- Components in a Blazor Server app can access services that are only available on the server, such as an Entity Framework database context.
- Components in a `BlazorWebView` can directly access native desktop and mobile device features, such as geolocation services. Blazor Server and Blazor WebAssembly apps must rely upon web API interfaces of apps on external servers to provide similar features.

Design principles

In order to author Razor components that can seamlessly work across hosting models and platforms, adhere to the following design principles:

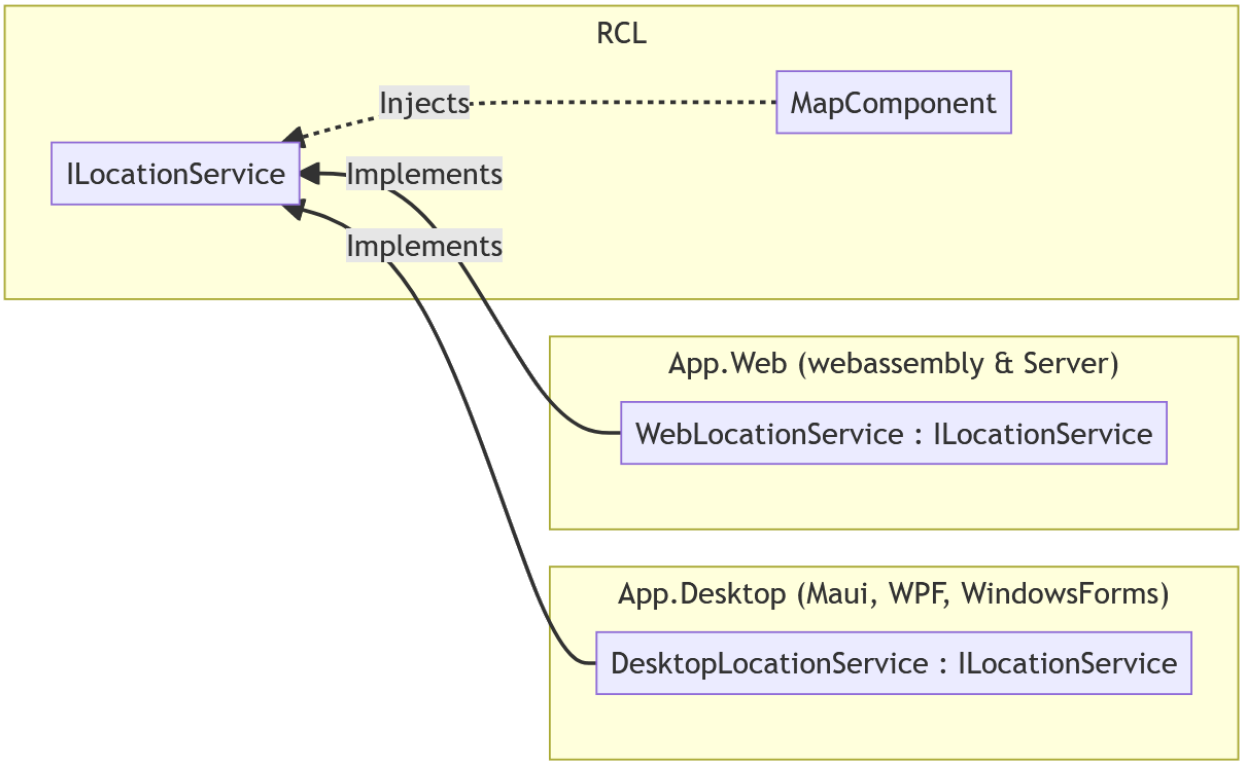


- Place shared UI code in Razor class libraries (RCLs), which are containers designed to maintain reusable pieces of UI for use across different hosting models and platforms.

- Implementations of unique features shouldn't exist in RCLs. Instead, the RCL should define abstractions (interfaces and base classes) that hosting models and platforms implement.
- Only opt-in to unique features by hosting model or platform. For example, Blazor WebAssembly supports the use of IJSInProcessRuntime and IJSInProcessObjectReference in a component as an optimization, but only use them with conditional casts and fallback implementations that rely on the universal IJSRuntime and IJSObjectReference abstractions that all hosting models and platforms support. For more information on IJSInProcessRuntime, see Call JavaScript functions from .NET methods in ASP.NET Core Blazor. For more information on IJSInProcessObjectReference, see Call .NET methods from JavaScript functions in ASP.NET Core Blazor.
- As a general rule, use CSS for HTML styling in components. The most common case is for consistency in the look and feel of an app. In places where UI styles must differ across hosting models or platforms, use CSS to style the differences.
- If some part of the UI requires additional or different content for a target hosting model or platform, the content can be encapsulated inside a component and rendered inside the RCL using DynamicComponent. Additional UI can also be provided to components via RenderFragment instances. For more information on RenderFragment, see Child content render fragments and Render fragments for reusable rendering logic.

Project code organization

As much as possible, place code and static content in Razor class libraries (RCLs). Each hosting model or platform references the RCL and registers individual implementations in the app's service collection that a Razor component might require.



Each target assembly should contain only the code that is specific to that hosting model or platform along with the code that helps bootstrap the app.

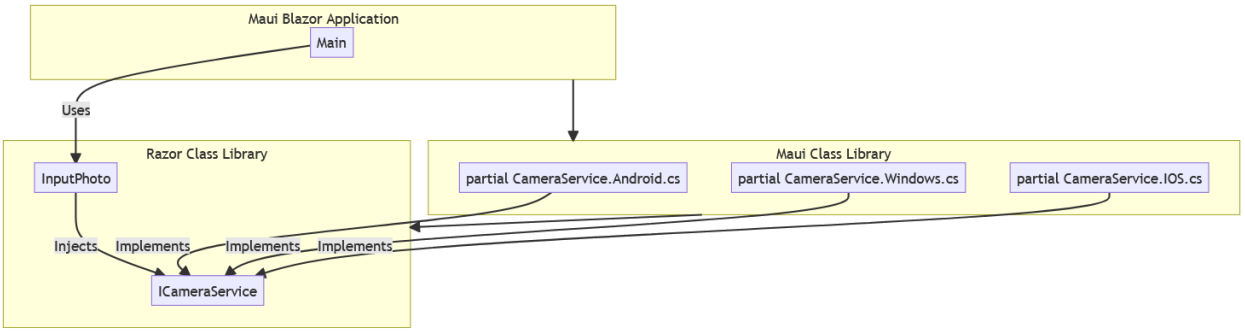
Use abstractions for unique features

The following example demonstrates how to use an abstraction for a geolocation service by hosting model and platform.

- In a Razor class library (RCL) used by the app to obtain geolocation data for the user's location on a map, the `MapComponent` Razor component injects an `ILocationService` service abstraction.
- `App.Web` for Blazor WebAssembly and Blazor Server projects implement `ILocationService` as `WebLocationService`, which uses web API calls to obtain geolocation data.
- `App.Desktop` for .NET MAUI, WPF, and Windows Forms, implement `ILocationService` as `DesktopLocationService`. `DesktopLocationService` uses platform-specific device features to obtain geolocation data.

.NET MAUI Blazor platform-specific code

A common pattern in .NET MAUI is to create separate implementations for different platforms, such as defining partial classes with platform-specific implementations. For example, see the following diagram, where partial classes for `CameraService` are implemented in each of `CameraService.Windows.cs`, `CameraService.iOS.cs`, `CameraService.Android.cs`, and `CameraService.cs`:



Where you want to pack platform-specific features into a class library that can be consumed by other apps, we recommend that you follow a similar approach to the one described in the preceding example and create an abstraction for the Razor component:

- Place the component in a Razor class library (RCL).
- From a .NET MAUI class library, reference the RCL and create the platform-specific implementations.
- Within the consuming app, reference the .NET MAUI class library.

The following example demonstrates the concepts for images in an app that organizes photographs:

- A .NET MAUI Blazor Hybrid app uses `InputPhoto` from an RCL that it references.
- The .NET MAUI app also references a .NET MAUI class library.

- `InputPhoto` in the RCL injects an `ICameraService` interface, which is defined in the RCL.
- `CameraService` partial class implementations for `ICameraService` are in the .NET MAUI class library (`CameraService.Windows.cs`, `CameraService.iOS.cs`, `CameraService.Android.cs`), which references the RCL.

For an example, see Build a .NET MAUI Blazor Hybrid app with a Blazor Web App.

Share assets across web and native clients using a Razor class library (RCL)

Article • 09/12/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

Use a Razor class library (RCL) to share Razor components, C# code, and static assets across web and native client projects.

This article builds on the general concepts found in the following articles:

- Consume ASP.NET Core Razor components from a Razor class library (RCL)
- Reusable Razor UI in class libraries with ASP.NET Core

The examples in this article share assets between a server-side Blazor app and a .NET MAUI Blazor Hybrid app in the same solution:

- Although a server-side Blazor app is used, the guidance applies equally to Blazor WebAssembly apps sharing assets with a Blazor Hybrid app.
- Projects are in the same solution, but an RCL can supply shared assets to projects outside of a solution.
- The RCL is added as a project to the solution, but any RCL can be published as a NuGet package. A NuGet package can supply shared assets to web and native client projects.
- The order that the projects are created isn't important. However, projects that rely on an RCL for assets must create a project reference to the RCL *after* the RCL is created.

For guidance on creating an RCL, see Consume ASP.NET Core Razor components from a Razor class library (RCL). Optionally, access the additional guidance on RCLs that apply broadly to ASP.NET Core apps in Reusable Razor UI in class libraries with ASP.NET Core.

Share web UI Razor components, code, and static assets

Components from an RCL can be simultaneously shared by web and native client apps built using Blazor. The guidance in Consume ASP.NET Core Razor components from a Razor class library (RCL) explains how to share Razor components using a Razor class library (RCL). The same guidance applies to reusing Razor components from an RCL in a Blazor Hybrid app.

Component namespaces are derived from the RCL's package ID or assembly name and the component's folder path within the RCL. For more information, see ASP.NET Core Razor components. @using directives can be placed in `_Imports.razor` files for components and code, as the following example demonstrates for an RCL named `SharedLibrary` with a `Shared` folder of shared Razor components and a `Data` folder of shared data classes:

razor

```
@using SharedLibrary
@using SharedLibrary.Shared
@using SharedLibrary.Data
```

Place shared static assets in the RCL's `wwwroot` folder and update static asset paths in the app to use the following path format:

> _content/{PACKAGE ID/ASSEMBLY NAME}/{PATH}/{FILE NAME}

Placeholders:

- `{PACKAGE ID/ASSEMBLY NAME}`: The package ID or assembly name of the RCL.
- `{PATH}`: Optional path within the RCL's `wwwroot` folder.
- `{FILE NAME}`: The file name of the static asset.

The preceding path format is also used in the app for static assets supplied by a NuGet package added to the RCL.

For an RCL named `SharedLibrary` and using the minified Bootstrap stylesheet as an example:

> _content/SharedLibrary/css/bootstrap/bootstrap.min.css

For additional information on how to share static assets across projects, see the following articles:

- Consume ASP.NET Core Razor components from a Razor class library (RCL)
- Reusable Razor UI in class libraries with ASP.NET Core

The root `index.html` file is usually specific to the app and should remain in the Blazor Hybrid app or the Blazor WebAssembly app. The `index.html` file typically isn't shared.

The root Razor Component (`App.razor` or `Main.razor`) can be shared, but often might need to be specific to the hosting app. For example, `App.razor` is different in the server-side Blazor and Blazor WebAssembly project templates when authentication is enabled. You can add the AdditionalAssemblies parameter to specify the location of any shared routable components, and you can specify a shared default layout component for the router by type name.

Provide code and services independent of hosting model

When code must differ across hosting models or target platforms, abstract the code as interfaces and inject the service implementations in each project.

The following weather data example abstracts different weather forecast service implementations:

- Using an HTTP request for Blazor Hybrid and Blazor WebAssembly.
- Requesting data directly for a server-side Blazor app.

The example uses the following specifications and conventions:

- The RCL is named `SharedLibrary` and contains the following folders and namespaces:
  - `Data`: Contains the `WeatherForecast` class, which serves as a model for weather data.
  - `Interfaces`: Contains the service interface for the service implementations, named `IWeatherForecastService`.
- The `FetchData` component is maintained in the `Pages` folder of the RCL, which is routable by any of the apps consuming the RCL.
- Each Blazor app maintains a service implementation that implements the `IWeatherForecastService` interface.

`Data/WeatherForecast.cs` in the RCL:

C#

```
namespace SharedLibrary.Data;

public class WeatherForecast
{
    public DateTime Date { get; set; }
    public int TemperatureC { get; set; }
    public int TemperatureF => 32 + (int)(TemperatureC / 0.5556);
    public string? Summary { get; set; }
}
```

`Interfaces/IWeatherForecastService.cs` in the RCL:

C#

```
using SharedLibrary.Data;

namespace SharedLibrary.Interfaces;

public interface IWeatherForecastService
{
    Task<WeatherForecast[]?> GetForecastAsync(DateTime startDate);
}
```

The `_Imports.razor` file in the RCL includes the following added namespaces:

razor

```
@using SharedLibrary.Data
@using SharedLibrary.Interfaces
```

`Services/WeatherForecastService.cs` in the Blazor Hybrid and Blazor WebAssembly apps:

C#

```
using System.Net.Http.Json;
using SharedLibrary.Data;
using SharedLibrary.Interfaces;

namespace {APP NAMESPACE}.Services;

public class WeatherForecastService : IWeatherForecastService
{
    private readonly HttpClient http;

    public WeatherForecastService(HttpClient http)
    {
```

```
        this.http = http;
    }

    public async Task<WeatherForecast[]?> GetForecastAsync(DateTime
startDate) =>
        await http.GetFromJsonAsync<WeatherForecast[]?>("WeatherForecast");
}
```

In the preceding example, the `{APP NAMESPACE}` placeholder is the app's namespace.

`Services/WeatherForecastService.cs` in the server-side Blazor app:

C#

```
using SharedLibrary.Data;
using SharedLibrary.Interfaces;

namespace {APP NAMESPACE}.Services;

public class WeatherForecastService : IWeatherForecastService
{
    private static readonly string[] Summaries = new[]
    {
        "Freezing", "Bracing", "Chilly", "Cool", "Mild", "Warm", "Balmy",
"Hot"
    };

    public async Task<WeatherForecast[]?> GetForecastAsync(DateTime
startDate) =>
        await Task.FromResult(Enumerable.Range(1, 5)
            .Select(index => new WeatherForecast
            {
                Date = startDate.AddDays(index),
                TemperatureC = Random.Shared.Next(-20, 55),
                Summary = Summaries[Random.Shared.Next(Summaries.Length)]
            }).ToArray());
}
```

In the preceding example, the `{APP NAMESPACE}` placeholder is the app's namespace.

The Blazor Hybrid, Blazor WebAssembly, and server-side Blazor apps register their weather forecast service implementations (`Services.WeatherForecastService`) for `IWeatherForecastService`.

The Blazor WebAssembly project also registers an HttpClient. The HttpClient registered in an app created from the Blazor WebAssembly project template is sufficient for this purpose. For more information, see Call a web API from an ASP.NET Core Blazor app.

`Pages/FetchData.razor` in the RCL:

razor

```razor
@page "/fetchdata"
@inject IWeatherForecastService ForecastService

<PageTitle>Weather forecast</PageTitle>

<h1>Weather forecast</h1>

@if (forecasts == null)
{
    <p><em>Loading...</em></p>
}
else
{
    <table class="table">
        <thead>
            <tr>
                <th>Date</th>
                <th>Temp. (C)</th>
                <th>Temp. (F)</th>
                <th>Summary</th>
            </tr>
        </thead>
        <tbody>
            @foreach (var forecast in forecasts)
            {
                <tr>
                    <td>@forecast.Date.ToShortDateString()</td>
                    <td>@forecast.TemperatureC</td>
                    <td>@forecast.TemperatureF</td>
                    <td>@forecast.Summary</td>
                </tr>
            }
        </tbody>
    </table>
}

@code {
    private WeatherForecast[]? forecasts;

    protected override async Task OnInitializedAsync()
    {
        forecasts = await ForecastService.GetForecastAsync(DateTime.Now);
    }
}
```

Pass root component parameters in ASP.NET Core Blazor Hybrid

Article • 02/09/2024

This article explains how to pass root component parameters in a Blazor Hybrid app.

The `RootComponent` class of a `BlazorWebView` defines a `Parameters` property of type `IDictionary<string, object?>?`, which represents an optional dictionary of parameters to pass to the root component:

- .NET MAUI: Microsoft.AspNetCore.Components.WebView.Maui.RootComponent
- WPF: Microsoft.AspNetCore.Components.WebView.Wpf.RootComponent
- Windows Forms: Microsoft.AspNetCore.Components.WebView.WindowsForms.RootComponent

The following example passes a view model to the root component, which further passes the view model as a cascading type to a Razor component in the Blazor portion of the app. The example is based on the keypad example in the .NET MAUI documentation:

- Data binding and MVVM: Commanding (.NET MAUI documentation): Explains data binding with MVVM using a keypad example.
- .NET MAUI Samples

Although the keypad example focuses on implementing the MVVM pattern in .NET MAUI Blazor Hybrid apps:

- The dictionary of objects passed to root components can include any type for any purpose where you need to pass one or more parameters to the root component for use by Razor components in the app.
- The concepts demonstrated by the following .NET MAUI Blazor example are the same for Windows Forms Blazor apps and WPF Blazor apps.

Place the following view model into your .NET MAUI Blazor Hybrid app.

`KeypadViewModel.cs`:

C#

```
using System.ComponentModel;
using System.Runtime.CompilerServices;
using System.Windows.Input;
```

```
namespace MauiBlazor;

public class KeypadViewModel : INotifyPropertyChanged
{
    public event PropertyChangedEventHandler PropertyChanged;

    private string _inputString = "";
    private string _displayText = "";
    private char[] _specialChars = { '*', '#' };

    public ICommand AddCharCommand { get; private set; }
    public ICommand DeleteCharCommand { get; private set; }

    public string InputString
    {
        get => _inputString;
        private set
        {
            if (_inputString != value)
            {
                _inputString = value;
                OnPropertyChanged();
                DisplayText = FormatText(_inputString);

                // Perhaps the delete button must be enabled/disabled.
                ((Command)DeleteCharCommand).ChangeCanExecute();
            }
        }
    }

    public string DisplayText
    {
        get => _displayText;
        set
        {
            if (_displayText != value)
            {
                _displayText = value;
                OnPropertyChanged();
            }
        }
    }

    public KeypadViewModel()
    {
        // Command to add the key to the input string
        AddCharCommand = new Command<string>((key) => InputString += key);

        // Command to delete a character from the input string when allowed
        DeleteCharCommand =
            new Command(
                // Command strips a character from the input string
                () => InputString = InputString.Substring(0,
InputString.Length - 1),
```

```
                // CanExecute is processed here to return true when there's
something to delete
                () => InputString.Length > 0
            );
    }

    string FormatText(string str)
    {
        bool hasNonNumbers = str.IndexOfAny(_specialChars) != -1;
        string formatted = str;

        // Format the string based on the type of data and the length
        if (hasNonNumbers || str.Length < 4 || str.Length > 10)
        {
            // Special characters exist, or the string is too small or large
for special formatting
            // Do nothing
        }

        else if (str.Length < 8)
            formatted = string.Format("{0}-{1}", str.Substring(0, 3),
str.Substring(3));

        else
            formatted = string.Format("({0}) {1}-{2}", str.Substring(0, 3),
str.Substring(3, 3), str.Substring(6));

        return formatted;
    }

    public void OnPropertyChanged([CallerMemberName] string name = "") =>
        PropertyChanged?.Invoke(this, new PropertyChangedEventArgs(name));
}
```

In this article's example, the app's root namespace is `MauiBlazor`. Change the namespace of `KeypadViewModel` to match the app's root namespace:

C#

```
namespace MauiBlazor;
```

> **Note**
>
> At the time the `KeypadViewModel` view model was created for the .NET MAUI sample app and the .NET MAUI documentation, view models were placed in a folder named `ViewModels`, but the namespace was set to the root of the app and didn't include the folder name. If you wish to update the namespace to include the folder in the `KeypadViewModel.cs` file, modify the example code in this article to match.

Add `using` (C#) and `@using` (Razor) statements to the following files or fully-qualify the references to the view model type as `{APP NAMESPACE}.ViewModels.KeypadViewModel`, where the `{APP NAMESPACE}` placeholder is the app's root namespace.

Although you can set `Parameters` directly in XAML, the following example names the root component (`rootComponent`) in the XAML file and sets the parameter dictionary in the code-behind file.

In `MainPage.xaml`:

XAML

```
<RootComponent x:Name="rootComponent"
               Selector="#app"
               ComponentType="{x:Type local:Main}" />
```

In the code-behind file (`MainPage.xaml.cs`), assign the view model in the constructor:

C#

```
public MainPage()
{
    InitializeComponent();

    rootComponent.Parameters =
        new Dictionary<string, object>
        {
            { "KeypadViewModel", new KeypadViewModel() }
        };
}
```

The following example cascades the object (`KeypadViewModel`) down component hierarchies in the Blazor portion of the app as a CascadingValue.

In the `Main` component (`Main.razor`):

- Add a parameter matching the type of the object passed to the root component:

  razor

  ```
  @code {
      [Parameter]
      public KeypadViewModel KeypadViewModel { get; set; }
  }
  ```

- Cascade the `KeypadViewModel` with the CascadingValue component. Update the `<Found>` XAML content to the following markup:

  XAML

  ```
  <Found Context="routeData">
      <CascadingValue Value="KeypadViewModel">
          <RouteView RouteData="routeData"
  DefaultLayout="typeof(MainLayout)" />
          <FocusOnNavigate RouteData="routeData" Selector="h1"/>
      </CascadingValue>
  </Found>
  ```

At this point, the cascaded type is available to Razor components throughout the app as a CascadingParameter.

The following `Keypad` component example:

- Displays the current value of `KeypadViewModel.DisplayText`.
- Permits character deletion by calling the `KeypadViewModel.DeleteCharCommand` command if the display string length is greater than 0 (zero), which is checked by the call to ICommand.CanExecute.
- Permits adding characters by calling `KeypadViewModel.AddCharCommand` with the key pressed in the UI.

`Pages/Keypad.razor`:

razor

```
@page "/keypad"

<h1>Keypad</h1>

<table id="keypad">
    <thead>
        <tr>
            <th colspan="2">@KeypadViewModel.DisplayText</th>
            <th><button @onclick="DeleteChar">&#x21E6;</button></th>
        </tr>
    </thead>
    <tbody>
        <tr>
            <td><button @onclick="@(e => AddChar("1"))">1</button></td>
            <td><button @onclick="@(e => AddChar("2"))">2</button></td>
            <td><button @onclick="@(e => AddChar("3"))">3</button></td>
        </tr>
        <tr>
            <td><button @onclick="@(e => AddChar("4"))">4</button></td>
            <td><button @onclick="@(e => AddChar("5"))">5</button></td>
```

```
            <td><button @onclick="@(e => AddChar("6"))">6</button></td>
        </tr>
        <tr>
            <td><button @onclick="@(e => AddChar("7"))">7</button></td>
            <td><button @onclick="@(e => AddChar("8"))">8</button></td>
            <td><button @onclick="@(e => AddChar("9"))">9</button></td>
        </tr>
        <tr>
            <td><button @onclick="@(e => AddChar("*"))">*</button></td>
            <td><button @onclick="@(e => AddChar("0"))">0</button></td>
            <td><button @onclick="@(e => AddChar("#"))">#</button></td>
        </tr>
    </tbody>
</table>

@code {
    [CascadingParameter]
    protected KeypadViewModel KeypadViewModel { get; set; }

    private void DeleteChar()
    {
        if (KeypadViewModel.DeleteCharCommand.CanExecute(null))
        {
            KeypadViewModel.DeleteCharCommand.Execute(null);
        }
    }

    private void AddChar(string key)
    {
        KeypadViewModel.AddCharCommand.Execute(key);
    }
}
```

Purely for demonstration purposes, style the buttons by placing the following CSS styles in the `wwwroot/index.html` file's `<head>` content:

HTML

```
<style>
    #keypad button {
        border: 1px solid black;
        border-radius:6px;
        height: 35px;
        width:80px;
    }
</style>
```

Create a sidebar navigation entry in the `NavMenu` component (`Shared/NavMenu.razor`) with the following markup:

razor

```
<div class="nav-item px-3">
    <NavLink class="nav-link" href="keypad">
        <span class="oi oi-list-rich" aria-hidden="true"></span> Keypad
    </NavLink>
</div>
```

ASP.NET Core Blazor Hybrid authentication and authorization

Article • 08/09/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article describes ASP.NET Core's support for the configuration and management of security and ASP.NET Core Identity in Blazor Hybrid apps.

Authentication in Blazor Hybrid apps is handled by native platform libraries, as they offer enhanced security guarantees that the browser sandbox can't offer. Authentication of native apps uses an OS-specific mechanism or via a federated protocol, such as OpenID Connect (OIDC). Follow the guidance for the identity provider that you've selected for the app and then further integrate identity with Blazor using the guidance in this article.

Integrating authentication must achieve the following goals for Razor components and services:

- Use the abstractions in the Microsoft.AspNetCore.Components.Authorization package, such as AuthorizeView.
- React to changes in the authentication context.
- Access credentials provisioned by the app from the identity provider, such as access tokens to perform authorized API calls.

After authentication is added to a .NET MAUI, WPF, or Windows Forms app and users are able to log in and log out successfully, integrate authentication with Blazor to make the authenticated user available to Razor components and services. Perform the following steps:

- Reference the Microsoft.AspNetCore.Components.Authorization package.

> **Note**

> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

- Implement a custom AuthenticationStateProvider, which is the abstraction that Razor components use to access information about the authenticated user and to receive updates when the authentication state changes.
- Register the custom authentication state provider in the dependency injection container.

.NET MAUI apps use Xamarin.Essentials: Web Authenticator: The `WebAuthenticator` class allows the app to initiate browser-based authentication flows that listen for a callback to a specific URL registered with the app.

For additional guidance, see the following resources:

- Web authenticator (.NET MAUI documentation)
- Sample.Server.WebAuthenticator sample app

Create a custom `AuthenticationStateProvider` without user change updates

If the app authenticates the user immediately after the app launches and the authenticated user remains the same for the entirety of the app lifetime, user change notifications aren't required, and the app only provides information about the authenticated user. In this scenario, the user logs into the app when the app is opened, and the app displays the login screen again after the user logs out. The following `ExternalAuthStateProvider` is an example implementation of a custom AuthenticationStateProvider for this authentication scenario.

> **Note**
>
> The following custom AuthenticationStateProvider doesn't declare a namespace in order to make the code example applicable to any Blazor Hybrid app. However, a best practice is to provide your app's namespace when you implement the example in a production app.

`ExternalAuthStateProvider.cs`:

```
C#
```

```
using System.Security.Claims;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Components.Authorization;

public class ExternalAuthStateProvider : AuthenticationStateProvider
{
    private readonly Task<AuthenticationState> authenticationState;

    public ExternalAuthStateProvider(AuthenticatedUser user) =>
        authenticationState = Task.FromResult(new
AuthenticationState(user.Principal));

    public override Task<AuthenticationState> GetAuthenticationStateAsync()
=>
        authenticationState;
}

public class AuthenticatedUser
{
    public ClaimsPrincipal Principal { get; set; } = new();
}
```

The following steps describe how to:

- Add required namespaces.
- Add the authorization services and Blazor abstractions to the service collection.
- Build the service collection.
- Resolve the `AuthenticatedUser` service to set the authenticated user's claims principal. See your identity provider's documentation for details.
- Return the built host.

In the `MauiProgram.CreateMauiApp` method of `MauiProgram.cs`, add namespaces for Microsoft.AspNetCore.Components.Authorization and System.Security.Claims:

C#

```
using Microsoft.AspNetCore.Components.Authorization;
using System.Security.Claims;
```

Remove the following line of code that returns a built Microsoft.Maui.Hosting.MauiApp:

diff

```
- return builder.Build();
```

Replace the preceding line of code with the following code. Add OpenID/MSAL code to authenticate the user. See your identity provider's documentation for details.

C#

```
builder.Services.AddAuthorizationCore();
builder.Services.TryAddScoped<AuthenticationStateProvider,
ExternalAuthStateProvider>();
builder.Services.AddSingleton<AuthenticatedUser>();
var host = builder.Build();

var authenticatedUser = host.Services.GetRequiredService<AuthenticatedUser>
();

/*
Provide OpenID/MSAL code to authenticate the user. See your identity
provider's
documentation for details.

The user is represented by a new ClaimsPrincipal based on a new
ClaimsIdentity.
*/
var user = new ClaimsPrincipal(new ClaimsIdentity());

authenticatedUser.Principal = user;

return host;
```

Create a custom `AuthenticationStateProvider` with user change updates

To update the user while the Blazor app is running, call NotifyAuthenticationStateChanged within the AuthenticationStateProvider implementation using ***either*** of the following approaches:

- Signal an authentication update from outside of the BlazorWebView)
- Handle authentication within the BlazorWebView

Signal an authentication update from outside of the `BlazorWebView` (Option 1)

A custom AuthenticationStateProvider can use a global service to signal an authentication update. We recommend that the service offer an event that the AuthenticationStateProvider can subscribe to, where the event invokes NotifyAuthenticationStateChanged.

> ⓘ Note

The following custom AuthenticationStateProvider doesn't declare a namespace in order to make the code example applicable to any Blazor Hybrid app. However, a best practice is to provide your app's namespace when you implement the example in a production app.

`ExternalAuthStateProvider.cs`:

C#

```
using System;
using System.Security.Claims;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Components.Authorization;

public class ExternalAuthStateProvider : AuthenticationStateProvider
{
    private AuthenticationState currentUser;

    public ExternalAuthStateProvider(ExternalAuthService service)
    {
        currentUser = new AuthenticationState(service.CurrentUser);

        service.UserChanged += (newUser) =>
        {
            currentUser = new AuthenticationState(newUser);
            NotifyAuthenticationStateChanged(Task.FromResult(currentUser));
        };
    }

    public override Task<AuthenticationState> GetAuthenticationStateAsync()
=>
        Task.FromResult(currentUser);
}

public class ExternalAuthService
{
    public event Action<ClaimsPrincipal>? UserChanged;
    private ClaimsPrincipal? currentUser;

    public ClaimsPrincipal CurrentUser
    {
        get { return currentUser ?? new(); }
        set
        {
            currentUser = value;

            if (UserChanged is not null)
            {
                UserChanged(currentUser);
            }
        }
```

```
    }
}
```

In the `MauiProgram.CreateMauiApp` method of `MauiProgram.cs`, add a namespace for Microsoft.AspNetCore.Components.Authorization:

C#

```
using Microsoft.AspNetCore.Components.Authorization;
```

Add the authorization services and Blazor abstractions to the service collection:

C#

```
builder.Services.AddAuthorizationCore();
builder.Services.TryAddScoped<AuthenticationStateProvider,
ExternalAuthStateProvider>();
builder.Services.AddSingleton<ExternalAuthService>();
```

Wherever the app authenticates a user, resolve the `ExternalAuthService` service:

C#

```
var authService = host.Services.GetRequiredService<ExternalAuthService>();
```

Execute your custom OpenID/MSAL code to authenticate the user. See your identity provider's documentation for details. The authenticated user (`authenticatedUser` in the following example) is a new ClaimsPrincipal based on a new ClaimsIdentity.

Set the current user to the authenticated user:

C#

```
authService.CurrentUser = authenticatedUser;
```

An alternative to the preceding approach is to set the user's principal on System.Threading.Thread.CurrentPrincipal instead of setting it via a service, which avoids use of the dependency injection container:

C#

```
public class CurrentThreadUserAuthenticationStateProvider :
AuthenticationStateProvider
{
    public override Task<AuthenticationState> GetAuthenticationStateAsync()
```

```
=>
        Task.FromResult(
            new AuthenticationState(Thread.CurrentPrincipal as
ClaimsPrincipal ??
                new ClaimsPrincipal(new ClaimsIdentity())));
}
```

Using the alternative approach, only authorization services (AddAuthorizationCore) and `CurrentThreadUserAuthenticationStateProvider` (`.TryAddScoped<AuthenticationStateProvider, CurrentThreadUserAuthenticationStateProvider>()`) are added to the service collection.

Handle authentication within the `BlazorWebView` (Option 2)

A custom AuthenticationStateProvider can include additional methods to trigger log in and log out and update the user.

> **Note**
>
> The following custom AuthenticationStateProvider doesn't declare a namespace in order to make the code example applicable to any Blazor Hybrid app. However, a best practice is to provide your app's namespace when you implement the example in a production app.

`ExternalAuthStateProvider.cs`:

C#

```
using System.Security.Claims;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Components.Authorization;

public class ExternalAuthStateProvider : AuthenticationStateProvider
{
    private ClaimsPrincipal currentUser = new ClaimsPrincipal(new
ClaimsIdentity());

    public override Task<AuthenticationState> GetAuthenticationStateAsync()
=>
        Task.FromResult(new AuthenticationState(currentUser));

    public Task LogInAsync()
    {
        var loginTask = LogInAsyncCore();
        NotifyAuthenticationStateChanged(loginTask);
```

```
        return loginTask;

        async Task<AuthenticationState> LogInAsyncCore()
        {
            var user = await LoginWithExternalProviderAsync();
            currentUser = user;

            return new AuthenticationState(currentUser);
        }
    }

    private Task<ClaimsPrincipal> LoginWithExternalProviderAsync()
    {
        /*
            Provide OpenID/MSAL code to authenticate the user. See your
identity
            provider's documentation for details.

            Return a new ClaimsPrincipal based on a new ClaimsIdentity.
        */
        var authenticatedUser = new ClaimsPrincipal(new ClaimsIdentity());

        return Task.FromResult(authenticatedUser);
    }

    public void Logout()
    {
        currentUser = new ClaimsPrincipal(new ClaimsIdentity());
        NotifyAuthenticationStateChanged(
            Task.FromResult(new AuthenticationState(currentUser)));
    }
}
```

In the preceding example:

- The call to `LogInAsyncCore` triggers the login process.
- The call to NotifyAuthenticationStateChanged notifies that an update is in progress, which allows the app to provide a temporary UI during the login or logout process.
- Returning `loginTask` returns the task so that the component that triggered the login can await and react after the task is complete.
- The `LoginWithExternalProviderAsync` method is implemented by the developer to log in the user with the identity provider's SDK. For more information, see your identity provider's documentation. The authenticated user (`authenticatedUser`) is a new ClaimsPrincipal based on a new ClaimsIdentity.

In the `MauiProgram.CreateMauiApp` method of `MauiProgram.cs`, add the authorization services and the Blazor abstraction to the service collection:

C#

```
builder.Services.AddAuthorizationCore();
builder.Services.TryAddScoped<AuthenticationStateProvider,
ExternalAuthStateProvider>();
```

The following `LoginComponent` component demonstrates how to log in a user. In a typical app, the `LoginComponent` component is only shown in a parent component if the user isn't logged into the app.

`Shared/LoginComponent.razor`:

razor

```
@inject AuthenticationStateProvider AuthenticationStateProvider

<button @onclick="Login">Log in</button>

@code
{
    public async Task Login()
    {
        await ((ExternalAuthStateProvider)AuthenticationStateProvider)
            .LogInAsync();
    }
}
```

The following `LogoutComponent` component demonstrates how to log out a user. In a typical app, the `LogoutComponent` component is only shown in a parent component if the user is logged into the app.

`Shared/LogoutComponent.razor`:

razor

```
@inject AuthenticationStateProvider AuthenticationStateProvider

<button @onclick="Logout">Log out</button>

@code
{
    public async Task Logout()
    {
        await ((ExternalAuthStateProvider)AuthenticationStateProvider)
            .Logout();
    }
}
```

Accessing other authentication information

Blazor doesn't define an abstraction to deal with other credentials, such as access tokens to use for HTTP requests to web APIs. We recommend following the identity provider's guidance to manage the user's credentials with the primitives that the identity provider's SDK provides.

It's common for identity provider SDKs to use a token store for user credentials stored in the device. If the SDK's token store primitive is added to the service container, consume the SDK's primitive within the app.

The Blazor framework isn't aware of a user's authentication credentials and doesn't interact with credentials in any way, so the app's code is free to follow whatever approach you deem most convenient. However, follow the general security guidance in the next section, Other authentication security considerations, when implementing authentication code in an app.

Other authentication security considerations

The authentication process is external to Blazor, and we recommend that developers access the identity provider's guidance for additional security guidance.

When implementing authentication:

- Avoid authentication in the context of the Web View. For example, avoid using a JavaScript OAuth library to perform the authentication flow. In a single-page app, authentication tokens aren't hidden in JavaScript and can be easily discovered by malicious users and used for nefarious purposes. Native apps don't suffer this risk because native apps are only able to obtain tokens outside of the browser context, which means that rogue third-party scripts can't steal the tokens and compromise the app.
- Avoid implementing the authentication workflow yourself. In most cases, platform libraries securely handle the authentication workflow, using the system's browser instead of using a custom Web View that can be hijacked.
- Avoid using the platform's Web View control to perform authentication. Instead, rely on the system's browser when possible.
- Avoid passing the tokens to the document context (JavaScript). In some situations, a JavaScript library within the document is required to perform an authorized call to an external service. Instead of making the token available to JavaScript via JS interop:
  - Provide a generated temporary token to the library and within the Web View.
  - Intercept the outgoing network request in code.

    - Replace the temporary token with the real token and confirm that the destination of the request is valid.

ASP.NET Core Blazor Hybrid security considerations

Article • 09/27/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article describes security considerations for Blazor Hybrid apps.

Blazor Hybrid apps that render web content execute .NET code inside a platform Web View. The .NET code interacts with the web content via an interop channel between the .NET code and the Web View.

The web content rendered into the Web View can come from assets provided by the app from either of the following locations:

- The `wwwroot` folder in the app.
- A source external to the app. For example, a network source, such as the Internet.

A trust boundary exists between the .NET code and the code that runs inside the Web View. .NET code is provided by the app and any trusted third-party packages that you've installed. After the app is built, the .NET code Web View content sources can't change.

In contrast to the .NET code sources of content, content sources from the code that runs inside the Web View can come not only from the app but also from external sources. For example, static assets from an external Content Delivery Network (CDN) might be used or rendered by an app's Web View.

Consider the code inside the Web View as **untrusted** in the same way that code running inside the browser for a web app isn't trusted. The same threats and general security recommendations apply to untrusted resources in Blazor Hybrid apps as for other types of apps.

If possible, avoid loading content from a third-party origin. To mitigate risk, you might be able to serve content directly from the app by downloading the external assets, verifying that they're safe to serve to users, and placing them into the app's `wwwroot` folder for packaging with the rest of the app. When the external content is downloaded for inclusion in the app, we recommend scanning it for viruses and malware before placing it into the `wwwroot` folder of the app.

If your app must reference content from an external origin, we recommend that you use common web security approaches to provide the app with an opportunity to block the content from loading if the content is compromised:

- Serve content securely with TLS/HTTPS.
- Institute a Content Security Policy (CSP).
- Perform subresource integrity checks.

Even if all of the resources are packed into the app and don't load from any external origin, remain cautious about problems in the resources' code that run inside the Web View, as the resources might have vulnerabilities that could allow cross-site scripting (XSS) attacks.

In general, the Blazor framework protects against XSS by dealing with HTML in safe ways. However, some programming patterns allow Razor components to inject raw HTML into rendered output, such as rendering content from an untrusted source. For example, rendering HTML content directly from a database should be avoided. Additionally, JavaScript libraries used by the app might manipulate HTML in unsafe ways to inadvertently or deliberately render unsafe output.

For these reasons, it's best to apply the same protections against XSS that are normally applied to web apps. Prevent loading scripts from unknown sources and don't implement potentially unsafe JavaScript features, such as eval and other unsafe JavaScript primitives. Establishing a CSP is recommended to reduce these security risks.

If the code inside the Web View is compromised, the code gains access to all of the content inside the Web View and might interact with the host via the interop channel. For that reason, any content coming from the Web View (events, JS interop) must be treated as **untrusted** and validated in the same way as for other sensitive contexts, such as in a compromised Blazor Server app that can lead to malicious attacks on the host system.

Don't store sensitive information, such as credentials, security tokens, or sensitive user data, in the context of the Web View, as it makes the information available to a cyberattacker if the Web View is compromised. There are safer alternatives, such as handling the sensitive information directly within the native portion of the app.

External content rendered in an `iframe`

When using an iframe to display external content within a Blazor Hybrid page, we recommend that users leverage sandboxing features to ensure that the content is isolated from the parent page containing the app. In the following Razor component example, the sandbox attribute is present for the `<iframe>` tag to apply sandboxing features to the `admin.html` page:

razor

```razor
<iframe sandbox src="https://contoso.com/admin.html" />
```

> ⚠ **Warning**
>
> The sandbox attribute isn't supported in early browser versions. For more information, see Can I use: sandbox.

Links to external URLs

Links to URLs outside of the app are opened in an appropriate external app, not loaded within the Web View. We don't recommend overriding the default behavior.

Keep the Web View current in deployed apps

The BlazorWebView control uses the currently-installed, platform-specific native Web View. Since the native Web View is periodically updated with support for new APIs and fixes for security issues, it may be necessary to ensure that an app is using a Web View version that meets the app's requirements.

Use one of the following approaches to keep the Web View current in deployed apps:

- **On all platforms**: Check the Web View version and prompt the user to take any necessary steps to update it.
- **Only on Windows**: Package a fixed-version Web View within the app, using it in place of the system's shared Web View.

Android

The Android Web View is distributed and updated via the Google Play Store. Check the Web View version by reading the User-Agent string. Read the Web View's navigator.userAgent property using JavaScript interop and optionally cache the value using a singleton service if the user agent string is required outside of a Razor component context.

When using the Android Emulator:

- Use an emulated device with **Google Play Services** preinstalled. Emulated devices without Google Play Services preinstalled aren't supported.
- Install Google Chrome from the Google Play Store. If Google Chrome is already installed, update Chrome from the Google Play Store. If an emulated device doesn't have the latest version of Chrome installed, it might not have the latest version of the Android Web View installed.

iOS/Mac Catalyst

iOS and Mac Catalyst both use WKWebView, a Safari-based control, which is updated by the operating system. Similar to the Android case, determine the Web View version by reading the Web View's User-Agent string.

Windows (.NET MAUI, WPF, Windows Forms)

On Windows, the Chromium-based Microsoft Edge WebView2 is required to run Blazor web apps.

The newest installed version of `WebView2`, known as the *Evergreen distribution*, is used. If you wish to ship a specific version of `WebView2` with the app, use the *Fixed Version distribution*.

For more information on checking the currently-installed `WebView2` version and the distribution modes, see the WebView2 distribution documentation.

Publish ASP.NET Core Blazor Hybrid apps

Article • 02/09/2024

This article explains how to publish Blazor Hybrid apps.

Publish for a specific framework

Blazor Hybrid supports .NET MAUI, WPF, and Windows Forms. The publishing steps for apps using Blazor Hybrid are nearly identical to the publishing steps for the target platform.

- WPF and Windows Forms
  - .NET application publishing overview
- .NET MAUI
  - Windows
  - Android
  - iOS
  - macOS

Blazor-specific considerations

Blazor Hybrid apps require a Web View on the host platform. For more information, see Keep the Web View current in deployed Blazor Hybrid apps.

Troubleshoot ASP.NET Core Blazor Hybrid

Article • 02/09/2024

BlazorWebView has built-in logging that can help you diagnose problems in your Blazor Hybrid app.

This article explains the steps to use BlazorWebView logging:

- Enable BlazorWebView and related components to log diagnostic information.
- Configure logging providers.
- View logger output.

Enable `BlazorWebView` logging

Enable logging configuration during service registration. To enable maximum logging for BlazorWebView and related components under the Microsoft.AspNetCore.Components.WebView namespace, add the following code in the `Program` file:

C#

```
services.AddLogging(logging =>
{
    logging.AddFilter("Microsoft.AspNetCore.Components.WebView",
LogLevel.Trace);
});
```

Alternatively, use the following code to enable maximum logging for every component that uses Microsoft.Extensions.Logging:

C#

```
services.AddLogging(logging =>
{
    logging.SetMinimumLevel(LogLevel.Trace);
});
```

Configure logging providers

After configuring components to write log information, configure where the loggers should write log information.

The **Debug** logging providers write the output using Debug statements.

To configure the **Debug** logging provider, add a reference to the Microsoft.Extensions.Logging.Debug NuGet package.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at **Package consumption workflow (NuGet documentation)**. Confirm correct package versions at **NuGet.org**.

Register the provider inside the call to AddLogging added in the previous step by calling the AddDebug extension method:

C#

```
services.AddLogging(logging =>
{
    logging.AddFilter("Microsoft.AspNetCore.Components.WebView",
LogLevel.Trace);
    logging.AddDebug();
});
```

View logger output

When the app is run from Visual Studio with debugging enabled, the debug output appears in Visual Studio's **Output** window.

ASP.NET Core Blazor project structure

Article • 09/12/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article describes the files and folders that make up a Blazor app generated from a Blazor project template.

Blazor Web App

Blazor Web App project template: `blazor`

The Blazor Web App project template provides a single starting point for using Razor components (`.razor`) to build any style of web UI, both server-side rendered and client-side rendered. It combines the strengths of the existing Blazor Server and Blazor WebAssembly hosting models with server-side rendering, streaming rendering, enhanced navigation and form handling, and the ability to add interactivity using either Blazor Server or Blazor WebAssembly on a per-component basis.

If both client-side rendering (CSR) and interactive server-side rendering (interactive SSR) are selected on app creation, the project template uses the Interactive Auto render mode. The automatic rendering mode initially uses interactive SSR while the .NET app bundle and runtime are downloaded to the browser. After the .NET WebAssembly runtime is activated, rendering switches to CSR.

The Blazor Web App template enables both static and interactive server-side rendering using a single project. If you also enable Interactive WebAssembly rendering, the project includes an additional client project (`.Client`) for your WebAssembly-based components. The built output from the client project is downloaded to the browser and executed on the client. Components using the Interactive WebAssembly or Interactive Auto render modes must be located in the `.Client` project.

The component folder structure of the `.Client` project differs from the Blazor Web App's main project folder structure because the main project is a standard ASP.NET Core

project. The main project must take into account other assets for ASP.NET Core projects that are unrelated to Blazor. You're welcome to use whatever component folder structure you wish in the `.Client` project. You're free to mirror the component folder layout of the main project in the `.Client` project if you wish. Note that namespaces might require adjustments for such assets as layout files if you move components into different folders than the project template uses.

More information on components and render modes is found in the ASP.NET Core Razor components and ASP.NET Core Blazor render modes articles.

Based on the interactive render mode selected at app creation, the `Layout` folder is either in the server project in the `Components` folder or at the root of the `.Client` project. The folder contains the following layout components and stylesheets:

- The `MainLayout` component (`MainLayout.razor`) is the app's layout component.
- The `MainLayout.razor.css` is the stylesheet for the app's main layout.
- The `NavMenu` component (`NavMenu.razor`) implements sidebar navigation. The component includes NavLink components (NavLink), which render navigation links to other Razor components. The NavLink component indicates to the user which component is currently displayed.
- The `NavMenu.razor.css` is the stylesheet for the app's navigation menu.

The `Routes` component (`Routes.razor`) is either in the server project or the `.Client` project and sets up routing using the Router component. For client-side interactive components, the Router component intercepts browser navigation and renders the page that matches the requested address.

The `Components` folder of the server project holds the app's server-side Razor components. Shared components are often placed at the root of the `Components` folder, while layout and page components are usually placed in folders within the `Components` folder.

The `Components/Pages` folder of the server project contains the app's routable server-side Razor components. The route for each page is specified using the @page directive.

The `App` component (`App.razor`) is the root component of the app with HTML `<head>` markup, the `Routes` component, and the Blazor `<script>` tag. The root component is the first component that the app loads.

An `_Imports.razor` file in each of the server and `.Client` projects includes common Razor directives for Razor components of either project, such as @using directives for namespaces.

The `Properties` folder of the server project holds development environment configuration in the `launchSettings.json` file.

> **Note**
>
> The `http` profile precedes the `https` profile in the `launchSettings.json` file. When an app is run with the .NET CLI, the app runs at an HTTP endpoint because the first profile found is `http`. The profile order eases the transition of adopting HTTPS for Linux and macOS users. If you prefer to start the app with the .NET CLI without having to pass the `-lp https` or `--launch-profile https` option to the `dotnet watch` (or `dotnet run`) command, simply place the `https` profile above the `http` profile in the file.

The `wwwroot` folder of the server project is the Web Root folder for the server project that holds the app's public static assets.

The `Program.cs` file of the server project is the project's entry point that sets up the ASP.NET Core web application host and contains the app's startup logic, including service registrations, configuration, logging, and request processing pipeline:

- Services for Razor components are added by calling AddRazorComponents. AddInteractiveServerComponents adds services to support rendering Interactive Server components. AddInteractiveWebAssemblyComponents adds services to support rendering Interactive WebAssembly components.
- MapRazorComponents discovers available components and specifies the root component for the app (the first component loaded), which by default is the `App` component (`App.razor`). AddInteractiveServerRenderMode configures interactive server-side rendering (interactive SSR) for the app. AddInteractiveWebAssemblyRenderMode configures the Interactive WebAssembly render mode for the app.

The app settings files (`appsettings.Development.json`, `appsettings.json`) in either the server or `.Client` project provide configuration settings. In the server project, settings files are at the root of the project. In the `.Client` project, settings files are consumed from the Web Root folder, `wwwroot`.

In the `.Client` project:

- The `Pages` folder contains routable client-side Razor components. The route for each page is specified using the @page directive.

- The `wwwroot` folder is the Web Root folder for the `.Client` project that holds the app's public static assets.
- The `Program.cs` file is the project's entry point that sets up the WebAssembly host and contains the project's startup logic, including service registrations, configuration, logging, and request processing pipeline.

Additional files and folders may appear in an app produced from a Blazor Web App project template when additional options are configured. For example, generating an app with ASP.NET Core Identity includes additional assets for authentication and authorization features.

Standalone Blazor WebAssembly

Standalone Blazor WebAssembly project template: `blazorwasm`

The Blazor WebAssembly template creates the initial files and directory structure for a standalone Blazor WebAssembly app:

- If the `blazorwasm` template is used, the app is populated with the following:
  - Demonstration code for a `Weather` component that loads data from a static asset (`weather.json`) and user interaction with a `Counter` component.
  - Bootstrap frontend toolkit.
- The `blazorwasm` template can also be generated without sample pages and styling.

Project structure:

- `Layout` folder: Contains the following layout components and stylesheets:
  - `MainLayout` component (`MainLayout.razor`): The app's layout component.
  - `MainLayout.razor.css`: Stylesheet for the app's main layout.
  - `NavMenu` component (`NavMenu.razor`): Implements sidebar navigation. Includes the NavLink component (NavLink), which renders navigation links to other Razor components. The NavLink component automatically indicates a selected state when its component is loaded, which helps the user understand which component is currently displayed.
  - `NavMenu.razor.css`: Stylesheet for the app's navigation menu.
- `Pages` folder: Contains the Blazor app's routable Razor components (`.razor`). The route for each page is specified using the @page directive. The template includes the following components:
  - `Counter` component (`Counter.razor`): Implements the Counter page.
  - `Index` component (`Index.razor`): Implements the Home page.

    - `Weather` component (`Weather.razor`): Implements the Weather page.

- `_Imports.razor`: Includes common Razor directives to include in the app's components (`.razor`), such as @using directives for namespaces.

- `App.razor`: The root component of the app that sets up client-side routing using the Router component. The Router component intercepts browser navigation and renders the page that matches the requested address.

- `Properties` folder: Holds development environment configuration in the `launchSettings.json` file.

  > **Note**
  >
  > The `http` profile precedes the `https` profile in the `launchSettings.json` file. When an app is run with the .NET CLI, the app runs at an HTTP endpoint because the first profile found is `http`. The profile order eases the transition of adopting HTTPS for Linux and macOS users. If you prefer to start the app with the .NET CLI without having to pass the `-lp https` or `--launch-profile https` option to the `dotnet watch` (or `dotnet run`) command, simply place the `https` profile above the `http` profile in the file.

- `wwwroot` folder: The Web Root folder for the app containing the app's public static assets, including `appsettings.json` and environmental app settings files for configuration settings and sample weather data (`sample-data/weather.json`). The `index.html` webpage is the root page of the app implemented as an HTML page:
    - When any page of the app is initially requested, this page is rendered and returned in the response.
    - The page specifies where the root `App` component is rendered. The component is rendered at the location of the `div` DOM element with an `id` of `app` (`<div id="app">Loading...</div>`).

- `Program.cs`: The app's entry point that sets up the WebAssembly host:
    - The `App` component is the root component of the app. The `App` component is specified as the `div` DOM element with an `id` of `app` (`<div id="app">Loading...</div>` in `wwwroot/index.html`) to the root component collection (`builder.RootComponents.Add<App>("#app")`).
    - Services are added and configured (for example, `builder.Services.AddSingleton<IMyDependency, MyDependency>()`).

Additional files and folders may appear in an app produced from a Blazor WebAssembly project template when additional options are configured. For example, generating an app with ASP.NET Core Identity includes additional assets for authentication and authorization features.

Location of the Blazor script

The Blazor script is served from an embedded resource in the ASP.NET Core shared framework.

In a Blazor Web App, the Blazor script is located in the `Components/App.razor` file:

```
HTML
<script src="_framework/blazor.web.js"></script>
```

In a Blazor Server app, the Blazor script is located in the `Pages/_Host.cshtml` file:

```
HTML
<script src="_framework/blazor.server.js"></script>
```

In a Blazor WebAssembly app, the Blazor script content is located in the `wwwroot/index.html` file:

```
HTML
<script src="_framework/blazor.webassembly.js"></script>
```

Location of `<head>` and `<body>` content

In a Blazor Web App, `<head>` and `<body>` content is located in the `Components/App.razor` file.

In a Blazor WebAssembly app, `<head>` and `<body>` content is located in the `wwwroot/index.html` file.

ASP.NET Core Blazor fundamentals

Article • 11/04/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

Fundamentals articles provide guidance on foundational Blazor concepts. Some of the concepts are connected to a basic understanding of *Razor components*, which are described further in the next section of this article and covered in detail in the *Components* articles.

Static and interactive rendering concepts

Razor components are either *statically* rendered or *interactively* rendered.

Static or *static rendering* is a server-side scenario that means the component is rendered without the capacity for interplay between the user and .NET/C# code. JavaScript and HTML DOM events remain unaffected, but no user events on the client can be processed with .NET running on the server.

Interactive or *interactive rendering* means that the component has the capacity to process .NET events via C# code. The .NET events are either processed on the server by the ASP.NET Core runtime or in the browser on the client by the WebAssembly-based Blazor runtime.

> **Important**
>
> When using a Blazor Web App, most of the Blazor documentation example components ***require*** interactivity to function and demonstrate the concepts covered by the articles. When you test an example component provided by an article, make sure that either the app adopts global interactivity or the component adopts an interactive render mode.

More information on these concepts and how to control static and interactive rendering is found in the ASP.NET Core Blazor render modes article later in the Blazor

documentation.

Client and server rendering concepts

Throughout the Blazor documentation, activity that takes place on the user's system is said to occur *on the client* or *client-side*. Activity that takes place on a server is said to occur *on the server* or *server-side*.

The term *rendering* means to produce the HTML markup that browsers display.

- **Client-side rendering (CSR)** means that the final HTML markup is generated by the .NET WebAssembly runtime on the client. No HTML for the app's client-generated UI is sent from a server to the client for this type of rendering. User interactivity with the page is assumed. There's no such concept as *static* client-side rendering. CSR is assumed to be interactive, so "*interactive* client-side rendering" and "*interactive* CSR" aren't used by the industry or in the Blazor documentation.

- **Server-side rendering (SSR)** means that the final HTML markup is generated by the ASP.NET Core runtime on the server. The HTML is sent to the client over a network for display by the client's browser. No HTML for the app's server-generated UI is created by the client for this type of rendering. SSR can be of two varieties:
  - **Static SSR**: The server produces static HTML that doesn't provide for user interactivity or maintaining Razor component state.
  - **Interactive SSR**: Blazor events permit user interactivity and Razor component state is maintained by the Blazor framework.

- **Prerendering** is the process of initially rendering page content on the server without enabling event handlers for rendered controls. The server outputs the HTML UI of the page as soon as possible in response to the initial request, which makes the app feel more responsive to users. Prerendering can also improve Search Engine Optimization (SEO) by rendering content for the initial HTTP response that search engines use to calculate page rank. Prerendering is always followed by final rendering, either on the server or the client.

Razor components

Blazor apps are based on *Razor components*, often referred to as just *components*. A *component* is an element of UI, such as a page, dialog, or data entry form. Components are .NET C# classes built into .NET assemblies.

Razor refers to how components are usually written in the form of a Razor markup page for client-side UI logic and composition. Razor is a syntax for combining HTML markup with C# code designed for developer productivity. Razor files use the `.razor` file extension.

Although some Blazor developers and online resources use the term "Blazor components," the documentation avoids that term and universally uses "Razor components" or "components."

Blazor documentation adopts several conventions for showing and discussing components:

- Generally, examples adhere to ASP.NET Core/C# coding conventions and engineering guidelines. For more information see the following resources:
  - ASP.NET Core framework engineering guidelines (dotnet/aspnetcore GitHub repository)
  - C# Coding Conventions (C# guide)
- Project code, file paths and names, project template names, and other specialized terms are in United States English and usually code-fenced.
- Components are usually referred to by their C# class name (Pascal case) followed by the word "component." For example, a typical file upload component is referred to as the "`FileUpload` component."
- Usually, a component's C# class name is the same as its file name.
- Routable components usually set their relative URLs to the component's class name in kebab-case. For example, a `FileUpload` component includes routing configuration to reach the rendered component at the relative URL `/file-upload`. Routing and navigation is covered in ASP.NET Core Blazor routing and navigation.
- When multiple versions of a component are used, they're numbered sequentially. For example, the `FileUpload3` component is reached at `/file-upload-3`.
- Razor directives at the top of a component definition (`.razor file`) are placed in the following order: `@page`, `@rendermode` (.NET 8 or later), `@using` statements, other directives in alphabetical order.
- Although not required for `private` members, access modifiers are used in article examples and sample apps. For example, `private` is stated for declaring a field named `maxAllowedFiles` as `private int maxAllowedFiles = 3;`.
- Component parameter values lead with a Razor reserved @ symbol, but it isn't required. Literals (for example, boolean values), keywords (for example, `this`), and `null` as component parameter values aren't prefixed with `@`, but this is also merely a documentation convention. Your own code can prefix literals with `@` if you wish.
- C# classes use the this keyword and avoid prefixing fields with an underscore (`_`) that are assigned to in constructors, which differs from the ASP.NET Core

framework engineering guidelines.

- In examples that use primary constructors (C# 12 or later), primary constructor parameters are typically used directly by class members.

Additional information on Razor component syntax is provided in the *Razor syntax* section of ASP.NET Core Razor components.

The following is an example counter component and part of an app created from a Blazor project template. Detailed components coverage is found in the *Components* articles later in the documentation. The following example demonstrates component concepts seen in the *Fundamentals* articles before reaching the *Components* articles later in the documentation.

`Counter.razor`:

The component assumes that an interactive render mode is inherited from a parent component or applied globally to the app.

razor

```razor
@page "/counter"

<PageTitle>Counter</PageTitle>

<h1>Counter</h1>

<p role="status">Current count: @currentCount</p>

<button class="btn btn-primary" @onclick="IncrementCount">Click me</button>

@code {
    private int currentCount = 0;

    private void IncrementCount() => currentCount++;
}
```

The preceding `Counter` component:

- Sets its route with the `@page` directive in the first line.
- Sets its page title and heading.
- Renders the current count with `@currentCount`. `currentCount` is an integer variable defined in the C# code of the `@code` block.
- Displays a button to trigger the `IncrementCount` method, which is also found in the `@code` block and increases the value of the `currentCount` variable.

Render modes

Articles in the *Fundamentals* node make reference to the concept of *render modes*. This subject is covered in detail in the ASP.NET Core Blazor render modes article in the *Components* node, which appears after the *Fundamentals* node of articles.

For the early references in this node of articles to render mode concepts, merely note the following at this time:

Every component in a Blazor Web App adopts a *render mode* to determine the hosting model that it uses, where it's rendered, and whether or not it's rendered statically on the server, rendered with for user interactivity on the server, or rendered for user interactivity on the client (usually with prerendering on the server).

Blazor Server and Blazor WebAssembly apps for ASP.NET Core releases prior to .NET 8 remain fixated on *hosting model* concepts, not render modes. Render modes are conceptually applied to Blazor Web Apps in .NET 8 or later.

The following table shows the available render modes for rendering Razor components in a Blazor Web App. Render modes are applied to components with the `@rendermode` directive on the component instance or on the component definition. It's also possible to set a render mode for the entire app.

Expand table

Name	Description	Render location	Interactive
Static Server	Static server-side rendering (static SSR)	Server	✗
Interactive Server	Interactive server-side rendering (interactive SSR) using Blazor Server	Server	✓
Interactive WebAssembly	Client-side rendering (CSR) using Blazor WebAssembly†	Client	✓
Interactive Auto	Interactive SSR using Blazor Server initially and then CSR on subsequent visits after the Blazor bundle is downloaded	Server, then client	✓

†Client-side rendering (CSR) is assumed to be interactive. "*Interactive* client-side rendering" and "*interactive* CSR" aren't used by the industry or in the Blazor documentation.

The preceding information on render modes is all that you need to know to understand the *Fundamentals* node articles. If you're new to Blazor and reading Blazor articles in

order down the table of contents, you can delay consuming in-depth information on render modes until you reach the ASP.NET Core Blazor render modes article in the *Components* node.

Document Object Model (DOM)

References to the *Document Object Model* use the abbreviation *DOM*.

For more information, see the following resources:

- Introduction to the DOM (MDN documentation)
- Level 1 Document Object Model Specification (W3C)

Subset of .NET APIs for Blazor WebAssembly apps

A curated list of specific .NET APIs that are supported on the browser for Blazor WebAssembly isn't available. However, you can manually search for a list of .NET APIs annotated with [UnsupportedOSPlatform("browser")] to discover .NET APIs that aren't supported in WebAssembly.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

For more information, see the following resources:

- Class libraries: Client-side browser compatibility analyzer
- Annotating APIs as unsupported on specific platforms (dotnet/designs GitHub repository

Sample apps

Documentation sample apps are available for inspection and download:

Blazor samples GitHub repository (dotnet/blazor-samples)

Locate a sample app by first selecting the version folder that matches the version of .NET that you're working with.

For more information and a list of the samples in the repository, see the Blazor samples GitHub repository README.md file.

The ASP.NET Core repository's Basic Test App is also a helpful set of samples for various Blazor scenarios:

BasicTestApp in ASP.NET Core reference source (dotnet/aspnetcore)

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

To download the sample apps:

- Download the Blazor samples repository ZIP file.
- Unzip the file.

Byte multiples

.NET byte sizes use metric prefixes for non-decimal multiples of bytes based on powers of 1024.

Expand table

Name (abbreviation)	Size	Example
Kilobyte (KB)	1,024 bytes	1 KB = 1,024 bytes
Megabyte (MB)	$1{,}024^2$ bytes	1 MB = 1,048,576 bytes
Gigabyte (GB)	$1{,}024^3$ bytes	1 GB = 1,073,741,824 bytes

Support requests

Only documentation-related issues are appropriate for the `dotnet/AspNetCore.Docs` repository. ***For product support, don't open a documentation issue.*** Seek assistance

through one or more of the following support channels:

- Stack Overflow (tagged: blazor)
- General ASP.NET Core Slack Team
- Blazor Gitter

For a potential bug in the framework or product feedback, open an issue for the ASP.NET Core product unit at dotnet/aspnetcore issues. Bug reports usually ***require*** the following:

- **Clear explanation of the problem**: Follow the instructions in the GitHub issue template provided by the product unit when opening the issue.
- **Minimal repro project**: Place a project on GitHub for the product unit engineers to download and run. Cross-link the project into the issue's opening comment.

For a potential problem with a Blazor article, open a documentation issue. To open a documentation issue, use the **Open a documentation issue** feedback link at the bottom of the article. Metadata added to your issue provides tracking data and automatically pings the author of the article. If the subject was discussed with the product unit prior to opening the documentation issue, place a cross-link to the engineering issue in the documentation issue's opening comment.

For problems or feedback on Visual Studio, use the **Report a Problem** or **Suggest a Feature** gestures from within Visual Studio, which open internal issues for Visual Studio. For more information, see Visual Studio Feedback.

For problems with Visual Studio Code, ask for support on community support forums. For bug reports and product feedback, open an issue on the microsoft/vscode GitHub repo.

GitHub issues for Blazor documentation are automatically marked for triage on the Blazor.Docs project (dotnet/AspNetCore.Docs GitHub repository). Please wait a short while for a response, especially over weekends and holidays. Usually, documentation authors respond within 24 hours on weekdays.

Community links to Blazor resources

ASP.NET Core Blazor routing and navigation

Article • 10/21/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article explains how to manage Blazor app request routing and how to use the NavLink component to create navigation links.

> **Important**
>
> Code examples throughout this article show methods called on `Navigation`, which is an injected NavigationManager in classes and components.

Static versus interactive routing

This section applies to Blazor Web Apps.

If prerendering is enabled, the Blazor router (`Router` component, `<Router>` in `Routes.razor`) performs static routing to components during static server-side rendering (static SSR). This type of routing is called *static routing*.

When an interactive render mode is assigned to the `Routes` component, the Blazor router becomes interactive after static SSR with static routing on the server. This type of routing is called *interactive routing*.

Static routers use endpoint routing and the HTTP request path to determine which component to render. When the router becomes interactive, it uses the document's URL (the URL in the browser's address bar) to determine which component to render. This means that the interactive router can dynamically change which component is rendered if the document's URL dynamically changes to another valid internal URL, and it can do so without performing an HTTP request to fetch new page content.

Interactive routing also prevents prerendering because new page content isn't requested from the server with a normal page request. For more information, see Prerender ASP.NET Core Razor components.

Route templates

The Router component enables routing to Razor components and is located in the app's `Routes` component (`Components/Routes.razor`).

When a Razor component (`.razor`) with an @page directive is compiled, the generated component class is provided a RouteAttribute specifying the component's route template.

When the app starts, the assembly specified as the Router's `AppAssembly` is scanned to gather route information for the app's components that have a RouteAttribute.

At runtime, the RouteView component:

- Receives the RouteData from the Router along with any route parameters.

- Renders the specified component with its layout, including any further nested layouts.

Optionally specify a DefaultLayout parameter with a layout class for components that don't specify a layout with the @layout directive. The framework's Blazor project templates specify the `MainLayout` component (`MainLayout.razor`) as the app's default layout. For more information on layouts, see ASP.NET Core Blazor layouts.

Components support multiple route templates using multiple @page directives. The following example component loads on requests for `/blazor-route` and `/different-blazor-route`.

`BlazorRoute.razor`:

razor

```
@page "/blazor-route"
@page "/different-blazor-route"

<PageTitle>Routing</PageTitle>

<h1>Routing Example</h1>

<p>
    This page is reached at either <code>/blazor-route</code> or
    <code>/different-blazor-route</code>.
</p>
```

> **Important**
>
> For URLs to resolve correctly, the app must include a `<base>` tag (location of <head> content) with the app base path specified in the `href` attribute. For more information, see Host and deploy ASP.NET Core Blazor.

As an alternative to specifying the route template as a string literal with the `@page` directive, constant-based route templates can be specified with the @attribute directive.

In the following example, the `@page` directive in a component is replaced with the `@attribute` directive and the constant-based route template in `Constants.CounterRoute`, which is set elsewhere in the app to "`/counter`":

diff

```
- @page "/counter"
+ @attribute [Route(Constants.CounterRoute)]
```

Focus an element on navigation

The FocusOnNavigate component sets the UI focus to an element based on a CSS selector after navigating from one page to another.

razor

```
<FocusOnNavigate RouteData="routeData" Selector="h1" />
```

When the Router component navigates to a new page, the FocusOnNavigate component sets the focus to the page's top-level header (`<h1>`). This is a common strategy for ensuring that a page navigation is announced when using a screen reader.

Provide custom content when content isn't found

The Router component allows the app to specify custom content if content isn't found for the requested route.

Set custom content for the Router component's NotFound parameter:

```razor
<Router ...>
    ...
    <NotFound>
        ...
    </NotFound>
</Router>
```

Arbitrary items are supported as content of the NotFound parameter, such as other interactive components. To apply a default layout to NotFound content, see ASP.NET Core Blazor layouts.

> **Important**
>
> Blazor Web Apps don't use the **NotFound** parameter (`<NotFound>...</NotFound>` markup), but the parameter is supported for backward compatibility to avoid a breaking change in the framework. The server-side ASP.NET Core middleware pipeline processes requests on the server. Use server-side techniques to handle bad requests. For more information, see **ASP.NET Core Blazor render modes**.

Route to components from multiple assemblies

This section applies to Blazor Web Apps.

Use the Router component's AdditionalAssemblies parameter and the endpoint convention builder AddAdditionalAssemblies to discover routable components in additional assemblies. The following subsections explain when and how to use each API.

Static routing

To discover routable components from additional assemblies for static server-side rendering (static SSR), even if the router later becomes interactive for interactive rendering, the assemblies must be disclosed to the Blazor framework. Call the AddAdditionalAssemblies method with the additional assemblies chained to MapRazorComponents in the server project's `Program` file.

The following example includes the routable components in the `BlazorSample.Client` project's assembly using the project's `_Imports.razor` file:

```C#
app.MapRazorComponents<App>()
    .AddAdditionalAssemblies(typeof(BlazorSample.Client._Imports).Assembly);
```

> **Note**
>
> The preceding guidance also applies in **component class library** scenarios. Additional important guidance for class libraries and static SSR is found in **ASP.NET Core Razor class libraries (RCLs) with static server-side**

rendering (static SSR).

Interactive routing

An interactive render mode can be assigned to the `Routes` component (`Routes.razor`) that makes the Blazor router become interactive after static SSR and static routing on the server. For example, `<Routes @rendermode="InteractiveServer" />` assigns interactive server-side rendering (interactive SSR) to the `Routes` component. The `Router` component inherits interactive server-side rendering (interactive SSR) from the `Routes` component. The router becomes interactive after static routing on the server.

Internal navigation for interactive routing doesn't involve requesting new page content from the server. Therefore, prerendering doesn't occur for internal page requests. For more information, see Prerender ASP.NET Core Razor components.

If the `Routes` component is defined in the server project, the AdditionalAssemblies parameter of the `Router` component should include the `.Client` project's assembly. This allows the router to work correctly when rendered interactively.

In the following example, the `Routes` component is in the server project, and the `_Imports.razor` file of the `BlazorSample.Client` project indicates the assembly to search for routable components:

razor

```
<Router
    AppAssembly="..."
    AdditionalAssemblies="new[] { typeof(BlazorSample.Client._Imports).Assembly }">
    ...
</Router>
```

Additional assemblies are scanned in addition to the assembly specified to AppAssembly.

> **Note**
>
> The preceding guidance also applies in component class library scenarios.

Alternatively, routable components only exist in the `.Client` project with global Interactive WebAssembly or Auto rendering applied, and the `Routes` component is defined in the `.Client` project, not the server project. In this case, there aren't external assemblies with routable components, so it isn't necessary to specify a value for AdditionalAssemblies.

Route parameters

The router uses route parameters to populate the corresponding component parameters with the same name. Route parameter names are case insensitive. In the following example, the `text` parameter assigns the value of the route segment to the component's `Text` property. When a request is made for `/route-parameter-1/amazing`, the content is rendered as `Blazor is amazing!`.

`RouteParameter1.razor`:

razor

```razor
@page "/route-parameter-1/{text}"

<PageTitle>Route Parameter 1</PageTitle>

<h1>Route Parameter Example 1</h1>

<p>Blazor is @Text!</p>

@code {
    [Parameter]
    public string? Text { get; set; }
}
```

Optional parameters are supported. In the following example, the `text` optional parameter assigns the value of the route segment to the component's `Text` property. If the segment isn't present, the value of `Text` is set to `fantastic`.

`RouteParameter2.razor`:

razor

```razor
@page "/route-parameter-2/{text?}"

<PageTitle>Route Parameter 2</PageTitle>

<h1>Route Parameter Example 2</h1>

<p>Blazor is @Text!</p>

@code {
    [Parameter]
    public string? Text { get; set; }

    protected override void OnParametersSet() => Text = Text ?? "fantastic";
}
```

When the OnInitialized{Async} lifecycle method is used instead of the OnParametersSet{Async} lifecycle method, the default assignment of the `Text` property to `fantastic` doesn't occur if the user navigates within the same component. For example, this situation arises when the user navigates from `/route-parameter-2/amazing` to `/route-parameter-2`. As the component instance persists and accepts new parameters, the `OnInitialized` method isn't invoked again.

Route constraints

A route constraint enforces type matching on a route segment to a component.

In the following example, the route to the `User` component only matches if:

- An `Id` route segment is present in the request URL.
- The `Id` segment is an integer (`int`) type.

`User.razor`:

razor

```razor
@page "/user/{Id:int}"

<PageTitle>User</PageTitle>
```

```razor
<h1>User Example</h1>

<p>User Id: @Id</p>

@code {
    [Parameter]
    public int Id { get; set; }
}
```

The route constraints shown in the following table are available. For the route constraints that match the invariant culture, see the warning below the table for more information.

Expand table

Constraint	Example	Example Matches	Invariant culture matching
`bool`	`{active:bool}`	`true`, `FALSE`	No
`datetime`	`{dob:datetime}`	`2016-12-31`, `2016-12-31 7:32pm`	Yes
`decimal`	`{price:decimal}`	`49.99`, `-1,000.01`	Yes
`double`	`{weight:double}`	`1.234`, `-1,001.01e8`	Yes
`float`	`{weight:float}`	`1.234`, `-1,001.01e8`	Yes
`guid`	`{id:guid}`	`00001111-aaaa-2222-bbbb-3333cccc4444`, `{00001111-aaaa-2222-bbbb-3333cccc4444}`	No
`int`	`{id:int}`	`123456789`, `-123456789`	Yes
`long`	`{ticks:long}`	`123456789`, `-123456789`	Yes
`nonfile`	`{parameter:nonfile}`	Not `BlazorSample.styles.css`, not `favicon.ico`	Yes

> ⚠ **Warning**
>
> Route constraints that verify the URL and are converted to a CLR type (such as `int` or DateTime) always use the invariant culture. These constraints assume that the URL is non-localizable.

Route constraints also work with optional parameters. In the following example, `Id` is required, but `Option` is an optional boolean route parameter.

`User.razor`:

```razor
@page "/user/{id:int}/{option:bool?}"

<p>
    Id: @Id
</p>

<p>
    Option: @Option
</p>

@code {
    [Parameter]
```

```
    public int Id { get; set; }

    [Parameter]
    public bool Option { get; set; }
}
```

Avoid file capture in a route parameter

The following route template inadvertently captures static asset paths in its optional route parameter (`Optional`). For example, the app's stylesheet (`.styles.css`) is captured, which breaks the app's styles:

razor

```
@page "/{optional?}"

...

@code {
    [Parameter]
    public string? Optional { get; set; }
}
```

To restrict a route parameter to capturing non-file paths, use the :nonfile constraint in the route template:

razor

```
@page "/{optional:nonfile?}"
```

Catch-all route parameters

Catch-all route parameters, which capture paths across multiple folder boundaries, are supported in components.

Catch-all route parameters are:

- Named to match the route segment name. Naming isn't case-sensitive.
- A `string` type. The framework doesn't provide automatic casting.
- At the end of the URL.

`CatchAll.razor`:

razor

```
@page "/catch-all/{*pageRoute}"

<PageTitle>Catch All</PageTitle>

<h1>Catch All Parameters Example</h1>

<p>Add some URI segments to the route and request the page again.</p>

<p>
    PageRoute: @PageRoute
</p>

@code {
    [Parameter]
    public string? PageRoute { get; set; }
}
```

For the URL `/catch-all/this/is/a/test` with a route template of `/catch-all/{*pageRoute}`, the value of `PageRoute` is set to `this/is/a/test`.

Slashes and segments of the captured path are decoded. For a route template of `/catch-all/{*pageRoute}`, the URL `/catch-all/this/is/a%2Ftest%2A` yields `this/is/a/test*`.

URI and navigation state helpers

Use NavigationManager to manage URIs and navigation in C# code. NavigationManager provides the event and methods shown in the following table.

Expand table

Member	Description
Uri	Gets the current absolute URI.
BaseUri	Gets the base URI (with a trailing slash) that can be prepended to relative URI paths to produce an absolute URI. Typically, BaseUri corresponds to the `href` attribute on the document's `<base>` element (location of <head> content).
NavigateTo	Navigates to the specified URI. If `forceLoad` is `false`: • And enhanced navigation is available at the current URL, Blazor's enhanced navigation is activated. • Otherwise, Blazor performs a full-page reload for the requested URL. If `forceLoad` is `true`: • Client-side routing is bypassed. • The browser is forced to load the new page from the server, whether or not the URI is normally handled by the client-side interactive router. For more information, see the Enhanced navigation and form handling section. If `replace` is `true`, the current URI in the browser history is replaced instead of pushing a new URI onto the history stack.
LocationChanged	An event that fires when the navigation location has changed. For more information, see the Location changes section.
ToAbsoluteUri	Converts a relative URI into an absolute URI.
ToBaseRelativePath	Based on the app's base URI, converts an absolute URI into a URI relative to the base URI prefix. For an example, see the Produce a URI relative to the base URI prefix section.
RegisterLocationChangingHandler	Registers a handler to process incoming navigation events. Calling NavigateTo always invokes the handler.
GetUriWithQueryParameter	Returns a URI constructed by updating NavigationManager.Uri with a single parameter added, updated, or removed. For more information, see the Query strings section.

Location changes

For the LocationChanged event, LocationChangedEventArgs provides the following information about navigation events:

- Location: The URL of the new location.

- IsNavigationIntercepted: If `true`, Blazor intercepted the navigation from the browser. If `false`, NavigationManager.NavigateTo caused the navigation to occur.

The following component:

- Navigates to the app's `Counter` component (`Counter.razor`) when the button is selected using NavigateTo.
- Handles the location changed event by subscribing to NavigationManager.LocationChanged.
  - The `HandleLocationChanged` method is unhooked when `Dispose` is called by the framework. Unhooking the method permits garbage collection of the component.
  - The logger implementation logs the following information when the button is selected:

    > BlazorSample.Pages.Navigate: Information: URL of new location: https://localhost:{PORT}/counter

`Navigate.razor`:

razor

```
@page "/navigate"
@implements IDisposable
@inject ILogger<Navigate> Logger
@inject NavigationManager Navigation

<PageTitle>Navigate</PageTitle>

<h1>Navigate Example</h1>

<button class="btn btn-primary" @onclick="NavigateToCounterComponent">
    Navigate to the Counter component
</button>

@code {
    private void NavigateToCounterComponent() => Navigation.NavigateTo("counter");

    protected override void OnInitialized() =>
        Navigation.LocationChanged += HandleLocationChanged;

    private void HandleLocationChanged(object? sender, LocationChangedEventArgs e) =>
        Logger.LogInformation("URL of new location: {Location}", e.Location);

    public void Dispose() => Navigation.LocationChanged -= HandleLocationChanged;
}
```

For more information on component disposal, see ASP.NET Core Razor component lifecycle.

Enhanced navigation and form handling

This section applies to Blazor Web Apps.

Blazor Web Apps are capable of two types of routing for page navigation and form handling requests:

- Normal navigation (cross-document navigation): a full-page reload is triggered for the request URL.
- Enhanced navigation (same-document navigation): Blazor intercepts the request and performs a `fetch` request instead. Blazor then patches the response content into the page's DOM. Blazor's enhanced navigation and form handling avoid the need for a full-page reload and preserves more of the page state, so pages load faster, usually without losing the user's scroll position on the page.

Enhanced navigation is available when:

- The Blazor Web App script (`blazor.web.js`) is used, not the Blazor Server script (`blazor.server.js`) or Blazor WebAssembly script (`blazor.webassembly.js`).
- The feature isn't explicitly disabled.
- The destination URL is within the internal base URI space (the app's base path).

If server-side routing and enhanced navigation are enabled, location changing handlers are only invoked for programmatic navigation initiated from an interactive runtime. In future releases, additional types of navigation, such as following a link, may also invoke location changing handlers.

When an enhanced navigation occurs, LocationChanged event handlers registered with Interactive Server and WebAssembly runtimes are typically invoked. There are cases when location changing handlers might not intercept an enhanced navigation. For example, the user might switch to another page before an interactive runtime becomes available. Therefore, it's important that app logic not rely on invoking a location changing handler, as there's no guarantee of the handler executing.

When calling NavigateTo:

- If `forceLoad` is `false`, which is the default:
  - And enhanced navigation is available at the current URL, Blazor's enhanced navigation is activated.
  - Otherwise, Blazor performs a full-page reload for the requested URL.
- If `forceLoad` is `true`: Blazor performs a full-page reload for the requested URL, whether enhanced navigation is available or not.

You can refresh the current page by calling `NavigationManager.Refresh(bool forceLoad = false)`, which always performs an enhanced navigation, if available. If enhanced navigation isn't available, Blazor performs a full-page reload.

C#

```
Navigation.Refresh();
```

Pass `true` to the `forceLoad` parameter to ensure a full-page reload is always performed, even if enhanced navigation is available:

C#

```
Navigation.Refresh(true);
```

Enhanced navigation is enabled by default, but it can be controlled hierarchically and on a per-link basis using the `data-enhance-nav` HTML attribute.

The following examples disable enhanced navigation:

HTML

```
<a href="redirect" data-enhance-nav="false">
    GET without enhanced navigation
</a>
```

razor

```
<ul data-enhance-nav="false">
    <li>
        <a href="redirect">GET without enhanced navigation</a>
    </li>
    <li>
```

```
        <a href="redirect-2">GET without enhanced navigation</a>
    </li>
</ul>
```

If the destination is a non-Blazor endpoint, enhanced navigation doesn't apply, and the client-side JavaScript retries as a full page load. This ensures no confusion to the framework about external pages that shouldn't be patched into an existing page.

To enable enhanced form handling, add the Enhance parameter to EditForm forms or the `data-enhance` attribute to HTML forms (`<form>`):

razor

```
<EditForm ... Enhance ...>
    ...
</EditForm>
```

HTML

```
<form ... data-enhance ...>
    ...
</form>
```

Enhanced form handling isn't hierarchical and doesn't flow to child forms:

❌ You can't set enhanced navigation on a form's ancestor element to enable enhanced navigation for the form.

HTML

```
<div ... data-enhance ...>
    <form ...>
        <!-- NOT enhanced -->
    </form>
</div>
```

Enhanced form posts only work with Blazor endpoints. Posting an enhanced form to non-Blazor endpoint results in an error.

To disable enhanced navigation:

- For an EditForm, remove the Enhance parameter from the form element (or set it to `false`: `Enhance="false"`).
- For an HTML `<form>`, remove the `data-enhance` attribute from form element (or set it to `false`: `data-enhance="false"`).

Blazor's enhanced navigation and form handing may undo dynamic changes to the DOM if the updated content isn't part of the server rendering. To preserve the content of an element, use the `data-permanent` attribute.

In the following example, the content of the `<div>` element is updated dynamically by a script when the page loads:

HTML

```
<div data-permanent>
    ...
</div>
```

Once Blazor has started on the client, you can use the `enhancedload` event to listen for enhanced page updates. This allows for re-applying changes to the DOM that may have been undone by an enhanced page update.

JavaScript

```
Blazor.addEventListener('enhancedload', () => console.log('Enhanced update!'));
```

To disable enhanced navigation and form handling globally, see ASP.NET Core Blazor startup.

Enhanced navigation with static server-side rendering (static SSR) requires special attention when loading JavaScript. For more information, see ASP.NET Core Blazor JavaScript with static server-side rendering (static SSR).

Produce a URI relative to the base URI prefix

Based on the app's base URI, ToBaseRelativePath converts an absolute URI into a URI relative to the base URI prefix.

Consider the following example:

C#

```
try
{
    baseRelativePath = Navigation.ToBaseRelativePath(inputURI);
}
catch (ArgumentException ex)
{
    ...
}
```

If the base URI of the app is `https://localhost:8000`, the following results are obtained:

- Passing `https://localhost:8000/segment` in `inputURI` results in a `baseRelativePath` of `segment`.
- Passing `https://localhost:8000/segment1/segment2` in `inputURI` results in a `baseRelativePath` of `segment1/segment2`.

If the base URI of the app doesn't match the base URI of `inputURI`, an ArgumentException is thrown.

Passing `https://localhost:8001/segment` in `inputURI` results in the following exception:

> System.ArgumentException: 'The URI 'https://localhost:8001/segment' is not contained by the base URI 'https://localhost:8000/'.'

Navigation history state

The NavigationManager uses the browser's History API to maintain navigation history state associated with each location change made by the app. Maintaining history state is particularly useful in external redirect scenarios, such as when authenticating users with external identity providers. For more information, see the Navigation options section.

Navigation options

Pass NavigationOptions to NavigateTo to control the following behaviors:

- ForceLoad: Bypass client-side routing and force the browser to load the new page from the server, whether or not the URI is handled by the client-side router. The default value is `false`.
- ReplaceHistoryEntry: Replace the current entry in the history stack. If `false`, append the new entry to the history stack. The default value is `false`.
- HistoryEntryState: Gets or sets the state to append to the history entry.

C#

```
Navigation.NavigateTo("/path", new NavigationOptions
{
    HistoryEntryState = "Navigation state"
});
```

For more information on obtaining the state associated with the target history entry while handling location changes, see the Handle/prevent location changes section.

Query strings

Use the [SupplyParameterFromQuery] attribute to specify that a component parameter comes from the query string.

Component parameters supplied from the query string support the following types:

- `bool`, `DateTime`, `decimal`, `double`, `float`, `Guid`, `int`, `long`, `string`.
- Nullable variants of the preceding types.
- Arrays of the preceding types, whether they're nullable or not nullable.

The correct culture-invariant formatting is applied for the given type (CultureInfo.InvariantCulture).

Specify the `[SupplyParameterFromQuery]` attribute's Name property to use a query parameter name different from the component parameter name. In the following example, the C# name of the component parameter is `{COMPONENT PARAMETER NAME}`. A different query parameter name is specified for the `{QUERY PARAMETER NAME}` placeholder:

Unlike component parameter properties (`[Parameter]`), `[SupplyParameterFromQuery]` properties can be marked `private` in addition to `public`.

C#

```
[SupplyParameterFromQuery(Name = "{QUERY PARAMETER NAME}")]
private string? {COMPONENT PARAMETER NAME} { get; set; }
```

In the following example with a URL of `/search?filter=scifi%20stars&page=3&star=LeVar%20Burton&star=Gary%20Oldman`:

- The `Filter` property resolves to `scifi stars`.
- The `Page` property resolves to `3`.
- The `Stars` array is filled from query parameters named `star` (`Name = "star"`) and resolves to `LeVar Burton` and `Gary Oldman`.

> **Note**
>
> The query string parameters in the following routable page component also work in a *non-routable* component without an `@page` directive (for example, `Search.razor` for a shared `Search` component used in

other components).

`Search.razor`:

razor

```razor
@page "/search"

<h1>Search Example</h1>

<p>Filter: @Filter</p>

<p>Page: @Page</p>

@if (Stars is not null)
{
    <p>Stars:</p>

    <ul>
        @foreach (var name in Stars)
        {
            <li>@name</li>
        }
    </ul>
}

@code {
    [SupplyParameterFromQuery]
    private string? Filter { get; set; }

    [SupplyParameterFromQuery]
    private int? Page { get; set; }

    [SupplyParameterFromQuery(Name = "star")]
    private string[]? Stars { get; set; }
}
```

Use GetUriWithQueryParameter to add, change, or remove one or more query parameters on the current URL:

razor

```razor
@inject NavigationManager Navigation

...

Navigation.GetUriWithQueryParameter("{NAME}", {VALUE})
```

For the preceding example:

- The `{NAME}` placeholder specifies the query parameter name. The `{VALUE}` placeholder specifies the value as a supported type. Supported types are listed later in this section.
- A string is returned equal to the current URL with a single parameter:
  - Added if the query parameter name doesn't exist in the current URL.
  - Updated to the value provided if the query parameter exists in the current URL.
  - Removed if the type of the provided value is nullable and the value is `null`.
- The correct culture-invariant formatting is applied for the given type (CultureInfo.InvariantCulture).
- The query parameter name and value are URL-encoded.
- All of the values with the matching query parameter name are replaced if there are multiple instances of the type.

Call GetUriWithQueryParameters to create a URI constructed from Uri with multiple parameters added, updated, or removed. For each value, the framework uses `value?.GetType()` to determine the runtime type for each query parameter and selects the correct culture-invariant formatting. The framework throws an error for unsupported types.

razor

```
@inject NavigationManager Navigation

...

Navigation.GetUriWithQueryParameters({PARAMETERS})
```

The `{PARAMETERS}` placeholder is an `IReadOnlyDictionary<string, object>`.

Pass a URI string to GetUriWithQueryParameters to generate a new URI from a provided URI with multiple parameters added, updated, or removed. For each value, the framework uses `value?.GetType()` to determine the runtime type for each query parameter and selects the correct culture-invariant formatting. The framework throws an error for unsupported types. Supported types are listed later in this section.

razor

```
@inject NavigationManager Navigation

...

Navigation.GetUriWithQueryParameters("{URI}", {PARAMETERS})
```

- The `{URI}` placeholder is the URI with or without a query string.
- The `{PARAMETERS}` placeholder is an `IReadOnlyDictionary<string, object>`.

Supported types are identical to supported types for route constraints:

- `bool`
- `DateTime`
- `decimal`
- `double`
- `float`
- `Guid`
- `int`
- `long`
- `string`

Supported types include:

- Nullable variants of the preceding types.
- Arrays of the preceding types, whether they're nullable or not nullable.

> ⚠ **Warning**
>
> With compression, which is enabled by default, avoid creating secure (authenticated/authorized) interactive server-side components that render data from untrusted sources. Untrusted sources include route parameters, query strings, data from JS interop, and any other source of data that a third-party user can

control (databases, external services). For more information, see ASP.NET Core Blazor SignalR guidance and Threat mitigation guidance for ASP.NET Core Blazor interactive server-side rendering.

Replace a query parameter value when the parameter exists

```
C#

Navigation.GetUriWithQueryParameter("full name", "Morena Baccarin")
```

Expand table

Current URL	Generated URL
`scheme://host/?full%20name=David%20Krumholtz&age=42`	`scheme://host/?full%20name=Morena%20Baccarin&age=42`
`scheme://host/?fUlL%20nAmE=David%20Krumholtz&AgE=42`	`scheme://host/?full%20name=Morena%20Baccarin&AgE=42`
`scheme://host/?full%20name=Jewel%20Staite&age=42&full%20name=Summer%20Glau`	`scheme://host/?full%20name=Morena%20Baccarin&age=42&full%20name=Morena%20Baccarin`
`scheme://host/?full%20name=&age=42`	`scheme://host/?full%20name=Morena%20Baccarin&age=42`
`scheme://host/?full%20name=`	`scheme://host/?full%20name=Morena%20Baccarin`

Append a query parameter and value when the parameter doesn't exist

```
C#

Navigation.GetUriWithQueryParameter("name", "Morena Baccarin")
```

Expand table

Current URL	Generated URL
`scheme://host/?age=42`	`scheme://host/?age=42&name=Morena%20Baccarin`
`scheme://host/`	`scheme://host/?name=Morena%20Baccarin`
`scheme://host/?`	`scheme://host/?name=Morena%20Baccarin`

Remove a query parameter when the parameter value is `null`

```
C#

Navigation.GetUriWithQueryParameter("full name", (string)null)
```

Expand table

Current URL	Generated URL
`scheme://host/?full%20name=David%20Krumholtz&age=42`	`scheme://host/?age=42`

Current URL	Generated URL
`scheme://host/?full%20name=Sally%20Smith&age=42&full%20name=Summer%20Glau`	`scheme://host/?age=42`
`scheme://host/?full%20name=Sally%20Smith&age=42&FuLl%20NaMe=Summer%20Glau`	`scheme://host/?age=42`
`scheme://host/?full%20name=&age=42`	`scheme://host/?age=42`
`scheme://host/?full%20name=`	`scheme://host/`

Add, update, and remove query parameters

In the following example:

- `name` is removed, if present.
- `age` is added with a value of `25` (`int`), if not present. If present, `age` is updated to a value of `25`.
- `eye color` is added or updated to a value of `green`.

C#

```
Navigation.GetUriWithQueryParameters(
    new Dictionary<string, object?>
    {
        ["name"] = null,
        ["age"] = (int?)25,
        ["eye color"] = "green"
    })
```

Expand table

Current URL	Generated URL
`scheme://host/?name=David%20Krumholtz&age=42`	`scheme://host/?age=25&eye%20color=green`
`scheme://host/?NaMe=David%20Krumholtz&AgE=42`	`scheme://host/?age=25&eye%20color=green`
`scheme://host/?name=David%20Krumholtz&age=42&keepme=true`	`scheme://host/?age=25&keepme=true&eye%20color=green`
`scheme://host/?age=42&eye%20color=87`	`scheme://host/?age=25&eye%20color=green`
`scheme://host/?`	`scheme://host/?age=25&eye%20color=green`
`scheme://host/`	`scheme://host/?age=25&eye%20color=green`

Support for enumerable values

In the following example:

- `full name` is added or updated to `Morena Baccarin`, a single value.
- `ping` parameters are added or replaced with `35`, `16`, `87` and `240`.

C#

```
Navigation.GetUriWithQueryParameters(
    new Dictionary<string, object?>
    {
        ["full name"] = "Morena Baccarin",
```

```
        ["ping"] = new int?[] { 35, 16, null, 87, 240 }
    })
```

Expand table

Current URL	Generated URL
`scheme://host/?full%20name=David%20Krumholtz&ping=8&ping=300`	`scheme://host/?full%20name=Morena%20Baccarin&ping=35&ping=16&ping=87&ping=240`
`scheme://host/?ping=8&full%20name=David%20Krumholtz&ping=300`	`scheme://host/?ping=35&full%20name=Morena%20Baccarin&ping=16&ping=87&ping=240`
`scheme://host/?ping=8&ping=300&ping=50&ping=68&ping=42`	`scheme://host/?ping=35&ping=16&ping=87&ping=240&full%20name=Morena%20Baccarin`

Navigate with an added or modified query string

To navigate with an added or modified query string, pass a generated URL to NavigateTo.

The following example calls:

- GetUriWithQueryParameter to add or replace the `name` query parameter using a value of `Morena Baccarin`.
- Calls NavigateTo to trigger navigation to the new URL.

C#

```
Navigation.NavigateTo(
    Navigation.GetUriWithQueryParameter("name", "Morena Baccarin"));
```

Hashed routing to named elements

Navigate to a named element using the following approaches with a hashed (`#`) reference to the element. Routes to elements within the component and routes to elements in external components use root-relative paths. A leading forward slash (`/`) is optional.

Examples for each of the following approaches demonstrate navigation to an element with an `id` of `targetElement` in the `Counter` component:

- Anchor element (`<a>`) with an `href`:

  razor

  ```
  <a href="/counter#targetElement">
  ```

- NavLink component with an `href`:

  razor

  ```
  <NavLink href="/counter#targetElement">
  ```

- NavigationManager.NavigateTo passing the relative URL:

  C#

```
Navigation.NavigateTo("/counter#targetElement");
```

The following example demonstrates hashed routing to named H2 headings within a component and to external components.

In the `Home` (`Home.razor`) and `Counter` (`Counter.razor`) components, place the following markup at the bottoms of the existing component markup to serve as navigation targets. The `<div>` creates artificial vertical space to demonstrate browser scrolling behavior:

razor

```
<div class="border border-info rounded bg-info" style="height:500px"></div>

<h2 id="targetElement">Target H2 heading</h2>
<p>Content!</p>
```

Add the following `HashedRouting` component to the app.

`HashedRouting.razor`:

razor

```
@page "/hashed-routing"
@inject NavigationManager Navigation

<PageTitle>Hashed routing</PageTitle>

<h1>Hashed routing to named elements</h1>

<ul>
    <li>
        <a href="/hashed-routing#targetElement">
            Anchor in this component
        </a>
    </li>
    <li>
        <a href="/#targetElement">
            Anchor to the <code>Home</code> component
        </a>
    </li>
    <li>
        <a href="/counter#targetElement">
            Anchor to the <code>Counter</code> component
        </a>
    </li>
    <li>
        <NavLink href="/hashed-routing#targetElement">
            Use a `NavLink` component in this component
        </NavLink>
    </li>
    <li>
        <button @onclick="NavigateToElement">
            Navigate with <code>NavigationManager</code> to the
            <code>Counter</code> component
        </button>
    </li>
</ul>

<div class="border border-info rounded bg-info" style="height:500px"></div>

<h2 id="targetElement">Target H2 heading</h2>
<p>Content!</p>
```

```
@code {
    private void NavigateToElement()
    {
        Navigation.NavigateTo("/counter#targetElement");
    }
}
```

User interaction with `<Navigating>` content

If there's a significant delay during navigation, such as while lazy-loading assemblies in a Blazor WebAssembly app or for a slow network connection to a Blazor server-side app, the Router component can indicate to the user that a page transition is occurring.

At the top of the component that specifies the Router component, add an @using directive for the Microsoft.AspNetCore.Components.Routing namespace:

razor

```
@using Microsoft.AspNetCore.Components.Routing
```

Provide content to the Navigating parameter for display during page transition events.

In the router element (`<Router>...</Router>`) content:

razor

```
<Navigating>
    <p>Loading the requested page&hellip;</p>
</Navigating>
```

For an example that uses the Navigating property, see Lazy load assemblies in ASP.NET Core Blazor WebAssembly.

Handle asynchronous navigation events with `OnNavigateAsync`

The Router component supports an OnNavigateAsync feature. The OnNavigateAsync handler is invoked when the user:

- Visits a route for the first time by navigating to it directly in their browser.
- Navigates to a new route using a link or a NavigationManager.NavigateTo invocation.

razor

```
<Router AppAssembly="typeof(App).Assembly"
    OnNavigateAsync="OnNavigateAsync">
    ...
</Router>

@code {
    private async Task OnNavigateAsync(NavigationContext args)
    {
        ...
    }
}
```

For an example that uses OnNavigateAsync, see Lazy load assemblies in ASP.NET Core Blazor WebAssembly.

When prerendering on the server, OnNavigateAsync is executed *twice*:

- Once when the requested endpoint component is initially rendered statically.
- A second time when the browser renders the endpoint component.

To prevent developer code in OnNavigateAsync from executing twice, the `Routes` component can store the NavigationContext for use in the OnAfterRender{Async} lifecycle method, where `firstRender` can be checked. For more information, see Prerendering with JavaScript interop.

Handle cancellations in `OnNavigateAsync`

The NavigationContext object passed to the OnNavigateAsync callback contains a CancellationToken that's set when a new navigation event occurs. The OnNavigateAsync callback must throw when this cancellation token is set to avoid continuing to run the OnNavigateAsync callback on an outdated navigation.

If a user navigates to an endpoint but then immediately navigates to a new endpoint, the app shouldn't continue running the OnNavigateAsync callback for the first endpoint.

In the following example:

- The cancellation token is passed in the call to `PostAsJsonAsync`, which can cancel the POST if the user navigates away from the `/about` endpoint.
- The cancellation token is set during a product prefetch operation if the user navigates away from the `/store` endpoint.

razor

```
@inject HttpClient Http
@inject ProductCatalog Products

<Router AppAssembly="typeof(App).Assembly"
    OnNavigateAsync="OnNavigateAsync">
    ...
</Router>

@code {
    private async Task OnNavigateAsync(NavigationContext context)
    {
        if (context.Path == "/about")
        {
            var stats = new Stats { Page = "/about" };
            await Http.PostAsJsonAsync("api/visited", stats,
                context.CancellationToken);
        }
        else if (context.Path == "/store")
        {
            var productIds = new[] { 345, 789, 135, 689 };

            foreach (var productId in productIds)
            {
                context.CancellationToken.ThrowIfCancellationRequested();
                Products.Prefetch(productId);
            }
        }
    }
}
```

> ⓘ Note

Not throwing if the cancellation token in NavigationContext is canceled can result in unintended behavior, such as rendering a component from a previous navigation.

Handle/prevent location changes

RegisterLocationChangingHandler registers a handler to process incoming navigation events. The handler's context provided by LocationChangingContext includes the following properties:

- TargetLocation: Gets the target location.
- HistoryEntryState: Gets the state associated with the target history entry.
- IsNavigationIntercepted: Gets whether the navigation was intercepted from a link.
- CancellationToken: Gets a CancellationToken to determine if the navigation was canceled, for example, to determine if the user triggered a different navigation.
- PreventNavigation: Called to prevent the navigation from continuing.

A component can register multiple location changing handlers in the OnAfterRender{Async} lifecycle method. Navigation invokes all of the location changing handlers registered across the entire app (across multiple components), and any internal navigation executes them all in parallel. In addition to NavigateTo handlers are invoked:

- When selecting internal links, which are links that point to URLs under the app's base path.
- When navigating using the forward and back buttons in a browser.

Handlers are only executed for internal navigation within the app. If the user selects a link that navigates to a different site or changes the address bar to a different site manually, location changing handlers aren't executed.

Implement IDisposable and dispose registered handlers to unregister them. For more information, see ASP.NET Core Razor component lifecycle.

> **Important**
>
> Don't attempt to execute DOM cleanup tasks via JavaScript (JS) interop when handling location changes. Use the MutationObserver pattern in JS on the client. For more information, see ASP.NET Core Blazor JavaScript interoperability (JS interop).

In the following example, a location changing handler is registered for navigation events.

`NavHandler.razor`:

razor

```
@page "/nav-handler"
@implements IDisposable
@inject NavigationManager Navigation

<p>
    <button @onclick="@(() => Navigation.NavigateTo("/"))">
        Home (Allowed)
    </button>
    <button @onclick="@(() => Navigation.NavigateTo("/counter"))">
        Counter (Prevented)
    </button>
</p>

@code {
    private IDisposable? registration;
```

```
    protected override void OnAfterRender(bool firstRender)
    {
        if (firstRender)
        {
            registration =
                Navigation.RegisterLocationChangingHandler(OnLocationChanging);
        }
    }

    private ValueTask OnLocationChanging(LocationChangingContext context)
    {
        if (context.TargetLocation == "/counter")
        {
            context.PreventNavigation();
        }

        return ValueTask.CompletedTask;
    }

    public void Dispose() => registration?.Dispose();
}
```

Since internal navigation can be canceled asynchronously, multiple overlapping calls to registered handlers may occur. For example, multiple handler calls may occur when the user rapidly selects the back button on a page or selects multiple links before a navigation is executed. The following is a summary of the asynchronous navigation logic:

- If any location changing handlers are registered, all navigation is initially reverted, then replayed if the navigation isn't canceled.
- If overlapping navigation requests are made, the latest request always cancels earlier requests, which means the following:
  - The app may treat multiple back and forward button selections as a single selection.
  - If the user selects multiple links before the navigation completes, the last link selected determines the navigation.

For more information on passing NavigationOptions to NavigateTo to control entries and state of the navigation history stack, see the Navigation options section.

For additional example code, see the NavigationManagerComponent in the BasicTestApp (dotnet/aspnetcore reference source).

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

The NavigationLock component intercepts navigation events as long as it is rendered, effectively "locking" any given navigation until a decision is made to either proceed or cancel. Use `NavigationLock` when navigation interception can be scoped to the lifetime of a component.

NavigationLock parameters:

- ConfirmExternalNavigation sets a browser dialog to prompt the user to either confirm or cancel external navigation. The default value is `false`. Displaying the confirmation dialog requires initial user interaction with

the page before triggering external navigation with the URL in the browser's address bar. For more information on the interaction requirement, see Window: beforeunload event (MDN documentation).
- OnBeforeInternalNavigation sets a callback for internal navigation events.

In the following `NavLock` component:

- An attempt to follow the link to Microsoft's website must be confirmed by the user before the navigation to `https://www.microsoft.com` succeeds.
- PreventNavigation is called to prevent navigation from occurring if the user declines to confirm the navigation via a JavaScript (JS) interop call that spawns the JS confirm dialog.

`NavLock.razor`:

razor

```razor
@page "/nav-lock"
@inject IJSRuntime JSRuntime
@inject NavigationManager Navigation

<NavigationLock ConfirmExternalNavigation="true"
    OnBeforeInternalNavigation="OnBeforeInternalNavigation" />

<p>
    <button @onclick="Navigate">Navigate</button>
</p>

<p>
    <a href="https://www.microsoft.com">Microsoft homepage</a>
</p>

@code {
    private void Navigate()
    {
        Navigation.NavigateTo("/");
    }

    private async Task OnBeforeInternalNavigation(LocationChangingContext context)
    {
        var isConfirmed = await JSRuntime.InvokeAsync<bool>("confirm",
            "Are you sure you want to navigate to the root page?");

        if (!isConfirmed)
        {
            context.PreventNavigation();
        }
    }
}
```

For additional example code, see the ConfigurableNavigationLock component in the BasicTestApp (dotnet/aspnetcore reference source).

`NavLink` component

Use a NavLink component in place of HTML hyperlink elements (`<a>`) when creating navigation links. A NavLink component behaves like an `<a>` element, except it toggles an `active` CSS class based on whether its `href` matches the current URL. The `active` class helps a user understand which page is the active page among the navigation links displayed. Optionally, assign a CSS class name to NavLink.ActiveClass to apply a custom CSS class to the rendered link when the current route matches the `href`.

There are two NavLinkMatch options that you can assign to the `Match` attribute of the `<NavLink>` element:

- NavLinkMatch.All: The NavLink is active when it matches the entire current URL.
- NavLinkMatch.Prefix (*default*): The NavLink is active when it matches any prefix of the current URL.

In the preceding example, the Home NavLink `href=""` matches the home URL and only receives the `active` CSS class at the app's default base path (`/`). The second NavLink receives the `active` class when the user visits any URL with a `component` prefix (for example, `/component` and `/component/another-segment`).

Additional NavLink component attributes are passed through to the rendered anchor tag. In the following example, the NavLink component includes the `target` attribute:

razor

```
<NavLink href="example-page" target="_blank">Example page</NavLink>
```

The following HTML markup is rendered:

HTML

```
<a href="example-page" target="_blank">Example page</a>
```

> ⚠ **Warning**
>
> Due to the way that Blazor renders child content, rendering `NavLink` components inside a `for` loop requires a local index variable if the incrementing loop variable is used in the `NavLink` (child) component's content:
>
> razor
>
> ```
> @for (int c = 1; c < 4; c++)
> {
>     var ct = c;
>     <li ...>
>         <NavLink ...>
>             <span ...> Product #@ct
>         </NavLink>
>     </li>
> }
> ```
>
> Using an index variable in this scenario is a requirement for **any** child component that uses a loop variable in its child content, not just the `NavLink` component.
>
> Alternatively, use a `foreach` loop with Enumerable.Range:
>
> razor
>
> ```
> @foreach (var c in Enumerable.Range(1, 3))
> {
>     <li ...>
>         <NavLink ...>
>             <span ...> Product #@c
>         </NavLink>
>     </li>
> }
> ```

NavLink component entries can be dynamically created from the app's components via reflection. The following example demonstrates the general approach for further customization.

For the following demonstration, a consistent, standard naming convention is used for the app's components:

- Routable component file names use Pascal case†, for example `Pages/ProductDetail.razor`.
- Routable component file paths match their URLs in kebab case‡ with hyphens appearing between words in a component's route template. For example, a `ProductDetail` component with a route template of `/product-detail` (`@page "/product-detail"`) is requested in a browser at the relative URL `/product-detail`.

†Pascal case (upper camel case) is a naming convention without spaces and punctuation and with the first letter of each word capitalized, including the first word.
‡Kebab case is a naming convention without spaces and punctuation that uses lowercase letters and dashes between words.

In the Razor markup of the `NavMenu` component (`NavMenu.razor`) under the default `Home` page, NavLink components are added from a collection:

diff

```
<div class="nav-scrollable"
    onclick="document.querySelector('.navbar-toggler').click()">
    <nav class="flex-column">
        <div class="nav-item px-3">
            <NavLink class="nav-link" href="" Match="NavLinkMatch.All">
                <span class="bi bi-house-door-fill-nav-menu"
                    aria-hidden="true"></span> Home
            </NavLink>
        </div>

+       @foreach (var name in GetRoutableComponents())
+       {
+           <div class="nav-item px-3">
+               <NavLink class="nav-link"
+                       href="@Regex.Replace(name, @"(\B[A-Z]|\d+)", "-$1").ToLower()">
+                   @Regex.Replace(name, @"(\B[A-Z]|\d+)", " $1")
+               </NavLink>
+           </div>
+       }

    </nav>
</div>
```

The `GetRoutableComponents` method in the `@code` block:

C#

```
public IEnumerable<string> GetRoutableComponents() =>
    Assembly.GetExecutingAssembly()
        .ExportedTypes
        .Where(t => t.IsSubclassOf(typeof(ComponentBase)))
        .Where(c => c.GetCustomAttributes(inherit: true)
                     .OfType<RouteAttribute>()
                     .Any())
        .Where(c => c.Name != "Home" && c.Name != "Error")
        .OrderBy(o => o.Name)
        .Select(c => c.Name);
```

The preceding example doesn't include the following pages in the rendered list of components:

- `Home` page: The page is listed separately from the automatically generated links because it should appear at the top of the list and set the `Match` parameter.
- `Error` page: The error page is only navigated to by the framework and shouldn't be listed.

For an example of the preceding code in a sample app that you can run locally, obtain the **Blazor Web App** or **Blazor WebAssembly** sample app.

ASP.NET Core endpoint routing integration

This section applies to Blazor Web Apps operating over a circuit.

A Blazor Web App is integrated into ASP.NET Core Endpoint Routing. An ASP.NET Core app is configured to accept incoming connections for interactive components with MapRazorComponents in the `Program` file. The default root component (first component loaded) is the `App` component (`App.razor`):

```
C#

app.MapRazorComponents<App>();
```

ASP.NET Core Blazor configuration

Article • 10/18/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article explains how to configure Blazor apps, including app settings, authentication, and logging configuration.

This guidance applies to client-side project configuration in a Blazor Web App or a standalone Blazor WebAssembly app.

Default behavior in Blazor Web Apps:

- For server-side configuration:
  - See Configuration in ASP.NET Core for guidance.
  - Only configuration in the project's root app settings files is loaded.
  - The remainder of this article only applies to client-side configuration in the `.Client` project.
- For client-side configuration (`.Client` project), configuration is loaded from the following app settings files:
  - `wwwroot/appsettings.json`.
  - `wwwroot/appsettings.{ENVIRONMENT}.json`, where the `{ENVIRONMENT}` placeholder is the app's runtime environment.

In standalone Blazor WebAssembly apps, configuration is loaded from the following app settings files:

- `wwwroot/appsettings.json`.
- `wwwroot/appsettings.{ENVIRONMENT}.json`, where the `{ENVIRONMENT}` placeholder is the app's runtime environment.

> **Note**
>
> Logging configuration placed into an app settings file in `wwwroot` isn't loaded by default. For more information, see the **Logging configuration** section later in this

article.

In some scenarios, such as with Azure services, it's important to use an environment file name segment that exactly matches the environment name. For example, use the file name `appsettings.Staging.json` with a capital "S" for the `Staging` environment. For recommended conventions, see the opening remarks of ASP.NET Core Blazor environments.

Other configuration providers registered by the app can also provide configuration, but not all providers or provider features are appropriate:

- Azure Key Vault configuration provider: The provider isn't supported for managed identity and application ID (client ID) with client secret scenarios. Application ID with a client secret isn't recommended for any ASP.NET Core app, especially client-side apps because the client secret can't be secured client-side to access the Azure Key Vault service.
- Azure App configuration provider: The provider isn't appropriate for a client-side app because the app doesn't run on a server in Azure.

For more information on configuration providers, see Configuration in ASP.NET Core.

> ⚠ **Warning**
>
> Configuration and settings files in the web root (`wwwroot` folder) are visible to users on the client, and users can tamper with the data. **Don't store app secrets, credentials, or any other sensitive data in any web root file.**

App settings configuration

Configuration in app settings files are loaded by default. In the following example, a UI configuration value is stored in an app settings file and loaded by the Blazor framework automatically. The value is read by a component.

`wwwroot/appsettings.json`:

JSON

```
{
    "h1FontSize": "50px"
}
```

Inject an IConfiguration instance into a component to access the configuration data.

`ConfigExample.razor`:

```razor
@page "/config-example"
@inject IConfiguration Configuration

<PageTitle>Configuration</PageTitle>

<h1 style="font-size:@Configuration["h1FontSize"]">
    Configuration example (50px)
</h1>
```

Client security restrictions prevent direct access to files via user code, including settings files for app configuration. To read configuration files in addition to `appsettings.json`/`appsettings.{ENVIRONMENT}.json` from the `wwwroot` folder into configuration, use an HttpClient.

> ⚠ **Warning**
>
> Configuration and settings files in the web root (`wwwroot` folder) are visible to users on the client, and users can tamper with the data. **Don't store app secrets, credentials, or any other sensitive data in any web root file.**

The following example reads a configuration file (`cars.json`) into the app's configuration.

`wwwroot/cars.json`:

```json
{
    "size": "tiny"
}
```

Add the namespace for Microsoft.Extensions.Configuration to the `Program` file:

```C#
using Microsoft.Extensions.Configuration;
```

Modify the existing HttpClient service registration to use the client to read the file:

C#

```
var http = new HttpClient()
{
    BaseAddress = new Uri(builder.HostEnvironment.BaseAddress)
};

builder.Services.AddScoped(sp => http);

using var response = await http.GetAsync("cars.json");
using var stream = await response.Content.ReadAsStreamAsync();

builder.Configuration.AddJsonStream(stream);
```

The preceding example sets the base address with `builder.HostEnvironment.BaseAddress` (IWebAssemblyHostEnvironment.BaseAddress), which gets the base address for the app and is typically derived from the `<base>` tag's `href` value in the host page.

Memory Configuration Source

The following example uses a MemoryConfigurationSource in the `Program` file to supply additional configuration.

Add the namespace for Microsoft.Extensions.Configuration.Memory to the `Program` file:

C#

```
using Microsoft.Extensions.Configuration.Memory;
```

In the `Program` file:

C#

```
var vehicleData = new Dictionary<string, string?>()
{
    { "color", "blue" },
    { "type", "car" },
    { "wheels:count", "3" },
    { "wheels:brand", "Blazin" },
    { "wheels:brand:type", "rally" },
    { "wheels:year", "2008" },
};

var memoryConfig = new MemoryConfigurationSource { InitialData = vehicleData
};
```

```
builder.Configuration.Add(memoryConfig);
```

Inject an IConfiguration instance into a component to access the configuration data.

`MemoryConfig.razor`:

razor

```razor
@page "/memory-config"
@inject IConfiguration Configuration

<PageTitle>Memory Configuration</PageTitle>

<h1>Memory Configuration Example</h1>

<h2>General specifications</h2>

<ul>
    <li>Color: @Configuration["color"]</li>
    <li>Type: @Configuration["type"]</li>
</ul>

<h2>Wheels</h2>

<ul>
    <li>Count: @Configuration["wheels:count"]</li>
    <li>Brand: @Configuration["wheels:brand"]</li>
    <li>Type: @Configuration["wheels:brand:type"]</li>
    <li>Year: @Configuration["wheels:year"]</li>
</ul>
```

Obtain a section of the configuration in C# code with IConfiguration.GetSection. The following example obtains the `wheels` section for the configuration in the preceding example:

razor

```razor
@code {
    protected override void OnInitialized()
    {
        var wheelsSection = Configuration.GetSection("wheels");

        ...
    }
}
```

Authentication configuration

Provide ***public*** authentication configuration in an app settings file.

`wwwroot/appsettings.json`:

JSON

```
{
  "Local": {
    "Authority": "{AUTHORITY}",
    "ClientId": "{CLIENT ID}"
  }
}
```

Load the configuration for an Identity provider with ConfigurationBinder.Bind in the `Program` file. The following example loads configuration for an OIDC provider:

C#

```
builder.Services.AddOidcAuthentication(options =>
    builder.Configuration.Bind("Local", options.ProviderOptions));
```

> ⚠ **Warning**
>
> Configuration and settings files in the web root (`wwwroot` folder) are visible to users on the client, and users can tamper with the data. **Don't store app secrets, credentials, or any other sensitive data in any web root file.**

Logging configuration

This section applies to apps that configure logging via an app settings file in the `wwwroot` folder.

Add the Microsoft.Extensions.Logging.Configuration package to the app.

> ⓘ **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

In the app settings file, provide logging configuration. The logging configuration is loaded in the `Program` file.

`wwwroot/appsettings.json`:

JSON

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft.AspNetCore": "Warning"
    }
  }
}
```

In the `Program` file:

C#

```
builder.Logging.AddConfiguration(
    builder.Configuration.GetSection("Logging"));
```

Host builder configuration

Read host builder configuration from WebAssemblyHostBuilder.Configuration in the `Program` file:

C#

```
var hostname = builder.Configuration["HostName"];
```

Cached configuration

Configuration files are cached for offline use. With Progressive Web Applications (PWAs), you can only update configuration files when creating a new deployment. Editing configuration files between deployments has no effect because:

- Users have cached versions of the files that they continue to use.
- The PWA's `service-worker.js` and `service-worker-assets.js` files must be rebuilt on compilation, which signal to the app on the user's next online visit that the app has been redeployed.

For more information on how background updates are handled by PWAs, see ASP.NET Core Blazor Progressive Web Application (PWA).

Options configuration

Options configuration requires adding a package reference for the Microsoft.Extensions.Options.ConfigurationExtensions NuGet package.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

Example:

```
C#

builder.Services.Configure<MyOptions>(
    builder.Configuration.GetSection("MyOptions"));
```

Not all of the ASP.NET Core Options features are supported in Razor components. For example, IOptionsSnapshot<TOptions> and IOptionsMonitor<TOptions> configuration is supported, but recomputing option values for these interfaces isn't supported outside of reloading the app by either requesting the app in a new browser tab or selecting the browser's reload button. Merely calling StateHasChanged doesn't update snapshot or monitored option values when the underlying configuration changes.

ASP.NET Core Blazor dependency injection

Article • 10/04/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Rainer Stropek and Mike Rousos

This article explains how Blazor apps can inject services into components.

Dependency injection (DI) is a technique for accessing services configured in a central location:

- Framework-registered services can be injected directly into Razor components.
- Blazor apps define and register custom services and make them available throughout the app via DI.

> **Note**
>
> We recommend reading Dependency injection in ASP.NET Core before reading this topic.

Default services

The services shown in the following table are commonly used in Blazor apps.

Expand table

Service	Lifetime	Description
HttpClient	Scoped	Provides methods for sending HTTP requests and receiving HTTP responses from a resource identified by a URI.

Service	Lifetime	Description
		Client-side, an instance of HttpClient is registered by the app in the `Program` file and uses the browser for handling the HTTP traffic in the background. Server-side, an HttpClient isn't configured as a service by default. In server-side code, provide an HttpClient. For more information, see Call a web API from an ASP.NET Core Blazor app. An HttpClient is registered as a scoped service, not singleton. For more information, see the Service lifetime section.
IJSRuntime	**Client-side**: Singleton **Server-side**: Scoped The Blazor framework registers IJSRuntime in the app's service container.	Represents an instance of a JavaScript runtime where JavaScript calls are dispatched. For more information, see Call JavaScript functions from .NET methods in ASP.NET Core Blazor. When seeking to inject the service into a singleton service on the server, take either of the following approaches: • Change the service registration to scoped to match IJSRuntime's registration, which is appropriate if the service deals with user-specific state. • Pass the IJSRuntime into the singleton service's implementation as an argument of its method calls instead of injecting it into the singleton.
NavigationManager	**Client-side**: Singleton **Server-side**: Scoped The Blazor framework registers NavigationManager in the app's service container.	Contains helpers for working with URIs and navigation state. For more information, see URI and navigation state helpers.

Additional services registered by the Blazor framework are described in the documentation where they're used to describe Blazor features, such as configuration and logging.

A custom service provider doesn't automatically provide the default services listed in the table. If you use a custom service provider and require any of the services shown in the table, add the required services to the new service provider.

Add client-side services

Configure services for the app's service collection in the `Program` file. In the following example, the `ExampleDependency` implementation is registered for `IExampleDependency`:

C#

```
var builder = WebAssemblyHostBuilder.CreateDefault(args);
...
builder.Services.AddSingleton<IExampleDependency, ExampleDependency>();
...

await builder.Build().RunAsync();
```

After the host is built, services are available from the root DI scope before any components are rendered. This can be useful for running initialization logic before rendering content:

C#

```
var builder = WebAssemblyHostBuilder.CreateDefault(args);
...
builder.Services.AddSingleton<WeatherService>();
...

var host = builder.Build();

var weatherService = host.Services.GetRequiredService<WeatherService>();
await weatherService.InitializeWeatherAsync();

await host.RunAsync();
```

The host provides a central configuration instance for the app. Building on the preceding example, the weather service's URL is passed from a default configuration source (for example, `appsettings.json`) to `InitializeWeatherAsync`:

C#

```
var builder = WebAssemblyHostBuilder.CreateDefault(args);
...
builder.Services.AddSingleton<WeatherService>();
...
```

```
var host = builder.Build();

var weatherService = host.Services.GetRequiredService<WeatherService>();
await weatherService.InitializeWeatherAsync(
    host.Configuration["WeatherServiceUrl"]);

await host.RunAsync();
```

Add server-side services

After creating a new app, examine part of the `Program` file:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorComponents()
    .AddInteractiveServerComponents();
```

The `builder` variable represents a WebApplicationBuilder with an IServiceCollection, which is a list of service descriptor objects. Services are added by providing service descriptors to the service collection. The following example demonstrates the concept with the `IDataAccess` interface and its concrete implementation `DataAccess`:

C#

```
builder.Services.AddSingleton<IDataAccess, DataAccess>();
```

Register common services

If one or more common services are required client- and server-side, you can place the common service registrations in a method client-side and call the method to register the services in both projects.

First, factor common service registrations into a separate method. For example, create a `ConfigureCommonServices` method client-side:

C#

```
public static void ConfigureCommonServices(IServiceCollection services)
{
```

```
    services.Add...;
}
```

For the client-side `Program` file, call `ConfigureCommonServices` to register the common services:

C#

```
var builder = WebAssemblyHostBuilder.CreateDefault(args);

...

ConfigureCommonServices(builder.Services);
```

In the server-side `Program` file, call `ConfigureCommonServices` to register the common services:

C#

```
var builder = WebApplication.CreateBuilder(args);

...

Client.Program.ConfigureCommonServices(builder.Services);
```

For an example of this approach, see ASP.NET Core Blazor WebAssembly additional security scenarios.

Client-side services that fail during prerendering

This section only applies to WebAssembly components in Blazor Web Apps.

Blazor Web Apps normally prerender client-side WebAssembly components. If an app is run with a required service only registered in the `.Client` project, executing the app results in a runtime error similar to the following when a component attempts to use the required service during prerendering:

> InvalidOperationException: Cannot provide a value for {PROPERTY} on type '{ASSEMBLY}}.Client.Pages.{COMPONENT NAME}'. There is no registered service of type '{SERVICE}'.

Use ***either*** of the following approaches to resolve this problem:

- Register the service in the main project to make it available during component prerendering.
- If prerendering isn't required for the component, disable prerendering by following the guidance in ASP.NET Core Blazor render modes. If you adopt this approach, you don't need to register the service in the main project.

For more information, see Client-side services fail to resolve during prerendering.

Service lifetime

Services can be configured with the lifetimes shown in the following table.

Expand table

Lifetime	Description
Scoped	Client-side doesn't currently have a concept of DI scopes. `Scoped`-registered services behave like `Singleton` services. Server-side development supports the `Scoped` lifetime across HTTP requests but not across SignalR connection/circuit messages among components that are loaded on the client. The Razor Pages or MVC portion of the app treats scoped services normally and recreates the services on *each HTTP request* when navigating among pages or views or from a page or view to a component. Scoped services aren't reconstructed when navigating among components on the client, where the communication to the server takes place over the SignalR connection of the user's circuit, not via HTTP requests. In the following component scenarios on the client, scoped services are reconstructed because a new circuit is created for the user: • The user closes the browser's window. The user opens a new window and navigates back to the app. • The user closes a tab of the app in a browser window. The user opens a new tab and navigates back to the app. • The user selects the browser's reload/refresh button. For more information on preserving user state in server-side apps, see ASP.NET Core Blazor state management.
Singleton	DI creates a *single instance* of the service. All components requiring a `Singleton` service receive the same instance of the service.
Transient	Whenever a component obtains an instance of a `Transient` service from the service container, it receives a *new instance* of the service.

The DI system is based on the DI system in ASP.NET Core. For more information, see Dependency injection in ASP.NET Core.

Request a service in a component

For injecting services into components, Blazor supports constructor injection and property injection.

Constructor injection

After services are added to the service collection, inject one or more services into components with constructor injection. The following example injects the `NavigationManager` service.

`ConstructorInjection.razor`:

razor

```razor
@page "/constructor-injection"

<button @onclick="HandleClick">
    Take me to the Counter component
</button>
```

`ConstructorInjection.razor.cs`:

C#

```
using Microsoft.AspNetCore.Components;

public partial class ConstructorInjection(NavigationManager navigation)
{
    private void HandleClick()
    {
        navigation.NavigateTo("/counter");
    }
}
```

Property injection

After services are added to the service collection, inject one or more services into components with the @inject Razor directive, which has two parameters:

- Type: The type of the service to inject.
- Property: The name of the property receiving the injected app service. The property doesn't require manual creation. The compiler creates the property.

For more information, see Dependency injection into views in ASP.NET Core.

Use multiple @inject statements to inject different services.

The following example demonstrates shows how to use the @inject directive. The service implementing `Services.NavigationManager` is injected into the component's property `Navigation`. Note how the code is only using the `NavigationManager` abstraction.

`PropertyInjection.razor`:

razor

```razor
@page "/property-injection"
@inject NavigationManager Navigation

<button @onclick="@(() => Navigation.NavigateTo("/counter"))">
    Take me to the Counter component
</button>
```

Internally, the generated property (`Navigation`) uses the [Inject] attribute. Typically, this attribute isn't used directly. If a base class is required for components and injected properties are also required for the base class, manually add the [Inject] attribute:

C#

```
using Microsoft.AspNetCore.Components;

public class ComponentBase : IComponent
{
    [Inject]
    protected NavigationManager Navigation { get; set; } = default!;

    ...
}
```

> **Note**
>
> Since injected services are expected to be available, the default literal with the null-forgiving operator (`default!`) is assigned in .NET 6 or later. For more information, see Nullable reference types (NRTs) and .NET compiler null-state static analysis.

In components derived from a base class, the @inject directive isn't required. The InjectAttribute of the base class is sufficient. The component only requires the @inherits directive. In the following example, any injected services of `CustomComponentBase` are available to the `Demo` component:

razor

```
@page "/demo"
@inherits CustomComponentBase
```

Use DI in services

Complex services might require additional services. In the following example, `DataAccess` requires the HttpClient default service. @inject (or the [Inject] attribute) isn't available for use in services. *Constructor injection* must be used instead. Required services are added by adding parameters to the service's constructor. When DI creates the service, it recognizes the services it requires in the constructor and provides them accordingly. In the following example, the constructor receives an HttpClient via DI. HttpClient is a default service.

C#

```
using System.Net.Http;

public class DataAccess : IDataAccess
{
    public DataAccess(HttpClient http)
    {
        ...
    }

    ...
}
```

Constructor injection is supported with primary constructors in C# 12 (.NET 8) or later:

C#

```
using System.Net.Http;

public class DataAccess(HttpClient http) : IDataAccess
{
    ...
}
```

Prerequisites for constructor injection:

- One constructor must exist whose arguments can all be fulfilled by DI. Additional parameters not covered by DI are allowed if they specify default values.
- The applicable constructor must be `public`.

- One applicable constructor must exist. In case of an ambiguity, DI throws an exception.

Inject keyed services into components

Blazor supports injecting keyed services using the `[Inject]` attribute. Keys allow for scoping of registration and consumption of services when using dependency injection. Use the InjectAttribute.Key property to specify the key for the service to inject:

```
C#

[Inject(Key = "my-service")]
public IMyService MyService { get; set; }
```

Utility base component classes to manage a DI scope

In non-Blazor ASP.NET Core apps, scoped and transient services are typically scoped to the current request. After the request completes, scoped and transient services are disposed by the DI system.

In interactive server-side Blazor apps, the DI scope lasts for the duration of the circuit (the SignalR connection between the client and server), which can result in scoped and disposable transient services living much longer than the lifetime of a single component. Therefore, don't directly inject a scoped service into a component if you intend the service lifetime to match the lifetime of the component. Transient services injected into a component that don't implement IDisposable are garbage collected when the component is disposed. However, injected transient services *that implement IDisposable* are maintained by the DI container for the lifetime of the circuit, which prevents service garbage collection when the component is disposed and results in a memory leak. An alternative approach for scoped services based on the OwningComponentBase type is described later in this section, and disposable transient services shouldn't be used at all. For more information, see Design for solving transient disposables on Blazor Server (dotnet/aspnetcore #26676).

Even in client-side Blazor apps that don't operate over a circuit, services registered with a scoped lifetime are treated as singletons, so they live longer than scoped services in typical ASP.NET Core apps. Client-side disposable transient services also live longer than the components where they're injected because the DI container, which holds references to disposable services, persists for the lifetime of the app, preventing garbage collection

on the services. Although long-lived disposable transient services are of greater concern on the server, they should be avoided as client service registrations as well. Use of the OwningComponentBase type is also recommended for client-side scoped services to control service lifetime, and disposable transient services shouldn't be used at all.

An approach that limits a service lifetime is use of the OwningComponentBase type. OwningComponentBase is an abstract type derived from ComponentBase that creates a DI scope corresponding to the *lifetime of the component*. Using this scope, a component can inject services with a scoped lifetime and have them live as long as the component. When the component is destroyed, services from the component's scoped service provider are disposed as well. This can be useful for services reused within a component but not shared across components.

Two versions of OwningComponentBase type are available and described in the next two sections:

- OwningComponentBase
- OwningComponentBase<TService>

`OwningComponentBase`

OwningComponentBase is an abstract, disposable child of the ComponentBase type with a protected ScopedServices property of type IServiceProvider. The provider can be used to resolve services that are scoped to the lifetime of the component.

DI services injected into the component using @inject or the [Inject] attribute aren't created in the component's scope. To use the component's scope, services must be resolved using ScopedServices with either GetRequiredService or GetService. Any services resolved using the ScopedServices provider have their dependencies provided in the component's scope.

The following example demonstrates the difference between injecting a scoped service directly and resolving a service using ScopedServices on the server. The following interface and implementation for a time travel class include a `DT` property to hold a DateTime value. The implementation calls DateTime.Now to set `DT` when the `TimeTravel` class is instantiated.

`ITimeTravel.cs`:

C#

```
public interface ITimeTravel
{
```

```
    public DateTime DT { get; set; }
}
```

`TimeTravel.cs`:

C#

```
public class TimeTravel : ITimeTravel
{
    public DateTime DT { get; set; } = DateTime.Now;
}
```

The service is registered as scoped in the server-side `Program` file. Server-side, scoped services have a lifetime equal to the duration of the circuit.

In the `Program` file:

C#

```
builder.Services.AddScoped<ITimeTravel, TimeTravel>();
```

In the following `TimeTravel` component:

- The time travel service is directly injected with `@inject` as `TimeTravel1`.
- The service is also resolved separately with ScopedServices and GetRequiredService as `TimeTravel2`.

`TimeTravel.razor`:

razor

```
@page "/time-travel"
@inject ITimeTravel TimeTravel1
@inherits OwningComponentBase

<h1><code>OwningComponentBase</code> Example</h1>

<ul>
    <li>TimeTravel1.DT: @TimeTravel1?.DT</li>
    <li>TimeTravel2.DT: @TimeTravel2?.DT</li>
</ul>

@code {
    private ITimeTravel TimeTravel2 { get; set; } = default!;

    protected override void OnInitialized()
    {
        TimeTravel2 = ScopedServices.GetRequiredService<ITimeTravel>();
```

```
    }
}
```

Initially navigating to the `TimeTravel` component, the time travel service is instantiated twice when the component loads, and `TimeTravel1` and `TimeTravel2` have the same initial value:

> TimeTravel1.DT: 8/31/2022 2:54:45 PM
> TimeTravel2.DT: 8/31/2022 2:54:45 PM

When navigating away from the `TimeTravel` component to another component and back to the `TimeTravel` component:

- `TimeTravel1` is provided the same service instance that was created when the component first loaded, so the value of `DT` remains the same.
- `TimeTravel2` obtains a new `ITimeTravel` service instance in `TimeTravel2` with a new DT value.

> TimeTravel1.DT: 8/31/2022 2:54:45 PM
> TimeTravel2.DT: 8/31/2022 2:54:48 PM

`TimeTravel1` is tied to the user's circuit, which remains intact and isn't disposed until the underlying circuit is deconstructed. For example, the service is disposed if the circuit is disconnected for the disconnected circuit retention period.

In spite of the scoped service registration in the `Program` file and the longevity of the user's circuit, `TimeTravel2` receives a new `ITimeTravel` service instance each time the component is initialized.

`OwningComponentBase<TService>`

OwningComponentBase<TService> derives from OwningComponentBase and adds a Service property that returns an instance of `T` from the scoped DI provider. This type is a convenient way to access scoped services without using an instance of IServiceProvider when there's one primary service the app requires from the DI container using the component's scope. The ScopedServices property is available, so the app can get services of other types, if necessary.

```
razor
```

```
@page "/users"
@attribute [Authorize]
@inherits OwningComponentBase<AppDbContext>

<h1>Users (@Service.Users.Count())</h1>

<ul>
    @foreach (var user in Service.Users)
    {
        <li>@user.UserName</li>
    }
</ul>
```

Detect client-side transient disposables

Custom code can be added to a client-side Blazor app to detect disposable transient services in an app that should use OwningComponentBase. This approach is useful if you're concerned that code added to the app in the future consumes one or more transient disposable services, including services added by libraries. Demonstration code is available in the Blazor samples GitHub repository (how to download).

Inspect the following in .NET 6 or later versions of the `BlazorSample_WebAssembly` sample:

- `DetectIncorrectUsagesOfTransientDisposables.cs`
- `Services/TransientDisposableService.cs`
- In `Program.cs`:
  - The app's `Services` namespace is provided at the top of the file (`using BlazorSample.Services;`).
  - `DetectIncorrectUsageOfTransients` is called immediately after the `builder` is assigned from WebAssemblyHostBuilder.CreateDefault.
  - The `TransientDisposableService` is registered (`builder.Services.AddTransient<TransientDisposableService>();`).
  - `EnableTransientDisposableDetection` is called on the built host in the processing pipeline of the app (`host.EnableTransientDisposableDetection();`).
- The app registers the `TransientDisposableService` service without throwing an exception. However, attempting to resolve the service in `TransientService.razor` throws an InvalidOperationException when the framework attempts to construct an instance of `TransientDisposableService`.

Detect server-side transient disposables

Custom code can be added to a server-side Blazor app to detect server-side disposable transient services in an app that should use OwningComponentBase. This approach is useful if you're concerned that code added to the app in the future consumes one or more transient disposable services, including services added by libraries. Demonstration code is available in the Blazor samples GitHub repository (how to download).

Inspect the following in .NET 8 or later versions of the `BlazorSample_BlazorWebApp` sample:

- `DetectIncorrectUsagesOfTransientDisposables.cs`
- `Services/TransitiveTransientDisposableDependency.cs`:
- In `Program.cs`:
  - The app's `Services` namespace is provided at the top of the file (`using BlazorSample.Services;`).
  - `DetectIncorrectUsageOfTransients` is called on the host builder (`builder.DetectIncorrectUsageOfTransients();`).
  - The `TransientDependency` service is registered (`builder.Services.AddTransient<TransientDependency>();`).
  - The `TransitiveTransientDisposableDependency` is registered for `ITransitiveTransientDisposableDependency` (`builder.Services.AddTransient<ITransitiveTransientDisposableDependency, TransitiveTransientDisposableDependency>();`).
- The app registers the `TransientDependency` service without throwing an exception. However, attempting to resolve the service in `TransientService.razor` throws an InvalidOperationException when the framework attempts to construct an instance of `TransientDependency`.

Transient service registrations for `IHttpClientFactory`/`HttpClient` handlers

Transient service registrations for IHttpClientFactory/HttpClient handlers are recommended. If the app contains IHttpClientFactory/HttpClient handlers and uses the IRemoteAuthenticationBuilder<TRemoteAuthenticationState,TAccount> to add support for authentication, the following transient disposables for client-side authentication are also discovered, which is expected and can be ignored:

- BaseAddressAuthorizationMessageHandler
- AuthorizationMessageHandler

Other instances of IHttpClientFactory/HttpClient are also discovered. These instances can also be ignored.

The Blazor sample apps in the Blazor samples GitHub repository (how to download) demonstrate the code to detect transient disposables. However, the code is deactivated because the sample apps include IHttpClientFactory/HttpClient handlers.

To activate the demonstration code and witness its operation:

- Uncomment the transient disposable lines in `Program.cs`.
- Remove the conditional check in `NavLink.razor` that prevents the `TransientService` component from displaying in the app's navigation sidebar:

  diff

  ```
  - else if (name != "TransientService")
  + else
  ```

- Run the sample app and navigate to the `TransientService` component at `/transient-service`.

Use of an Entity Framework Core (EF Core) DbContext from DI

For more information, see ASP.NET Core Blazor with Entity Framework Core (EF Core).

Access server-side Blazor services from a different DI scope

Circuit activity handlers provide an approach for accessing scoped Blazor services from other non-Blazor dependency injection (DI) scopes, such as scopes created using IHttpClientFactory.

Prior to the release of ASP.NET Core in .NET 8, accessing circuit-scoped services from other dependency injection scopes required using a custom base component type. With circuit activity handlers, a custom base component type isn't required, as the following example demonstrates:

C#

```
public class CircuitServicesAccessor
{
    static readonly AsyncLocal<IServiceProvider> blazorServices = new();

    public IServiceProvider? Services
    {
        get => blazorServices.Value;
        set => blazorServices.Value = value;
    }
}

public class ServicesAccessorCircuitHandler(
    IServiceProvider services, CircuitServicesAccessor servicesAccessor)
    : CircuitHandler
{
    public override Func<CircuitInboundActivityContext, Task>
CreateInboundActivityHandler(
        Func<CircuitInboundActivityContext, Task> next) =>
            async context =>
            {
                servicesAccessor.Services = services;
                await next(context);
                servicesAccessor.Services = null;
            };
}

public static class CircuitServicesServiceCollectionExtensions
{
    public static IServiceCollection AddCircuitServicesAccessor(
        this IServiceCollection services)
    {
        services.AddScoped<CircuitServicesAccessor>();
        services.AddScoped<CircuitHandler, ServicesAccessorCircuitHandler>
();

        return services;
    }
}
```

Access the circuit-scoped services by injecting the `CircuitServicesAccessor` where it's needed.

For an example that shows how to access the AuthenticationStateProvider from a DelegatingHandler set up using IHttpClientFactory, see Server-side ASP.NET Core Blazor additional security scenarios.

ASP.NET Core Blazor startup

Article • 09/27/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article explains Blazor app startup configuration.

For general guidance on ASP.NET Core app configuration for server-side development, see Configuration in ASP.NET Core.

Startup process and configuration

The Blazor startup process is automatic and asynchronous via the Blazor script (`blazor.*.js`), where the `*` placeholder is:

- `web` for a Blazor Web App
- `server` for a Blazor Server app
- `webassembly` for a Blazor WebAssembly app

For the location of the script, see ASP.NET Core Blazor project structure.

To manually start Blazor:

Blazor Web App:

- Add an `autostart="false"` attribute and value to the Blazor `<script>` tag.
- Place a script that calls `Blazor.start()` after the Blazor `<script>` tag and inside the closing `</body>` tag.
- Place static server-side rendering (static SSR) options in the `ssr` property.
- Place server-side Blazor-SignalR circuit options in the `circuit` property.
- Place client-side WebAssembly options in the `webAssembly` property.

```
HTML
```

```
<script src="{BLAZOR SCRIPT}" autostart="false"></script>
<script>
  ...
  Blazor.start({
    ssr: {
      ...
    },
    circuit: {
      ...
    },
    webAssembly: {
      ...
    }
  });
  ...
</script>
```

Standalone Blazor WebAssembly and Blazor Server:

- Add an `autostart="false"` attribute and value to the Blazor `<script>` tag.
- Place a script that calls `Blazor.start()` after the Blazor `<script>` tag and inside the closing `</body>` tag.
- You can provide additional options in the `Blazor.start()` parameter.

HTML

```
<script src="{BLAZOR SCRIPT}" autostart="false"></script>
<script>
  ...
  Blazor.start({
    ...
  });
  ...
</script>
```

In the preceding example, the `{BLAZOR SCRIPT}` placeholder is the Blazor script path and file name. For the location of the script, see ASP.NET Core Blazor project structure.

JavaScript initializers

JavaScript (JS) initializers execute logic before and after a Blazor app loads. JS initializers are useful in the following scenarios:

- Customizing how a Blazor app loads.
- Initializing libraries before Blazor starts up.
- Configuring Blazor settings.

JS initializers are detected as part of the build process and imported automatically. Use of JS initializers often removes the need to manually trigger script functions from the app when using Razor class libraries (RCLs).

To define a JS initializer, add a JS module to the project named `{NAME}.lib.module.js`, where the `{NAME}` placeholder is the assembly name, library name, or package identifier. Place the file in the project's web root, which is typically the `wwwroot` folder.

For Blazor Web Apps:

- `beforeWebStart(options)`: Called before the Blazor Web App starts. For example, `beforeWebStart` is used to customize the loading process, logging level, and other options. Receives the Blazor Web options (`options`).
- `afterWebStarted(blazor)`: Called after all `beforeWebStart` promises resolve. For example, `afterWebStarted` can be used to register Blazor event listeners and custom event types. The Blazor instance is passed to `afterWebStarted` as an argument (`blazor`).
- `beforeServerStart(options, extensions)`: Called before the first Server runtime is started. Receives SignalR circuit start options (`options`) and any extensions (`extensions`) added during publishing.
- `afterServerStarted(blazor)`: Called after the first Interactive Server runtime is started.
- `beforeWebAssemblyStart(options, extensions)`: Called before the Interactive WebAssembly runtime is started. Receives the Blazor options (`options`) and any extensions (`extensions`) added during publishing. For example, options can specify the use of a custom boot resource loader.
- `afterWebAssemblyStarted(blazor)`: Called after the Interactive WebAssembly runtime is started.

> **Note**
>
> Legacy JS initializers (`beforeStart`, `afterStarted`) aren't invoked by default in a Blazor Web App. You can enable the legacy initializers to run with the `enableClassicInitializers` option. However, legacy initializer execution is unpredictable.

```
HTML
```

```
<script>
  Blazor.start({ enableClassicInitializers: true });
</script>
```

For Blazor Server, Blazor WebAssembly, and Blazor Hybrid apps:

- `beforeStart(options, extensions)`: Called before Blazor starts. For example, `beforeStart` is used to customize the loading process, logging level, and other options specific to the hosting model.
  - Client-side, `beforeStart` receives the Blazor options (`options`) and any extensions (`extensions`) added during publishing. For example, options can specify the use of a custom boot resource loader.
  - Server-side, `beforeStart` receives SignalR circuit start options (`options`).
  - In a BlazorWebView, no options are passed.
- `afterStarted(blazor)`: Called after Blazor is ready to receive calls from JS. For example, `afterStarted` is used to initialize libraries by making JS interop calls and registering custom elements. The Blazor instance is passed to `afterStarted` as an argument (`blazor`).

Additional .NET WebAssembly runtime callbacks:

- `onRuntimeConfigLoaded(config)`: Called when the boot configuration is downloaded. Allows the app to modify parameters (config) before the runtime starts (the parameter is `MonoConfig` from dotnet.d.ts):

  JavaScript

  ```
  export function onRuntimeConfigLoaded(config) {
    // Sample: Enable startup diagnostic logging when the URL contains
    // parameter debug=1
    const params = new URLSearchParams(location.search);
    if (params.get("debug") == "1") {
      config.diagnosticTracing = true;
    }
  }
  ```

- `onRuntimeReady({ getAssemblyExports, getConfig })`: Called after the .NET WebAssembly runtime has started (the parameter is `RuntimeAPI` from dotnet.d.ts):

  JavaScript

```
export function onRuntimeReady({ getAssemblyExports, getConfig }) {
  // Sample: After the runtime starts, but before Main method is
called,
  // call [JSExport]ed method.
  const config = getConfig();
  const exports = await getAssemblyExports(config.mainAssemblyName);
  exports.Sample.Greet();
}
```

Both callbacks can return a `Promise`, and the promise is awaited before the startup continues.

For the file name:

- If the JS initializers are consumed as a static asset in the project, use the format `{ASSEMBLY NAME}.lib.module.js`, where the `{ASSEMBLY NAME}` placeholder is the app's assembly name. For example, name the file `BlazorSample.lib.module.js` for a project with an assembly name of `BlazorSample`. Place the file in the app's `wwwroot` folder.
- If the JS initializers are consumed from an RCL, use the format `{LIBRARY NAME/PACKAGE ID}.lib.module.js`, where the `{LIBRARY NAME/PACKAGE ID}` placeholder is the project's library name or package identifier. For example, name the file `RazorClassLibrary1.lib.module.js` for an RCL with a package identifier of `RazorClassLibrary1`. Place the file in the library's `wwwroot` folder.

For Blazor Web Apps:

The following example demonstrates JS initializers that load custom scripts before and after the Blazor Web App has started by appending them to the `<head>` in `beforeWebStart` and `afterWebStarted`:

JavaScript

```
export function beforeWebStart() {
  var customScript = document.createElement('script');
  customScript.setAttribute('src', 'beforeStartScripts.js');
  document.head.appendChild(customScript);
}

export function afterWebStarted() {
  var customScript = document.createElement('script');
  customScript.setAttribute('src', 'afterStartedScripts.js');
  document.head.appendChild(customScript);
}
```

The preceding `beforeWebStart` example only guarantees that the custom script loads before Blazor starts. It doesn't guarantee that awaited promises in the script complete their execution before Blazor starts.

For Blazor Server, Blazor WebAssembly, and Blazor Hybrid apps:

The following example demonstrates JS initializers that load custom scripts before and after Blazor has started by appending them to the `<head>` in `beforeStart` and `afterStarted`:

JavaScript

```
export function beforeStart(options, extensions) {
  var customScript = document.createElement('script');
  customScript.setAttribute('src', 'beforeStartScripts.js');
  document.head.appendChild(customScript);
}

export function afterStarted(blazor) {
  var customScript = document.createElement('script');
  customScript.setAttribute('src', 'afterStartedScripts.js');
  document.head.appendChild(customScript);
}
```

The preceding `beforeStart` example only guarantees that the custom script loads before Blazor starts. It doesn't guarantee that awaited promises in the script complete their execution before Blazor starts.

> **Note**
>
> MVC and Razor Pages apps don't automatically load JS initializers. However, developer code can include a script to fetch the app's manifest and trigger the load of the JS initializers.

For examples of JS initializers, see the following resources:

- ASP.NET Core Blazor JavaScript with static server-side rendering (static SSR)
- Use Razor components in JavaScript apps and SPA frameworks (*`quoteContainer2` example*)
- ASP.NET Core Blazor event handling (*Custom clipboard paste event example*)
- Enable QR code generation for TOTP authenticator apps in an ASP.NET Core Blazor Web App
- Basic Test App in the ASP.NET Core GitHub repository (BasicTestApp.lib.module.js)

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Ensure libraries are loaded in a specific order

Append custom scripts to the `<head>` in `beforeStart` and `afterStarted` in the order that they should load.

The following example loads `script1.js` before `script2.js` and `script3.js` before `script4.js`:

JavaScript

```
export function beforeStart(options, extensions) {
    var customScript1 = document.createElement('script');
    customScript1.setAttribute('src', 'script1.js');
    document.head.appendChild(customScript1);

    var customScript2 = document.createElement('script');
    customScript2.setAttribute('src', 'script2.js');
    document.head.appendChild(customScript2);
}

export function afterStarted(blazor) {
    var customScript1 = document.createElement('script');
    customScript1.setAttribute('src', 'script3.js');
    document.head.appendChild(customScript1);

    var customScript2 = document.createElement('script');
    customScript2.setAttribute('src', 'script4.js');
    document.head.appendChild(customScript2);
}
```

Import additional modules

Use top-level import statements in the JS initializers file to import additional modules.

`additionalModule.js`:

JavaScript

```
export function logMessage() {
  console.log('logMessage is logging');
}
```

In the JS initializers file (`.lib.module.js`):

JavaScript

```
import { logMessage } from "/additionalModule.js";

export function beforeStart(options, extensions) {
  ...

  logMessage();
}
```

Import map

Import maps are supported by ASP.NET Core and Blazor.

Initialize Blazor when the document is ready

The following example starts Blazor when the document is ready:

HTML

```
<script src="{BLAZOR SCRIPT}" autostart="false"></script>
<script>
  document.addEventListener("DOMContentLoaded", function() {
    Blazor.start();
  });
</script>
```

In the preceding example, the `{BLAZOR SCRIPT}` placeholder is the Blazor script path and file name. For the location of the script, see ASP.NET Core Blazor project structure.

Chain to the `Promise` that results from a manual start

To perform additional tasks, such as JS interop initialization, use then to chain to the Promise that results from a manual Blazor app start:

HTML

```
<script src="{BLAZOR SCRIPT}" autostart="false"></script>
<script>
  Blazor.start().then(function () {
    ...
  });
</script>
```

In the preceding example, the `{BLAZOR SCRIPT}` placeholder is the Blazor script path and file name. For the location of the script, see ASP.NET Core Blazor project structure.

> ⓘ Note
>
> For a library to automatically execute additional tasks after Blazor has started, use a JavaScript initializer. Use of a JS initializer doesn't require the consumer of the library to chain JS calls to Blazor's manual start.

Load client-side boot resources

When an app loads in the browser, the app downloads boot resources from the server:

- JavaScript code to bootstrap the app
- .NET runtime and assemblies
- Locale specific data

Customize how these boot resources are loaded using the `loadBootResource` API. The `loadBootResource` function overrides the built-in boot resource loading mechanism. Use `loadBootResource` for the following scenarios:

- Load static resources, such as timezone data or `dotnet.wasm`, from a CDN.
- Load compressed assemblies using an HTTP request and decompress them on the client for hosts that don't support fetching compressed contents from the server.
- Alias resources to a different name by redirecting each `fetch` request to a new name.

> ⓘ Note
>
> External sources must return the required Cross-Origin Resource Sharing (CORS) headers for browsers to allow cross-origin resource loading. CDNs usually provide the required headers.

`loadBootResource` parameters appear in the following table.

Expand table

Parameter	Description
`type`	The type of the resource. Permissible types include: `assembly`, `pdb`, `dotnetjs`, `dotnetwasm`, and `timezonedata`. You only need to specify types for custom behaviors. Types not specified to `loadBootResource` are loaded by the framework per their default loading behaviors. The `dotnetjs` boot resource (`dotnet.*.js`) must either return `null` for default loading behavior or a URI for the source of the `dotnetjs` boot resource.
`name`	The name of the resource.
`defaultUri`	The relative or absolute URI of the resource.
`integrity`	The integrity string representing the expected content in the response.

The `loadBootResource` function can return a URI string to override the loading process. In the following example, the following files from `bin/Release/{TARGET FRAMEWORK}/wwwroot/_framework` are served from a CDN at `https://cdn.example.com/blazorwebassembly/{VERSION}/`:

- `dotnet.*.js`
- `dotnet.wasm`
- Timezone data

The `{TARGET FRAMEWORK}` placeholder is the target framework moniker (for example, `net7.0`). The `{VERSION}` placeholder is the shared framework version (for example, `7.0.0`).

Blazor Web App:

HTML

```
<script src="{BLAZOR SCRIPT}" autostart="false"></script>
<script>
  Blazor.start({
    webAssembly: {
      loadBootResource: function (type, name, defaultUri, integrity) {
        console.log(`Loading: '${type}', '${name}', '${defaultUri}',
'${integrity}'`);
        switch (type) {
          case 'dotnetjs':
          case 'dotnetwasm':
          case 'timezonedata':
```

```
            return
`https://cdn.example.com/blazorwebassembly/{VERSION}/${name}`;
        }
      }
    }
  });
</script>
```

Standalone Blazor WebAssembly:

HTML

```
<script src="{BLAZOR SCRIPT}" autostart="false"></script>
<script>
  Blazor.start({
    loadBootResource: function (type, name, defaultUri, integrity) {
      console.log(`Loading: '${type}', '${name}', '${defaultUri}',
'${integrity}'`);
      switch (type) {
        case 'dotnetjs':
        case 'dotnetwasm':
        case 'timezonedata':
          return
`https://cdn.example.com/blazorwebassembly/{VERSION}/${name}`;
      }
    }
  });
</script>
```

In the preceding example, the `{BLAZOR SCRIPT}` placeholder is the Blazor script path and file name. For the location of the script, see ASP.NET Core Blazor project structure.

To customize more than just the URLs for boot resources, the `loadBootResource` function can call `fetch` directly and return the result. The following example adds a custom HTTP header to the outbound requests. To retain the default integrity checking behavior, pass through the `integrity` parameter.

Blazor Web App:

HTML

```
<script src="{BLAZOR SCRIPT}" autostart="false"></script>
<script>
  Blazor.start({
    webAssembly: {
      loadBootResource: function (type, name, defaultUri, integrity) {
        if (type == 'dotnetjs') {
          return null;
        } else {
```

```
          return fetch(defaultUri, {
            cache: 'no-cache',
            integrity: integrity,
            headers: { 'Custom-Header': 'Custom Value' }
          });
        }
      }
    }
  });
</script>
```

Standalone Blazor WebAssembly:

HTML

```
<script src="{BLAZOR SCRIPT}" autostart="false"></script>
<script>
  Blazor.start({
    loadBootResource: function (type, name, defaultUri, integrity) {
      if (type == 'dotnetjs') {
        return null;
      } else {
        return fetch(defaultUri, {
          cache: 'no-cache',
          integrity: integrity,
          headers: { 'Custom-Header': 'Custom Value' }
        });
      }
    }
  });
</script>
```

In the preceding example, the `{BLAZOR SCRIPT}` placeholder is the Blazor script path and file name. For the location of the script, see ASP.NET Core Blazor project structure.

When the `loadBootResource` function returns `null`, Blazor uses the default loading behavior for the resource. For example, the preceding code returns `null` for the `dotnetjs` boot resource (`dotnet.*.js`) because the `dotnetjs` boot resource must either return `null` for default loading behavior or a URI for the source of the `dotnetjs` boot resource.

The `loadBootResource` function can also return a Response promise. For an example, see Host and deploy ASP.NET Core Blazor WebAssembly.

For more information, see ASP.NET Core Blazor WebAssembly .NET runtime and app bundle caching.

Control headers in C# code

Control headers at startup in C# code using the following approaches.

In the following examples, a Content Security Policy (CSP) is applied to the app via a CSP header. The `{POLICY STRING}` placeholder is the CSP policy string.

Server-side and prerendered client-side scenarios

Use ASP.NET Core Middleware to control the headers collection.

In the `Program` file:

C#

```
app.Use(async (context, next) =>
{
    context.Response.Headers.Append("Content-Security-Policy", "{POLICY
STRING}");
    await next();
});
```

The preceding example uses inline middleware, but you can also create a custom middleware class and call the middleware with an extension method in the `Program` file. For more information, see Write custom ASP.NET Core middleware.

For more information on CSPs, see Enforce a Content Security Policy for ASP.NET Core Blazor.

Client-side loading progress indicators

A loading progress indicator shows the loading progress of the app to users, indicating that the app is loading normally and that the user should wait until loading is finished.

Blazor Web App loading progress

The loading progress indicator used in Blazor WebAssembly apps isn't present in an app created from the Blazor Web App project template. Usually, a loading progress indicator isn't desirable for interactive WebAssembly components because Blazor Web Apps prerender client-side components on the server for fast initial load times. For mixed-render-mode situations, the framework or developer code must also be careful to avoid the following problems:

- Showing multiple loading indicators on the same rendered page.
- Inadvertently discarding prerendered content while the .NET WebAssembly runtime is loading.

A future release of .NET might provide a framework-based loading progress indicator. In the meantime, you can add a custom loading progress indicator to a Blazor Web App.

Create a `LoadingProgress` component in the `.Client` app that calls OperatingSystem.IsBrowser:

- When `false`, display a loading progress indicator while the Blazor bundle is downloaded and before the Blazor runtime activates on the client.
- When `true`, render the requested component's content.

The following demonstration uses the loading progress indicator found in apps created from the Blazor WebAssembly template, including a modification of the styles that the template provides. The styles are loaded into the app's `<head>` content by the HeadContent component. For more information, see Control head content in ASP.NET Core Blazor apps.

`LoadingProgress.razor`:

razor

```
@if (!OperatingSystem.IsBrowser())
{
    <HeadContent>
        <style>
            .loading-progress {
                position: relative;
                display: block;
                width: 8rem;
                height: 8rem;
                margin: 20vh auto 1rem auto;
            }

                .loading-progress circle {
                    fill: none;
                    stroke: #e0e0e0;
                    stroke-width: 0.6rem;
                    transform-origin: 50% 50%;
                    transform: rotate(-90deg);
                }

                    .loading-progress circle:last-child {
                        stroke: #1b6ec2;
                        stroke-dasharray:
                            calc(3.142 * var(--blazor-load-percentage, 0%) *
0.8),
```

```
                            500%;
                        transition: stroke-dasharray 0.05s ease-in-out;
                    }

            .loading-progress-text {
                position: relative;
                text-align: center;
                font-weight: bold;
                top: -90px;
            }

                .loading-progress-text:after {
                    content: var(--blazor-load-percentage-text, "Loading");
                }

            code {
                color: #c02d76;
            }
        </style>
    </HeadContent>
    <svg class="loading-progress">
        <circle r="40%" cx="50%" cy="50%" />
        <circle r="40%" cx="50%" cy="50%" />
    </svg>
    <div class="loading-progress-text"></div>
}
else
{
    @ChildContent
}

@code {
    [Parameter]
    public RenderFragment? ChildContent { get; set; }
}
```

In a component that adopts Interactive WebAssembly rendering, wrap the component's Razor markup with the `LoadingProgress` component. The following example demonstrates the approach with the `Counter` component of an app created from the Blazor Web App project template.

`Pages/Counter.razor`:

razor

```
@page "/counter"
@rendermode InteractiveWebAssembly

<PageTitle>Counter</PageTitle>

<LoadingProgress>
    <h1>Counter</h1>
```

```
    <p role="status">Current count: @currentCount</p>

    <button class="btn btn-primary" @onclick="IncrementCount">Click
me</button>
</LoadingProgress>

@code {
    private int currentCount = 0;

    private void IncrementCount()
    {
        currentCount++;
    }
}
```

Blazor WebAssembly app loading progress

The project template contains Scalable Vector Graphics (SVG) and text indicators that show the loading progress of the app.

The progress indicators are implemented with HTML and CSS using two CSS custom properties (variables) provided by Blazor:

- `--blazor-load-percentage`: The percentage of app files loaded.
- `--blazor-load-percentage-text`: The percentage of app files loaded, rounded to the nearest whole number.

Using the preceding CSS variables, you can create custom progress indicators that match the styling of your app.

In the following example:

- `resourcesLoaded` is an instantaneous count of the resources loaded during app startup.
- `totalResources` is the total number of resources to load.

JavaScript

```
const percentage = resourcesLoaded / totalResources * 100;
document.documentElement.style.setProperty(
  '--blazor-load-percentage', `${percentage}%`);
document.documentElement.style.setProperty(
  '--blazor-load-percentage-text', `"${Math.floor(percentage)}%"`);
```

The default round progress indicator is implemented in HTML in the `wwwroot/index.html` file:

HTML

```
<div id="app">
    <svg class="loading-progress">
        <circle r="40%" cx="50%" cy="50%" />
        <circle r="40%" cx="50%" cy="50%" />
    </svg>
    <div class="loading-progress-text"></div>
</div>
```

To review the project template markup and styling for the default progress indicators, see the ASP.NET Core reference source:

- wwwroot/index.html
- app.css

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Instead of using the default round progress indicator, the following example shows how to implement a linear progress indicator.

Add the following styles to `wwwroot/css/app.css`:

css

```
.linear-progress {
    background: silver;
    width: 50vw;
    margin: 20% auto;
    height: 1rem;
    border-radius: 10rem;
    overflow: hidden;
    position: relative;
}

.linear-progress:after {
    content: '';
    position: absolute;
    inset: 0;
    background: blue;
    scale: var(--blazor-load-percentage, 0%) 100%;
```

```
    transform-origin: left top;
    transition: scale ease-out 0.5s;
}
```

A CSS variable (`var(...)`) is used to pass the value of `--blazor-load-percentage` to the `scale` property of a blue pseudo-element that indicates the loading progress of the app's files. As the app loads, `--blazor-load-percentage` is updated automatically, which dynamically changes the progress indicator's visual representation.

In `wwwroot/index.html`, remove the default SVG round indicator in `<div id="app">...</div>` and replace it with the following markup:

HTML

```
<div class="linear-progress"></div>
```

Configure the .NET WebAssembly runtime

In advanced programming scenarios, the `configureRuntime` function with the `dotnet` runtime host builder is used to configure the .NET WebAssembly runtime. For example, `dotnet.withEnvironmentVariable` sets an environment variable that:

- Configures the .NET WebAssembly runtime.
- Changes the behavior of a C library.

> **Note**
>
> A documentation request is pending in the `dotnet/runtime` GitHub repository for more information on environment variables that configure the .NET WebAssembly runtime or affect the behavior of C libraries. Although the documentation request is pending, more information and cross-links to additional resources are available in the request, Question/request for documentation on .NET WASM runtime env vars (dotnet/runtime #98225).

The `configureRuntime` function can also be used to enable integration with a browser profiler.

For the placeholders in the following examples that set an environment variable:

- The `{BLAZOR SCRIPT}` placeholder is the Blazor script path and file name. For the location of the script, see ASP.NET Core Blazor project structure.

- The `{NAME}` placeholder is the environment variable's name.
- The `{VALUE}` placeholder is the environment variable's value.

Blazor Web App:

HTML

```
<script src="{BLAZOR SCRIPT}" autostart="false"></script>
<script>
  Blazor.start({
    webAssembly: {
      configureRuntime: dotnet => {
        dotnet.withEnvironmentVariable("{NAME}", "{VALUE}");
      }
    }
  });
</script>
```

Standalone Blazor WebAssembly:

HTML

```
<script src="{BLAZOR SCRIPT}" autostart="false"></script>
<script>
  Blazor.start({
    configureRuntime: dotnet => {
      dotnet.withEnvironmentVariable("{NAME}", "{VALUE}");
    }
  });
</script>
```

> **Note**
>
> The .NET runtime instance can be accessed using the .NET WebAssembly Runtime API (`Blazor.runtime`). For example, the app's build configuration can be obtained using `Blazor.runtime.runtimeBuildInfo.buildConfiguration`.
>
> For more information on the .NET WebAssembly runtime configuration, see the runtime's TypeScript definition file (dotnet.d.ts) in the dotnet/runtime GitHub repository.
>
> > **Note**
> >
> > Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags**

dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Disable enhanced navigation and form handling

This section applies to Blazor Web Apps.

To disable enhanced navigation and form handling, set `disableDomPreservation` to `true` for `Blazor.start`:

HTML

```
<script src="{BLAZOR SCRIPT}" autostart="false"></script>
<script>
  Blazor.start({
    ssr: { disableDomPreservation: true }
  });
</script>
```

In the preceding example, the `{BLAZOR SCRIPT}` placeholder is the Blazor script path and file name. For the location of the script, see ASP.NET Core Blazor project structure.

Additional resources

ASP.NET Core Blazor environments

Article • 09/16/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article explains how to configure and read the environment in a Blazor app.

When running an app locally, the environment defaults to `Development`. When the app is published, the environment defaults to `Production`.

We recommend the following conventions:

- Always use the "`Development`" environment name for local development. This is because the ASP.NET Core framework expects exactly that name when configuring the app and tooling for local development runs of an app.
- For testing, staging, and production environments, always publish and deploy the app. You can use any environment naming scheme that you wish for published apps, but always use app setting file names with casing of the environment segment that exactly matches the environment name. For staging, use "`Staging`" (capital "S") as the environment name, and name the app settings file to match (`appsettings.Staging.json`). For production, use "`Production`" (capital "P") as the environment name, and name the app settings file to match (`appsettings.Production.json`).

Set the environment

The environment is set using any of the following approaches:

- Blazor Web App: Use any of the approaches described in Use multiple environments in ASP.NET Core for general ASP.NET Core apps.
- Blazor Web App or standalone Blazor WebAssembly: Blazor start configuration
- Standalone Blazor WebAssembly: blazor-environment header
- Blazor Web App or standalone Blazor WebAssembly: Azure App Service

On the client for a Blazor Web App, the environment is determined from the server via a middleware that communicates the environment to the browser via a header named `blazor-environment`. The header sets the environment when the WebAssemblyHost is created in the client-side `Program` file (WebAssemblyHostBuilder.CreateDefault).

For a standalone Blazor WebAssembly app running locally, the development server adds the `blazor-environment` header.

For app's running locally in development, the app defaults to the `Development` environment. Publishing the app defaults the environment to `Production`.

Set the client-side environment via Blazor startup configuration

The following example starts Blazor in the `Staging` environment if the hostname includes `localhost`. Otherwise, the environment is set to its default value.

Blazor Web App:

HTML

```
<script src="{BLAZOR SCRIPT}" autostart="false"></script>
<script>
  if (window.location.hostname.includes("localhost")) {
    Blazor.start({
      webAssembly: {
        environment: "Staging"
      }
    });
  } else {
    Blazor.start();
  }
</script>
```

In the preceding example, the `{BLAZOR SCRIPT}` placeholder is the Blazor script path and file name. For the location of the script, see ASP.NET Core Blazor project structure.

> **Note**
>
> For Blazor Web Apps that set the `webAssembly` > `environment` property in `Blazor.start` configuration, it's wise to match the server-side environment to the environment set on the `environment` property. Otherwise, prerendering on the server will operate under a different environment than rendering on the client,

which results in arbitrary effects. For general guidance on setting the environment for a Blazor Web App, see Use multiple environments in ASP.NET Core.

Standalone Blazor WebAssembly:

HTML

```
<script src="{BLAZOR SCRIPT}" autostart="false"></script>
<script>
  if (window.location.hostname.includes("localhost")) {
    Blazor.start({
      environment: "Staging"
    });
  } else {
    Blazor.start();
  }
</script>
```

In the preceding example, the `{BLAZOR SCRIPT}` placeholder is the Blazor script path and file name. For the location of the script, see ASP.NET Core Blazor project structure.

Using the `environment` property overrides the environment set by the blazor-environment header.

The preceding approach sets the client's environment without changing the `blazor-environment` header's value, nor does it change the server project's console logging of the startup environment for a Blazor Web App that has adopted global Interactive WebAssembly rendering.

To log the environment to the console in either a standalone Blazor WebAssembly project or the `.Client` project of a Blazor Web App, place the following C# code in the `Program` file after the WebAssemblyHost is created with WebAssemblyHostBuilder.CreateDefault and before the line that builds and runs the project (`await builder.Build().RunAsync();`):

C#

```
Console.WriteLine(
    $"Client Hosting Environment: {builder.HostEnvironment.Environment}");
```

For more information on Blazor startup, see ASP.NET Core Blazor startup.

Set the client-side environment via header

Blazor WebAssembly apps can set the environment with the `blazor-environment` header.

In the following example for IIS, the custom header (`blazor-environment`) is added to the published `web.config` file. The `web.config` file is located in the `bin/Release/{TARGET FRAMEWORK}/publish` folder, where the `{TARGET FRAMEWORK}` placeholder is the target framework:

XML

```
<?xml version="1.0" encoding="UTF-8"?>
<configuration>
  <system.webServer>

    ...

    <httpProtocol>
      <customHeaders>
        <add name="blazor-environment" value="Staging" />
      </customHeaders>
    </httpProtocol>
  </system.webServer>
</configuration>
```

> **Note**
>
> To use a custom `web.config` file for IIS that isn't overwritten when the app is published to the `publish` folder, see Host and deploy ASP.NET Core Blazor WebAssembly.
>
> Although the Blazor framework issues the header name in all lowercase letters (`blazor-environment`), you're welcome to use any casing that you desire. For example, a header name that capitalizes each word (`Blazor-Environment`) is supported.

Set the environment for Azure App Service

For a standalone Blazor WebAssembly app, you can set the environment manually via start configuration or the blazor-environment header.

For a server-side app, set the environment via an `ASPNETCORE_ENVIRONMENT` app setting in Azure:

1. ***Confirm that the casing of environment segments in app settings file names match their environment name casing exactly***. For example, the matching app

settings file name for the `Staging` environment is `appsettings.Staging.json`. If the file name is `appsettings.staging.json` (lowercase "`s`"), the file isn't located, and the settings in the file aren't used in the `Staging` environment.

2. For Visual Studio deployment, confirm that the app is deployed to the correct deployment slot. For an app named `BlazorAzureAppSample`, the app is deployed to the `Staging` deployment slot.

3. In the Azure portal for the environment's deployment slot, set the environment with the `ASPNETCORE_ENVIRONMENT` app setting. For an app named `BlazorAzureAppSample`, the staging App Service Slot is named `BlazorAzureAppSample/Staging`. For the `Staging` slot's configuration, create an app setting for `ASPNETCORE_ENVIRONMENT` with a value of `Staging`. **Deployment slot setting** is enabled for the setting.

When requested in a browser, the `BlazorAzureAppSample/Staging` app loads in the `Staging` environment at `https://blazorazureappsample-staging.azurewebsites.net`.

When the app is loaded in the browser, the response header collection for `blazor.boot.json` indicates that the `blazor-environment` header value is `Staging`.

App settings from the `appsettings.{ENVIRONMENT}.json` file are loaded by the app, where the `{ENVIRONMENT}` placeholder is the app's environment. In the preceding example, settings from the `appsettings.Staging.json` file are loaded.

Read the environment in a Blazor WebAssembly app

Obtain the app's environment in a component by injecting IWebAssemblyHostEnvironment and reading the Environment property.

`ReadEnvironment.razor`:

razor

```razor
@page "/read-environment"
@using Microsoft.AspNetCore.Components.WebAssembly.Hosting
@inject IWebAssemblyHostEnvironment Env

<h1>Environment example</h1>

<p>Environment: @Env.Environment</p>
```

Read the environment client-side in a Blazor Web App

Assuming that prerendering isn't disabled for a component or the app, a component in the `.Client` project is prerendered on the server. Because the server doesn't have a registered IWebAssemblyHostEnvironment service, it isn't possible to inject the service and use the service implementation's host environment extension methods and properties during server prerendering. Injecting the service into an Interactive WebAssembly or Interactive Auto component results in the following runtime error:

> There is no registered service of type 'Microsoft.AspNetCore.Components.WebAssembly.Hosting.IWebAssemblyHostEnvironment'.

To address this, create a custom service implementation for IWebAssemblyHostEnvironment on the server. Add the following class to the server project.

`ServerHostEnvironment.cs`:

C#

```
using Microsoft.AspNetCore.Components.WebAssembly.Hosting;
using Microsoft.AspNetCore.Components;

public class ServerHostEnvironment(IWebHostEnvironment env,
NavigationManager nav) :
    IWebAssemblyHostEnvironment
{
    public string Environment => env.EnvironmentName;
    public string BaseAddress => nav.BaseUri;
}
```

In the server project's `Program` file, register the service:

C#

```
builder.Services.TryAddScoped<IWebAssemblyHostEnvironment,
ServerHostEnvironment>();
```

At this point, the IWebAssemblyHostEnvironment service can be injected into an interactive WebAssembly or interactive Auto component and used as shown in the Read the environment in a Blazor WebAssembly app section.

The preceding example can demonstrate that it's possible to have a different server environment than client environment, which isn't recommended and may lead to arbitrary results. When setting the environment in a Blazor Web App, it's best to match server and `.Client` project environments. Consider the following scenario in a test app:

- Implement the client-side (`webassembly`) environment property with the `Staging` environment via `Blazor.start`. See the Set the client-side environment via startup configuration section for an example.
- Don't change the server-side `Properties/launchSettings.json` file. Leave the `environmentVariables` section with the `ASPNETCORE_ENVIRONMENT` environment variable set to `Development`.

You can see the value of the IWebAssemblyHostEnvironment.Environment property change in the UI.

When prerendering occurs on the server, the component is rendered in the `Development` environment:

> **Environment:** Development

When the component is rerendered just a second or two later, after the Blazor bundle is downloaded and the .NET WebAssembly runtime activates, the values change to reflect that the client is operating in the `Staging` environment on the client:

> **Environment:** Staging

The preceding example demonstrates why we recommend setting the server environment to match the client environment for development, testing, and production deployments.

For more information, see the Client-side services fail to resolve during prerendering section of the *Render modes* article, which appears later in the Blazor documentation.

Read the client-side environment during startup

During startup, the WebAssemblyHostBuilder exposes the IWebAssemblyHostEnvironment through the HostEnvironment property, which enables environment-specific logic in host builder code.

In the `Program` file:

C#

```
if (builder.HostEnvironment.Environment == "Custom")
{
    ...
};
```

The following convenience extension methods provided through WebAssemblyHostEnvironmentExtensions permit checking the current environment for `Development`, `Production`, `Staging`, and custom environment names:

- IsDevelopment
- IsProduction
- IsStaging
- IsEnvironment

In the `Program` file:

C#

```
if (builder.HostEnvironment.IsStaging())
{
    ...
};

if (builder.HostEnvironment.IsEnvironment("Custom"))
{
    ...
};
```

The IWebAssemblyHostEnvironment.BaseAddress property can be used during startup when the NavigationManager service isn't available.

ASP.NET Core Blazor logging

Article • 10/18/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article explains Blazor app logging, including configuration and how to write log messages from Razor components.

Configuration

Logging configuration can be loaded from app settings files. For more information, see ASP.NET Core Blazor configuration.

At default log levels and without configuring additional logging providers:

- On the server, logging only occurs to the server-side .NET console in the `Development` environment at the LogLevel.Information level or higher.
- On the client, logging only occurs to the client-side browser developer tools console at the LogLevel.Information level or higher.

When the app is configured in the project file to use implicit namespaces (`<ImplicitUsings>enable</ImplicitUsings>`), a `using` directive for Microsoft.Extensions.Logging or any API in the LoggerExtensions class isn't required to support API Visual Studio IntelliSense completions or building apps. If implicit namespaces aren't enabled, Razor components must explicitly define @using directives for logging namespaces that aren't imported via the `_Imports.razor` file.

Log levels

Log levels conform to ASP.NET Core app log levels, which are listed in the API documentation at LogLevel.

Razor component logging

The following example:

- Injects an ILogger (`ILogger<Counter1>`) object to create a logger. The log's *category* is the fully qualified name of the component's type, `Counter`.
- Calls LogWarning to log at the Warning level.

`Counter1.razor`:

razor

```
@page "/counter-1"
@inject ILogger<Counter1> Logger

<PageTitle>Counter 1</PageTitle>

<h1>Counter 1</h1>

<p>Current count: @currentCount</p>

<button class="btn btn-primary" @onclick="IncrementCount">Click me</button>

@code {
    private int currentCount = 0;

    private void IncrementCount()
    {
        Logger.LogWarning("Someone has clicked me!");

        currentCount++;
    }
}
```

The following example demonstrates logging with an ILoggerFactory in components.

`Counter2.razor`:

razor

```
@page "/counter-2"
@inject ILoggerFactory LoggerFactory

<PageTitle>Counter 2</PageTitle>

<h1>Counter 2</h1>

<p>Current count: @currentCount</p>

<button class="btn btn-primary" @onclick="IncrementCount">Click me</button>

@code {
    private int currentCount = 0;
```

```
    private void IncrementCount()
    {
        var logger = LoggerFactory.CreateLogger<Counter2>();
        logger.LogWarning("Someone has clicked me!");

        currentCount++;
    }
}
```

Server-side logging

For general ASP.NET Core logging guidance, see Logging in .NET Core and ASP.NET Core.

Client-side logging

Not every feature of ASP.NET Core logging is supported client-side. For example, client-side components don't have access to the client's file system or network, so writing logs to the client's physical or network storage isn't possible. When using a third-party logging service designed to work with single-page apps (SPAs), follow the service's security guidance. Keep in mind that every piece of data, including keys or secrets stored client-side are ***insecure*** and can be easily discovered by malicious users.

Configure logging in client-side apps with the WebAssemblyHostBuilder.Logging property. The Logging property is of type ILoggingBuilder, so the extension methods of ILoggingBuilder are supported.

To set the minimum logging level, call LoggingBuilderExtensions.SetMinimumLevel on the host builder in the `Program` file with the LogLevel. The following example sets the minimum log level to Warning:

C#

```
builder.Logging.SetMinimumLevel(LogLevel.Warning);
```

Log in the client-side `Program` file

Logging is supported in client-side apps after the WebAssemblyHostBuilder is built using the framework's internal console logger provider (WebAssemblyConsoleLoggerProvider (reference source)).

In the `Program` file:

```
C#

var host = builder.Build();

var logger = host.Services.GetRequiredService<ILoggerFactory>()
    .CreateLogger<Program>();

logger.LogInformation("Logged after the app is built in the Program file.");

await host.RunAsync();
```

Developer tools console output:

```
info: Program[0]
Logged after the app is built in the Program file.
```

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Client-side log category

Log categories are supported.

The following example shows how to use log categories with the `Counter` component of an app created from a Blazor project template.

In the `IncrementCount` method of the app's `Counter` component (`Counter.razor`) that injects an ILoggerFactory as `LoggerFactory`:

```
C#

var logger = LoggerFactory.CreateLogger("CustomCategory");
logger.LogWarning("Someone has clicked me!");
```

Developer tools console output:

> warn: CustomCategory[0]
> Someone has clicked me!

Client-side log event ID

Log event ID is supported.

The following example shows how to use log event IDs with the `Counter` component of an app created from a Blazor project template.

`LogEvent.cs`:

C#

```
public class LogEvent
{
    public const int Event1 = 1000;
    public const int Event2 = 1001;
}
```

In the `IncrementCount` method of the app's `Counter` component (`Counter.razor`):

C#

```
logger.LogInformation(LogEvent.Event1, "Someone has clicked me!");
logger.LogWarning(LogEvent.Event2, "Someone has clicked me!");
```

Developer tools console output:

> info: BlazorSample.Pages.Counter[1000]
> Someone has clicked me!
> warn: BlazorSample.Pages.Counter[1001]
> Someone has clicked me!

Client-side log message template

Log message templates are supported:

The following example shows how to use log message templates with the `Counter` component of an app created from a Blazor project template.

In the `IncrementCount` method of the app's `Counter` component (`Counter.razor`):

C#

```
logger.LogInformation("Someone clicked me at {CurrentDT}!",
DateTime.UtcNow);
```

Developer tools console output:

```
info: BlazorSample.Pages.Counter[0]
Someone clicked me at 04/21/2022 12:15:57!
```

Client-side log exception parameters

Log exception parameters are supported.

The following example shows how to use log exception parameters with the `Counter` component of an app created from a Blazor project template.

In the `IncrementCount` method of the app's `Counter` component (`Counter.razor`):

C#

```
currentCount++;

try
{
    if (currentCount == 3)
    {
        currentCount = 4;
        throw new OperationCanceledException("Skip 3");
    }
}
catch (Exception ex)
{
    logger.LogWarning(ex, "Exception (currentCount: {Count})!",
currentCount);
}
```

Developer tools console output:

```
warn: BlazorSample.Pages.Counter[0]
Exception (currentCount: 4)!
System.OperationCanceledException: Skip 3
at BlazorSample.Pages.Counter.IncrementCount() in
C:UsersAlabaDesktopBlazorSamplePagesCounter.razor:line 28
```

Client-side filter function

Filter functions are supported.

The following example shows how to use a filter with the `Counter` component of an app created from a Blazor project template.

In the `Program` file:

C#

```
builder.Logging.AddFilter((provider, category, logLevel) =>
    category.Equals("CustomCategory2") && logLevel == LogLevel.Information);
```

In the `IncrementCount` method of the app's `Counter` component (`Counter.razor`) that injects an ILoggerFactory as `LoggerFactory`:

C#

```
var logger1 = LoggerFactory.CreateLogger("CustomCategory1");
logger1.LogInformation("Someone has clicked me!");

var logger2 = LoggerFactory.CreateLogger("CustomCategory1");
logger2.LogWarning("Someone has clicked me!");

var logger3 = LoggerFactory.CreateLogger("CustomCategory2");
logger3.LogInformation("Someone has clicked me!");

var logger4 = LoggerFactory.CreateLogger("CustomCategory2");
logger4.LogWarning("Someone has clicked me!");
```

In the developer tools console output, the filter only permits logging for the `CustomCategory2` category and Information log level message:

> info: CustomCategory2[0]
> Someone has clicked me!

The app can also configure log filtering for specific namespaces. For example, set the log level to Trace in the `Program` file:

C#

```
builder.Logging.SetMinimumLevel(LogLevel.Trace);
```

Normally at the Trace log level, developer tools console output at the **Verbose** level includes Microsoft.AspNetCore.Components.RenderTree logging messages, such as the following:

> dbug: Microsoft.AspNetCore.Components.RenderTree.Renderer[3]
> Rendering component 14 of type
> Microsoft.AspNetCore.Components.Web.HeadOutlet

In the `Program` file, logging messages specific to Microsoft.AspNetCore.Components.RenderTree can be disabled using ***either*** of the following approaches:

- C#

```
builder.Logging.AddFilter("Microsoft.AspNetCore.Components.RenderTree.*
", LogLevel.None);
```

- C#

```
builder.Services.PostConfigure<LoggerFilterOptions>(options =>
    options.Rules.Add(
        new LoggerFilterRule(null,

"Microsoft.AspNetCore.Components.RenderTree.*",
                             LogLevel.None,
                             null)
    ));
```

After ***either*** of the preceding filters is added to the app, the console output at the **Verbose** level doesn't show logging messages from the Microsoft.AspNetCore.Components.RenderTree API.

Client-side custom logger provider

The example in this section demonstrates a custom logger provider for further customization.

Add a package reference to the app for the Microsoft.Extensions.Logging.Configuration package.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

Add the following custom logger configuration. The configuration establishes a `LogLevels` dictionary that sets a custom log format for three log levels: Information, Warning, and Error. A `LogFormat` enum is used to describe short (`LogFormat.Short`) and long (`LogFormat.Long`) formats.

`CustomLoggerConfiguration.cs`:

C#

```
using Microsoft.Extensions.Logging;

public class CustomLoggerConfiguration
{
    public int EventId { get; set; }

    public Dictionary<LogLevel, LogFormat> LogLevels { get; set; } =
        new()
        {
            [LogLevel.Information] = LogFormat.Short,
            [LogLevel.Warning] = LogFormat.Short,
            [LogLevel.Error] = LogFormat.Long
        };

    public enum LogFormat
    {
        Short,
        Long
    }
}
```

Add the following custom logger to the app. The `CustomLogger` outputs custom log formats based on the `logLevel` values defined in the preceding `CustomLoggerConfiguration` configuration.

C#

```
using Microsoft.Extensions.Logging;
using static CustomLoggerConfiguration;

public sealed class CustomLogger : ILogger
{
    private readonly string name;
    private readonly Func<CustomLoggerConfiguration> getCurrentConfig;

    public CustomLogger(
        string name,
        Func<CustomLoggerConfiguration> getCurrentConfig) =>
        (this.name, this.getCurrentConfig) = (name, getCurrentConfig);

    public IDisposable BeginScope<TState>(TState state) => default!;
```

```
    public bool IsEnabled(LogLevel logLevel) =>
        getCurrentConfig().LogLevels.ContainsKey(logLevel);

    public void Log<TState>(
        LogLevel logLevel,
        EventId eventId,
        TState state,
        Exception? exception,
        Func<TState, Exception?, string> formatter)
    {
        if (!IsEnabled(logLevel))
        {
            return;
        }

        CustomLoggerConfiguration config = getCurrentConfig();

        if (config.EventId == 0 || config.EventId == eventId.Id)
        {
            switch (config.LogLevels[logLevel])
            {
                case LogFormat.Short:
                    Console.WriteLine($"{name}: {formatter(state,
exception)}");
                    break;
                case LogFormat.Long:
                    Console.WriteLine($"[{eventId.Id, 2}: {logLevel, -12}]
{name} - {formatter(state, exception)}");
                    break;
                default:
                    // No-op
                    break;
            }
        }
    }
}
```

Add the following custom logger provider to the app. `CustomLoggerProvider` adopts an Options-based approach to configure the logger via built-in logging configuration features. For example, the app can set or change log formats via an `appsettings.json` file without requiring code changes to the custom logger, which is demonstrated at the end of this section.

`CustomLoggerProvider.cs`:

C#

```
using System.Collections.Concurrent;
using Microsoft.Extensions.Options;
```

```
[ProviderAlias("CustomLog")]
public sealed class CustomLoggerProvider : ILoggerProvider
{
    private readonly IDisposable onChangeToken;
    private CustomLoggerConfiguration config;
    private readonly ConcurrentDictionary<string, CustomLogger> loggers =
        new(StringComparer.OrdinalIgnoreCase);

    public CustomLoggerProvider(
        IOptionsMonitor<CustomLoggerConfiguration> config)
    {
        this.config = config.CurrentValue;
        onChangeToken = config.OnChange(updatedConfig => this.config =
updatedConfig);
    }

    public ILogger CreateLogger(string categoryName) =>
        loggers.GetOrAdd(categoryName, name => new CustomLogger(name,
GetCurrentConfig));

    private CustomLoggerConfiguration GetCurrentConfig() => config;

    public void Dispose()
    {
        loggers.Clear();
        onChangeToken.Dispose();
    }
}
```

Add the following custom logger extensions.

`CustomLoggerExtensions.cs`:

C#

```
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.DependencyInjection.Extensions;
using Microsoft.Extensions.Logging;
using Microsoft.Extensions.Logging.Configuration;

public static class CustomLoggerExtensions
{
    public static ILoggingBuilder AddCustomLogger(
        this ILoggingBuilder builder)
    {
        builder.AddConfiguration();

        builder.Services.TryAddEnumerable(
            ServiceDescriptor.Singleton<ILoggerProvider,
CustomLoggerProvider>());

        LoggerProviderOptions.RegisterProviderOptions
            <CustomLoggerConfiguration, CustomLoggerProvider>
```

```
(builder.Services);

        return builder;
    }
}
```

In the `Program` file on the host builder, clear the existing provider by calling ClearProviders and add the custom logging provider:

C#

```
builder.Logging.ClearProviders().AddCustomLogger();
```

In the following `CustomLoggerExample` component:

- The debug message isn't logged.
- The information message is logged in the short format (`LogFormat.Short`).
- The warning message is logged in the short format (`LogFormat.Short`).
- The error message is logged in the long format (`LogFormat.Long`).
- The trace message isn't logged.

`CustomLoggerExample.razor`:

razor

```
@page "/custom-logger-example"
@inject ILogger<CustomLoggerExample> Logger

<p>
    <button @onclick="LogMessages">Log Messages</button>
</p>

@code{
    private void LogMessages()
    {
        Logger.LogDebug(1, "This is a debug message.");
        Logger.LogInformation(3, "This is an information message.");
        Logger.LogWarning(5, "This is a warning message.");
        Logger.LogError(7, "This is an error message.");
        Logger.LogTrace(5!, "This is a trace message.");
    }
}
```

The following output is seen in the browser's developer tools console when the **`Log Messages`** button is selected. The log entries reflect the appropriate formats applied by the custom logger (the client app is named `LoggingTest`):

> LoggingTest.Pages.CustomLoggerExample: This is an information message.
> LoggingTest.Pages.CustomLoggerExample: This is a warning message.
> [7: Error] LoggingTest.Pages.CustomLoggerExample - This is an error message.

From a casual inspection of the preceding example, it's apparent that setting the log line formats via the dictionary in `CustomLoggerConfiguration` isn't strictly necessary. The line formats applied by the custom logger (`CustomLogger`) could have been applied by merely checking the `logLevel` in the `Log` method. The purpose of assigning the log format via configuration is that the developer can change the log format easily via app configuration, as the following example demonstrates.

In the client-side app, add or update the `appsettings.json` file to include logging configuration. Set the log format to `Long` for all three log levels:

JSON

```
{
  "Logging": {
    "CustomLog": {
      "LogLevels": {
        "Information": "Long",
        "Warning": "Long",
        "Error": "Long"
      }
    }
  }
}
```

In the preceding example, notice that the entry for the custom logger configuration is `CustomLog`, which was applied to the custom logger provider (`CustomLoggerProvider`) as an alias with `[ProviderAlias("CustomLog")]`. The logging configuration could have been applied with the name `CustomLoggerProvider` instead of `CustomLog`, but use of the alias `CustomLog` is more user friendly.

In the `Program` file, consume the logging configuration. Add the following code:

C#

```
builder.Logging.AddConfiguration(
    builder.Configuration.GetSection("Logging"));
```

The call to LoggingBuilderConfigurationExtensions.AddConfiguration can be placed either before or after adding the custom logger provider.

Run the app again. Select the **`Log Messages`** button. Notice that the logging configuration is applied from the `appsettings.json` file. All three log entries are in the long (`LogFormat.Long`) format (the client app is named `LoggingTest`):

> [3: Information] LoggingTest.Pages.CustomLoggerExample - This is an information message.
> [5: Warning] LoggingTest.Pages.CustomLoggerExample - This is a warning message.
> [7: Error] LoggingTest.Pages.CustomLoggerExample - This is an error message.

Client-side log scopes

The developer tools console logger doesn't support log scopes. However, a custom logger can support log scopes. For an unsupported example that you can further develop to suit your needs, see the `BlazorWebAssemblyScopesLogger` sample app in the Blazor samples GitHub repository (how to download).

The sample app uses standard ASP.NET Core BeginScope logging syntax to indicate scopes for logged messages. The `Logger` service in the following example is an `ILogger<CustomLoggerExample>`, which is injected into the app's `CustomLoggerExample` component (`CustomLoggerExample.razor`).

C#

```
using (Logger.BeginScope("L1"))
{
    Logger.LogInformation(3, "INFO: ONE scope.");
}

using (Logger.BeginScope("L1"))
{
    using (Logger.BeginScope("L2"))
    {
        Logger.LogInformation(3, "INFO: TWO scopes.");
    }
}

using (Logger.BeginScope("L1"))
{
    using (Logger.BeginScope("L2"))
    {
        using (Logger.BeginScope("L3"))
        {
            Logger.LogInformation(3, "INFO: THREE scopes.");
        }
```

```
    }
}
```

Output:

```
[ 3: Information ] {CLASS} - INFO: ONE scope. => L1 blazor.webassembly.js:1:35542
[ 3: Information ] {CLASS} - INFO: TWO scopes. => L1 => L2
blazor.webassembly.js:1:35542
[ 3: Information ] {CLASS} - INFO: THREE scopes. => L1 => L2 => L3
```

The `{CLASS}` placeholder in the preceding example is `BlazorWebAssemblyScopesLogger.Pages.CustomLoggerExample`.

Prerendered component logging

Prerendered components execute component initialization code twice. Logging takes place server-side on the first execution of initialization code and client-side on the second execution of initialization code. Depending on the goal of logging during initialization, check logs server-side, client-side, or both.

SignalR client logging with the SignalR client builder

This section applies to server-side apps.

In Blazor script start configuration, pass in the `configureSignalR` configuration object that calls `configureLogging` with the log level.

For the `configureLogging` log level value, pass the argument as either the string or integer log level shown in the following table.

Expand table

LogLevel	String setting	Integer setting
Trace	`trace`	0
Debug	`debug`	1
Information	`information`	2
Warning	`warning`	3

LogLevel	String setting	Integer setting
Error	`error`	4
Critical	`critical`	5
None	`none`	6

Example 1: Set the Information log level with a string value.

Blazor Web App:

HTML

```
<script src="{BLAZOR SCRIPT}" autostart="false"></script>
<script>
  Blazor.start({
    circuit: {
      configureSignalR: function (builder) {
        builder.configureLogging("information");
      }
    }
  });
</script>
```

Blazor Server:

HTML

```
<script src="{BLAZOR SCRIPT}" autostart="false"></script>
<script>
  Blazor.start({
    configureSignalR: function (builder) {
      builder.configureLogging("information");
    }
  });
</script>
```

In the preceding example, the `{BLAZOR SCRIPT}` placeholder is the Blazor script path and file name. For the location of the script, see ASP.NET Core Blazor project structure.

Example 2: Set the Information log level with an integer value.

Blazor Web App:

HTML

```
<script src="{BLAZOR SCRIPT}" autostart="false"></script>
<script>
```

```
  Blazor.start({
    circuit: {
      configureSignalR: function (builder) {
        builder.configureLogging(2); // LogLevel.Information
      }
    }
  });
</script>
```

Blazor Server:

HTML

```
<script src="{BLAZOR SCRIPT}" autostart="false"></script>
<script>
  Blazor.start({
    configureSignalR: function (builder) {
      builder.configureLogging(2); // LogLevel.Information
    }
  });
</script>
```

In the preceding example, the `{BLAZOR SCRIPT}` placeholder is the Blazor script path and file name. For the location of the script, see ASP.NET Core Blazor project structure.

> ⓘ Note
>
> Using an integer to specify the logging level in Example 2, often referred to as a *magic number* or *magic constant*, is considered a poor coding practice because the integer doesn't clearly identify the logging level when viewing the source code. If minimizing the bytes transferred to the browser is a priority, using an integer might be justified (consider removing the comment in such cases).

For more information on Blazor startup (`Blazor.start()`), see ASP.NET Core Blazor startup.

SignalR client logging with app configuration

Set up app settings configuration as described in ASP.NET Core Blazor configuration. Place app settings files in `wwwroot` that contain a `Logging:LogLevel:HubConnection` app setting.

> ⓘ Note

As an alternative to using app settings, you can pass the LogLevel as the argument to LoggingBuilderExtensions.SetMinimumLevel when the hub connection is created in a Razor component. However, accidentally deploying the app to a production hosting environment with verbose logging may result in a performance penalty. We recommend using app settings to set the log level.

Provide a `Logging:LogLevel:HubConnection` app setting in the default `appsettings.json` file and in the `Development` environment app settings file. Use a typical less-verbose log level for the default, such as LogLevel.Warning. The default app settings value is what is used in `Staging` and `Production` environments if no app settings files for those environments are present. Use a verbose log level in the `Development` environment app settings file, such as LogLevel.Trace.

`wwwroot/appsettings.json`:

JSON

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft.AspNetCore": "Warning",
      "HubConnection": "Warning"
    }
  }
}
```

`wwwroot/appsettings.Development.json`:

JSON

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft.AspNetCore": "Warning",
      "HubConnection": "Trace"
    }
  }
}
```

ⓘ Important

Configuration in the preceding app settings files is only used by the app if the guidance in ASP.NET Core Blazor configuration is followed.

At the top of the Razor component file (`.razor`):

- Inject an ILoggerProvider to add a `WebAssemblyConsoleLogger` to the logging providers passed to HubConnectionBuilder. Unlike a ConsoleLoggerProvider, `WebAssemblyConsoleLogger` is a wrapper around browser-specific logging APIs (for example, `console.log`). Use of `WebAssemblyConsoleLogger` makes logging possible within Mono inside a browser context.
- Inject an `IConfiguration` to read the `Logging:LogLevel:HubConnection` app setting.

> ⓘ Note
>
> `WebAssemblyConsoleLogger` is internal and not supported for direct use in developer code.

C#

```
@inject ILoggerProvider LoggerProvider
@inject IConfiguration Config
```

> ⓘ Note
>
> The following example is based on the demonstration in the SignalR with Blazor tutorial. Consult the tutorial for further details.

In the component's OnInitializedAsync method, use HubConnectionBuilderExtensions.ConfigureLogging to add the logging provider and set the minimum log level from configuration:

C#

```
protected override async Task OnInitializedAsync()
{
    hubConnection = new HubConnectionBuilder()
        .WithUrl(Navigation.ToAbsoluteUri("/chathub"))
        .ConfigureLogging(builder =>
        {
            builder.AddProvider(LoggerProvider);
            builder.SetMinimumLevel(
                Config.GetValue<LogLevel>
("Logging:LogLevel:HubConnection"));
```

```
        })
        .Build();

    hubConnection.On<string, string>("ReceiveMessage", (user, message) =>
...

    await hubConnection.StartAsync();
}
```

> **Note**
>
> In the preceding example, `Navigation` is an injected NavigationManager.

For more information on setting the app's environment, see ASP.NET Core Blazor environments.

Client-side authentication logging

Log Blazor authentication messages at the LogLevel.Debug or LogLevel.Trace logging levels with a logging configuration in app settings or by using a log filter for Microsoft.AspNetCore.Components.WebAssembly.Authentication in the `Program` file.

Use ***either*** of the following approaches:

- In an app settings file (for example, `wwwroot/appsettings.Development.json`):

  JSON

  ```
  "Logging": {
    "LogLevel": {
      "Microsoft.AspNetCore.Components.WebAssembly.Authentication":
  "Debug"
    }
  }
  ```

  For more information on how to configure a client-side app to read app settings files, see ASP.NET Core Blazor configuration.

- Using a log filter, the following example:
  - Activates logging for the `Debug` build configuration using a C# preprocessor directive.
  - Logs Blazor authentication messages at the Debug log level.

  C#

```
#if DEBUG
    builder.Logging.AddFilter(
        "Microsoft.AspNetCore.Components.WebAssembly.Authentication",
        LogLevel.Debug);
#endif
```

> **Note**
>
> Razor components rendered on the client only log to the client-side browser developer tools console.

Handle errors in ASP.NET Core Blazor apps

Article • 10/18/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article describes how Blazor manages unhandled exceptions and how to develop apps that detect and handle errors.

Detailed errors during development

When a Blazor app isn't functioning properly during development, receiving detailed error information from the app assists in troubleshooting and fixing the issue. When an error occurs, Blazor apps display a light yellow bar at the bottom of the screen:

- During development, the bar directs you to the browser console, where you can see the exception.
- In production, the bar notifies the user that an error has occurred and recommends refreshing the browser.

The UI for this error handling experience is part of the Blazor project templates. Not all versions of the Blazor project templates use the data-nosnippet attribute to signal to browsers not to cache the contents of the error UI, but all versions of the Blazor documentation apply the attribute.

In a Blazor Web App, customize the experience in the `MainLayout` component. Because the Environment Tag Helper (for example, `<environment include="Production">...</environment>`) isn't supported in Razor components, the following example injects IHostEnvironment to configure error messages for different environments.

At the top of `MainLayout.razor`:

```
razor
```

```
@inject IHostEnvironment HostEnvironment
```

Create or modify the Blazor error UI markup:

razor

```
<div id="blazor-error-ui" data-nosnippet>
    @if (HostEnvironment.IsProduction())
    {
        <span>An error has occurred.</span>
    }
    else
    {
        <span>An unhandled exception occurred.</span>
    }
    <a href="" class="reload">Reload</a>
    <a class="dismiss">✕</a>
</div>
```

In a Blazor WebAssembly app, customize the experience in the `wwwroot/index.html` file:

HTML

```
<div id="blazor-error-ui" data-nosnippet>
    An unhandled error has occurred.
    <a href="" class="reload">Reload</a>
    <a class="dismiss">✕</a>
</div>
```

The `blazor-error-ui` element is normally hidden due to the presence of the `display: none` style of the `blazor-error-ui` CSS class in the app's auto-generated stylesheet. When an error occurs, the framework applies `display: block` to the element.

Detailed circuit errors

This section applies to Blazor Web Apps operating over a circuit.

Client-side errors don't include the call stack and don't provide detail on the cause of the error, but server logs do contain such information. For development purposes, sensitive circuit error information can be made available to the client by enabling detailed errors.

Set CircuitOptions.DetailedErrors to `true`. For more information and an example, see ASP.NET Core Blazor SignalR guidance.

An alternative to setting CircuitOptions.DetailedErrors is to set the `DetailedErrors` configuration key to `true` in the app's `Development` environment settings file (`appsettings.Development.json`). Additionally, set SignalR server-side logging (`Microsoft.AspNetCore.SignalR`) to Debug or Trace for detailed SignalR logging.

`appsettings.Development.json`:

JSON

```
{
  "DetailedErrors": true,
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information",
      "Microsoft.AspNetCore.SignalR": "Debug"
    }
  }
}
```

The DetailedErrors configuration key can also be set to `true` using the `ASPNETCORE_DETAILEDERRORS` environment variable with a value of `true` on `Development`/`Staging` environment servers or on your local system.

> ⚠ **Warning**
>
> Always avoid exposing error information to clients on the Internet, which is a security risk.

Detailed errors for Razor component server-side rendering

This section applies to Blazor Web Apps.

Use the RazorComponentsServiceOptions.DetailedErrors option to control producing detailed information on errors for Razor component server-side rendering. The default value is `false`.

The following example enables detailed errors:

C#

```
builder.Services.AddRazorComponents(options =>
    options.DetailedErrors = builder.Environment.IsDevelopment());
```

> ⚠ **Warning**
>
> **Only enable detailed errors in the `Development` environment.** Detailed errors may contain sensitive information about the app that malicious users can use in an attack.
>
> The preceding example provides a degree of safety by setting the value of DetailedErrors based on the value returned by IsDevelopment. When the app is in the `Development` environment, DetailedErrors is set to `true`. This approach isn't foolproof because it's possible to host a production app on a public server in the `Development` environment.

Manage unhandled exceptions in developer code

For an app to continue after an error, the app must have error handling logic. Later sections of this article describe potential sources of unhandled exceptions.

In production, don't render framework exception messages or stack traces in the UI. Rendering exception messages or stack traces could:

- Disclose sensitive information to end users.
- Help a malicious user discover weaknesses in an app that can compromise the security of the app, server, or network.

Unhandled exceptions for circuits

This section applies to server-side apps operating over a circuit.

Razor components with server interactivity enabled are stateful on the server. While users interact with the component on the server, they maintain a connection to the server known as a *circuit*. The circuit holds active component instances, plus many other aspects of state, such as:

- The most recent rendered output of components.
- The current set of event-handling delegates that could be triggered by client-side events.

If a user opens the app in multiple browser tabs, the user creates multiple independent circuits.

Blazor treats most unhandled exceptions as fatal to the circuit where they occur. If a circuit is terminated due to an unhandled exception, the user can only continue to interact with the app by reloading the page to create a new circuit. Circuits outside of the one that's terminated, which are circuits for other users or other browser tabs, aren't affected. This scenario is similar to a desktop app that crashes. The crashed app must be restarted, but other apps aren't affected.

The framework terminates a circuit when an unhandled exception occurs for the following reasons:

- An unhandled exception often leaves the circuit in an undefined state.
- The app's normal operation can't be guaranteed after an unhandled exception.
- Security vulnerabilities may appear in the app if the circuit continues in an undefined state.

Global exception handling

For approaches to handling exceptions globally, see the following sections:

- Error boundaries: Applies to all Blazor apps.
- Alternative global exception handling: Applies to Blazor Server, Blazor WebAssembly, and Blazor Web Apps (8.0 or later) that adopt a global interactive render mode.

Error boundaries

Error boundaries provide a convenient approach for handling exceptions. The ErrorBoundary component:

- Renders its child content when an error hasn't occurred.
- Renders error UI when an unhandled exception is thrown by any component within the error boundary.

To define an error boundary, use the ErrorBoundary component to wrap one or more other components. The error boundary manages unhandled exceptions thrown by the components that it wraps.

```
razor
```

```
<ErrorBoundary>
    ...
</ErrorBoundary>
```

To implement an error boundary in a global fashion, add the boundary around the body content of the app's main layout.

In `MainLayout.razor`:

razor

```
<article class="content px-4">
    <ErrorBoundary>
        @Body
    </ErrorBoundary>
</article>
```

In Blazor Web Apps with the error boundary only applied to a static `MainLayout` component, the boundary is only active during static server-side rendering (static SSR). The boundary doesn't activate just because a component further down the component hierarchy is interactive.

An interactive render mode can't be applied to the `MainLayout` component because the component's `Body` parameter is a RenderFragment delegate, which is arbitrary code and can't be serialized. To enable interactivity broadly for the `MainLayout` component and the rest of the components further down the component hierarchy, the app must adopt a global interactive render mode by applying the interactive render mode to the `HeadOutlet` and `Routes` component instances in the app's root component, which is typically the `App` component. The following example adopts the Interactive Server (`InteractiveServer`) render mode globally.

In `Components/App.razor`:

razor

```
<HeadOutlet @rendermode="InteractiveServer" />

...

<Routes @rendermode="InteractiveServer" />
```

If you prefer not to enable global interactivity, place the error boundary farther down the component hierarchy. The important concepts to keep in mind are that wherever the error boundary is placed:

- If the component where the error boundary is placed isn't interactive, the error boundary is only capable of activating on the server during static SSR. For example, the boundary can activate when an error is thrown in a component lifecycle method but not for an event triggered by user interactivity within the component, such as an error thrown by a button click handler.
- If the component where the error boundary is placed is interactive, the error boundary is capable of activating for interactive components that it wraps.

> **Note**
>
> The preceding considerations aren't relevant for standalone Blazor WebAssembly apps because the client-side rendering (CSR) of a Blazor WebAssembly app is completely interactive.

Consider the following example, where an exception thrown by an embedded counter component is caught by an error boundary in the `Home` component, which adopts an interactive render mode.

`EmbeddedCounter.razor`:

razor

```
<h1>Embedded Counter</h1>

<p role="status">Current count: @currentCount</p>
<button class="btn btn-primary" @onclick="IncrementCount">Click me</button>

@code {
    private int currentCount = 0;

    private void IncrementCount()
    {
        currentCount++;

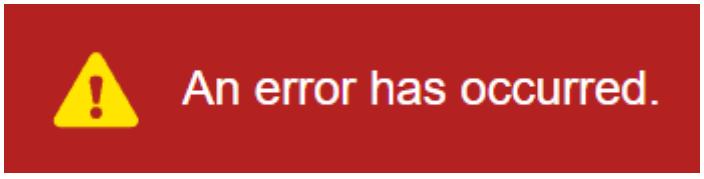
        if (currentCount > 5)
        {
            throw new InvalidOperationException("Current count is too
big!");
        }
    }
}
```

`Home.razor`:

razor

```razor
@page "/"
@rendermode InteractiveServer

<PageTitle>Home</PageTitle>



<h1>Home</h1>

<ErrorBoundary>
    <EmbeddedCounter />
</ErrorBoundary>
```

If the unhandled exception is thrown for a `currentCount` over five:

- The error is logged normally (`System.InvalidOperationException: Current count is too big!`).
- The exception is handled by the error boundary.
- The default error UI is rendered by the error boundary.

The ErrorBoundary component renders an empty `<div>` element using the `blazor-error-boundary` CSS class for its error content. The colors, text, and icon for the default UI are defined in the app's stylesheet in the `wwwroot` folder, so you're free to customize the error UI.

To change the default error content:

- Wrap the components of the error boundary in the ChildContent property.
- Set the ErrorContent property to the error content.

The following example wraps the `EmbeddedCounter` component and supplies custom error content:

razor

```razor
<ErrorBoundary>
    <ChildContent>
        <EmbeddedCounter />
    </ChildContent>
    <ErrorContent>
        <p class="errorUI">😈 A rotten gremlin got us. Sorry!</p>
    </ErrorContent>
</ErrorBoundary>
```

For the preceding example, the app's stylesheet presumably includes an `errorUI` CSS class to style the content. The error content is rendered from the ErrorContent property without a block-level element. A block-level element, such as a division (`<div>`) or a paragraph (`<p>`) element, can wrap the error content markup, but it isn't required.

Optionally, use the context (`@context`) of the ErrorContent to obtain error data:

razor

```
<ErrorContent>
    @context.HelpLink
</ErrorContent>
```

The ErrorContent can also name the context. In the following example, the context is named `exception`:

razor

```
<ErrorContent Context="exception">
    @exception.HelpLink
</ErrorContent>
```

> ⚠ **Warning**
>
> Always avoid exposing error information to clients on the Internet, which is a security risk.

If the error boundary is defined in the app's layout, the error UI is seen regardless of which page the user navigates to after the error occurs. We recommend narrowly scoping error boundaries in most scenarios. If you broadly scope an error boundary, you can reset it to a non-error state on subsequent page navigation events by calling the error boundary's Recover method.

In `MainLayout.razor`:

- Add a field for the ErrorBoundary to capture a reference to it with the @ref attribute directive.
- In the OnParameterSet lifecycle method, you can trigger a recovery on the error boundary with Recover to clear the error when the user navigates to a different component.

razor

```
...

<ErrorBoundary @ref="errorBoundary">
    @Body
</ErrorBoundary>

...

@code {
    private ErrorBoundary? errorBoundary;

    protected override void OnParametersSet()
    {
        errorBoundary?.Recover();
    }
}
```

To avoid the infinite loop where recovering merely rerenders a component that throws the error again, don't call Recover from rendering logic. Only call Recover when:

- The user performs a UI gesture, such as selecting a button to indicate that they want to retry a procedure or when the user navigates to a new component.
- Additional logic that executes also clears the exception. When the component is rerendered, the error doesn't reoccur.

The following example permits the user to recover from the exception with a button:

razor

```
<ErrorBoundary @ref="errorBoundary">
    <ChildContent>
        <EmbeddedCounter />
    </ChildContent>
    <ErrorContent>
        <div class="alert alert-danger" role="alert">
            <p class="fs-3 fw-bold">😈 A rotten gremlin got us. Sorry!</p>
            <p>@context.HelpLink</p>
            <button class="btn btn-info" @onclick="_ =>
errorBoundary?.Recover()">
                Clear
            </button>
        </div>
    </ErrorContent>
</ErrorBoundary>

@code {
    private ErrorBoundary? errorBoundary;
}
```

You can also subclass ErrorBoundary for custom processing by overriding OnErrorAsync. The following example merely logs the error, but you can implement any error handling code you wish. You can remove the line that returns a CompletedTask if your code awaits an asynchronous task.

`CustomErrorBoundary.razor`:

razor

```razor
@inherits ErrorBoundary
@inject ILogger<CustomErrorBoundary> Logger

@if (CurrentException is null)
{
    @ChildContent
}
else if (ErrorContent is not null)
{
    @ErrorContent(CurrentException)
}

@code {
    protected override Task OnErrorAsync(Exception ex)
    {
        Logger.LogError(ex, "😈 A rotten gremlin got us. Sorry!");
        return Task.CompletedTask;
    }
}
```

The preceding example can also be implemented as a class.

`CustomErrorBoundary.cs`:

C#

```csharp
using Microsoft.AspNetCore.Components;
using Microsoft.AspNetCore.Components.Web;

namespace BlazorSample;

public class CustomErrorBoundary : ErrorBoundary
{
    [Inject]
    ILogger<CustomErrorBoundary> Logger {  get; set; } = default!;

    protected override Task OnErrorAsync(Exception ex)
    {
        Logger.LogError(ex, "😈 A rotten gremlin got us. Sorry!");
        return Task.CompletedTask;
```

```
    }
}
```

Either of the preceding implementations used in a component:

razor

```razor
<CustomErrorBoundary>
    ...
</CustomErrorBoundary>
```

Alternative global exception handling

The approach described in this section applies to Blazor Server, Blazor WebAssembly, and Blazor Web Apps that adopt a global interactive render mode (`InteractiveServer`, `InteractiveWebAssembly`, or `InteractiveAuto`). The approach doesn't work with Blazor Web Apps that adopt per-page/component render modes or static server-side rendering (static SSR) because the approach relies on a CascadingValue/CascadingParameter, which don't work across render mode boundaries or with components that adopt static SSR.

An alternative to using Error boundaries (ErrorBoundary) is to pass a custom error component as a CascadingValue to child components. An advantage of using a component over using an injected service or a custom logger implementation is that a cascaded component can render content and apply CSS styles when an error occurs.

The following `ProcessError` component example merely logs errors, but methods of the component can process errors in any way required by the app, including through the use of multiple error processing methods.

`ProcessError.razor`:

razor

```razor
@inject ILogger<ProcessError> Logger

<CascadingValue Value="this">
    @ChildContent
</CascadingValue>

@code {
    [Parameter]
    public RenderFragment? ChildContent { get; set; }

    public void LogError(Exception ex)
```

```
    {
        Logger.LogError("ProcessError.LogError: {Type} Message: {Message}",
            ex.GetType(), ex.Message);

        // Call StateHasChanged if LogError directly participates in
        // rendering. If LogError only logs or records the error,
        // there's no need to call StateHasChanged.
        //StateHasChanged();
    }
}
```

> **Note**
>
> For more information on RenderFragment, see ASP.NET Core Razor components.

When using this approach in a Blazor Web App, open the `Routes` component and wrap the Router component (`<Router>...</Router>`) with the `ProcessError` component. This permits the `ProcessError` component to cascade down to any component of the app where the `ProcessError` component is received as a CascadingParameter.

In `Routes.razor`:

razor

```
<ProcessError>
    <Router ...>
        ...
    </Router>
</ProcessError>
```

When using this approach in a Blazor Server or Blazor WebAssembly app, open the `App` component, wrap the Router component (`<Router>...</Router>`) with the `ProcessError` component. This permits the `ProcessError` component to cascade down to any component of the app where the `ProcessError` component is received as a CascadingParameter.

In `App.razor`:

razor

```
<ProcessError>
    <Router ...>
        ...
    </Router>
</ProcessError>
```

To process errors in a component:

- Designate the `ProcessError` component as a CascadingParameter in the @code block. In an example `Counter` component in an app based on a Blazor project template, add the following `ProcessError` property:

  C#

  ```
  [CascadingParameter]
  public ProcessError? ProcessError { get; set; }
  ```

- Call an error processing method in any `catch` block with an appropriate exception type. The example `ProcessError` component only offers a single `LogError` method, but the error processing component can provide any number of error processing methods to address alternative error processing requirements throughout the app. The following `Counter` component `@code` block example includes the `ProcessError` cascading parameter and traps an exception for logging when the count is greater than five:

  razor

  ```
  @code {
      private int currentCount = 0;

      [CascadingParameter]
      public ProcessError? ProcessError { get; set; }

      private void IncrementCount()
      {
          try
          {
              currentCount++;

              if (currentCount > 5)
              {
                  throw new InvalidOperationException("Current count is
  over five!");
              }
          }
          catch (Exception ex)
          {
              ProcessError?.LogError(ex);
          }
      }
  }
  ```

The logged error:

> fail: {COMPONENT NAMESPACE}.ProcessError[0]
> ProcessError.LogError: System.InvalidOperationException Message: Current count is over five!

If the `LogError` method directly participates in rendering, such as showing a custom error message bar or changing the CSS styles of the rendered elements, call StateHasChanged at the end of the `LogError` method to rerender the UI.

Because the approaches in this section handle errors with a try-catch statement, an app's SignalR connection between the client and server isn't broken when an error occurs and the circuit remains alive. Other unhandled exceptions remain fatal to a circuit. For more information, see the section on how a circuit reacts to unhandled exceptions.

Log errors with a persistent provider

If an unhandled exception occurs, the exception is logged to ILogger instances configured in the service container. Blazor apps log console output with the Console Logging Provider. Consider logging to a location on the server (or backend web API for client-side apps) with a provider that manages log size and log rotation. Alternatively, the app can use an Application Performance Management (APM) service, such as Azure Application Insights (Azure Monitor).

> **Note**
>
> Native Application Insights features to support client-side apps and native Blazor framework support for Google Analytics might become available in future releases of these technologies. For more information, see Support App Insights in Blazor WASM Client Side (microsoft/ApplicationInsights-dotnet #2143) and Web analytics and diagnostics (includes links to community implementations) (dotnet/aspnetcore #5461). In the meantime, a client-side app can use the Application Insights JavaScript SDK with JS interop to log errors directly to Application Insights from a client-side app.

During development in a Blazor app operating over a circuit, the app usually sends the full details of exceptions to the browser's console to aid in debugging. In production, detailed errors aren't sent to clients, but an exception's full details are logged on the server.

You must decide which incidents to log and the level of severity of logged incidents. Hostile users might be able to trigger errors deliberately. For example, don't log an incident from an error where an unknown `ProductId` is supplied in the URL of a component that displays product details. Not all errors should be treated as incidents for logging.

For more information, see the following articles:

- ASP.NET Core Blazor logging
- Handle errors in ASP.NET Core‡
- Create web APIs with ASP.NET Core

‡Applies to server-side Blazor apps and other server-side ASP.NET Core apps that are web API backend apps for Blazor. Client-side apps can trap and send error information on the client to a web API, which logs the error information to a persistent logging provider.

Places where errors may occur

Framework and app code may trigger unhandled exceptions in any of the following locations, which are described further in the following sections of this article:

- Component instantiation
- Lifecycle methods
- Rendering logic
- Event handlers
- Component disposal
- JavaScript interop
- Prerendering

Component instantiation

When Blazor creates an instance of a component:

- The component's constructor is invoked.
- The constructors of DI services supplied to the component's constructor via the @inject directive or the [Inject] attribute are invoked.

An error in an executed constructor or a setter for any `[Inject]` property results in an unhandled exception and stops the framework from instantiating the component. If the app is operating over a circuit, the circuit fails. If constructor logic may throw exceptions,

the app should trap the exceptions using a try-catch statement with error handling and logging.

Lifecycle methods

During the lifetime of a component, Blazor invokes lifecycle methods. If any lifecycle method throws an exception, synchronously or asynchronously, the exception is fatal to a circuit. For components to deal with errors in lifecycle methods, add error handling logic.

In the following example where OnParametersSetAsync calls a method to obtain a product:

- An exception thrown in the `ProductRepository.GetProductByIdAsync` method is handled by a try-catch statement.
- When the `catch` block is executed:
  - `loadFailed` is set to `true`, which is used to display an error message to the user.
  - The error is logged.

razor

```
@page "/product-details/{ProductId:int?}"
@inject ILogger<ProductDetails> Logger
@inject IProductRepository Product

<PageTitle>Product Details</PageTitle>

<h1>Product Details Example</h1>

@if (details != null)
{
    <h2>@details.ProductName</h2>
    <p>
        @details.Description
        <a href="@details.Url">Company Link</a>
    </p>

}
else if (loadFailed)
{
    <h1>Sorry, we could not load this product due to an error.</h1>
}
else
{
    <h1>Loading...</h1>
}

@code {
    private ProductDetail? details;
```

```
    private bool loadFailed;

    [Parameter]
    public int ProductId { get; set; }

    protected override async Task OnParametersSetAsync()
    {
        try
        {
            loadFailed = false;

            // Reset details to null to display the loading indicator
            details = null;

            details = await Product.GetProductByIdAsync(ProductId);
        }
        catch (Exception ex)
        {
            loadFailed = true;
            Logger.LogWarning(ex, "Failed to load product {ProductId}",
ProductId);
        }
    }

    public class ProductDetail
    {
        public string? ProductName { get; set; }
        public string? Description { get; set; }
        public string? Url { get; set; }
    }

    /*
    * Register the service in Program.cs:
    * using static BlazorSample.Components.Pages.ProductDetails;
    * builder.Services.AddScoped<IProductRepository, ProductRepository>();
    */

    public interface IProductRepository
    {
        public Task<ProductDetail> GetProductByIdAsync(int id);
    }

    public class ProductRepository : IProductRepository
    {
        public Task<ProductDetail> GetProductByIdAsync(int id)
        {
            return Task.FromResult(
                new ProductDetail()
                {
                    ProductName = "Flowbee ",
                    Description = "The Revolutionary Haircutting System
You've Come to Love!",
                    Url = "https://flowbee.com/"
                });
        }
```

```
    }
}
```

Rendering logic

The declarative markup in a Razor component file (`.razor`) is compiled into a C# method called BuildRenderTree. When a component renders, BuildRenderTree executes and builds up a data structure describing the elements, text, and child components of the rendered component.

Rendering logic can throw an exception. An example of this scenario occurs when `@someObject.PropertyName` is evaluated but `@someObject` is `null`. For Blazor apps operating over a circuit, an unhandled exception thrown by rendering logic is fatal to the app's circuit.

To prevent a NullReferenceException in rendering logic, check for a `null` object before accessing its members. In the following example, `person.Address` properties aren't accessed if `person.Address` is `null`:

razor

```
@if (person.Address != null)
{
    <div>@person.Address.Line1</div>
    <div>@person.Address.Line2</div>
    <div>@person.Address.City</div>
    <div>@person.Address.Country</div>
}
```

The preceding code assumes that `person` isn't `null`. Often, the structure of the code guarantees that an object exists at the time the component is rendered. In those cases, it isn't necessary to check for `null` in rendering logic. In the prior example, `person` might be guaranteed to exist because `person` is created when the component is instantiated, as the following example shows:

razor

```
@code {
    private Person person = new();

    ...
}
```

Event handlers

Client-side code triggers invocations of C# code when event handlers are created using:

- `@onclick`
- `@onchange`
- Other `@on...` attributes
- `@bind`

Event handler code might throw an unhandled exception in these scenarios.

If the app calls code that could fail for external reasons, trap exceptions using a try-catch statement with error handling and logging.

If an event handler throws an unhandled exception (for example, a database query fails) that isn't trapped and handled by developer code:

- The framework logs the exception.
- In a Blazor app operating over a circuit, the exception is fatal to the app's circuit.

Component disposal

A component may be removed from the UI, for example, because the user has navigated to another page. When a component that implements System.IDisposable is removed from the UI, the framework calls the component's Dispose method.

If the component's `Dispose` method throws an unhandled exception in a Blazor app operating over a circuit, the exception is fatal to the app's circuit.

If disposal logic may throw exceptions, the app should trap the exceptions using a try-catch statement with error handling and logging.

For more information on component disposal, see ASP.NET Core Razor component lifecycle.

JavaScript interop

IJSRuntime is registered by the Blazor framework. IJSRuntime.InvokeAsync allows .NET code to make asynchronous calls to the JavaScript (JS) runtime in the user's browser.

The following conditions apply to error handling with InvokeAsync:

- If a call to InvokeAsync fails synchronously, a .NET exception occurs. A call to InvokeAsync may fail, for example, because the supplied arguments can't be

serialized. Developer code must catch the exception. If app code in an event handler or component lifecycle method doesn't handle an exception in a Blazor app operating over a circuit, the resulting exception is fatal to the app's circuit.

- If a call to InvokeAsync fails asynchronously, the .NET Task fails. A call to InvokeAsync may fail, for example, because the JS-side code throws an exception or returns a `Promise` that completed as `rejected`. Developer code must catch the exception. If using the await operator, consider wrapping the method call in a try-catch statement with error handling and logging. Otherwise in a Blazor app operating over a circuit, the failing code results in an unhandled exception that's fatal to the app's circuit.
- Calls to InvokeAsync must complete within a certain period or else the call times out. The default timeout period is one minute. The timeout protects the code against a loss in network connectivity or JS code that never sends back a completion message. If the call times out, the resulting System.Threading.Tasks fails with an OperationCanceledException. Trap and process the exception with logging.

Similarly, JS code may initiate calls to .NET methods indicated by the [JSInvokable] attribute. If these .NET methods throw an unhandled exception:

- In a Blazor app operating over a circuit, the exception isn't treated as fatal to the app's circuit.
- The JS-side `Promise` is rejected.

You have the option of using error handling code on either the .NET side or the JS side of the method call.

For more information, see the following articles:

- Call JavaScript functions from .NET methods in ASP.NET Core Blazor
- Call .NET methods from JavaScript functions in ASP.NET Core Blazor

Prerendering

Razor components are prerendered by default so that their rendered HTML markup is returned as part of the user's initial HTTP request.

In a Blazor app operating over a circuit, prerendering works by:

- Creating a new circuit for all of the prerendered components that are part of the same page.
- Generating the initial HTML.

- Treating the circuit as `disconnected` until the user's browser establishes a SignalR connection back to the same server. When the connection is established, interactivity on the circuit is resumed and the components' HTML markup is updated.

For prerendered client-side components, prerendering works by:

- Generating initial HTML on the server for all of the prerendered components that are part of the same page.
- Making the component interactive on the client after the browser has loaded the app's compiled code and the .NET runtime (if not already loaded) in the background.

If a component throws an unhandled exception during prerendering, for example, during a lifecycle method or in rendering logic:

- In a Blazor app operating over a circuit, the exception is fatal to the circuit. For prerendered client-side components, the exception prevents rendering the component.
- The exception is thrown up the call stack from the ComponentTagHelper.

Under normal circumstances when prerendering fails, continuing to build and render the component doesn't make sense because a working component can't be rendered.

To tolerate errors that may occur during prerendering, error handling logic must be placed inside a component that may throw exceptions. Use try-catch statements with error handling and logging. Instead of wrapping the ComponentTagHelper in a try-catch statement, place error handling logic in the component rendered by the ComponentTagHelper.

Advanced scenarios

Recursive rendering

Components can be nested recursively. This is useful for representing recursive data structures. For example, a `TreeNode` component can render more `TreeNode` components for each of the node's children.

When rendering recursively, avoid coding patterns that result in infinite recursion:

- Don't recursively render a data structure that contains a cycle. For example, don't render a tree node whose children includes itself.

- Don't create a chain of layouts that contain a cycle. For example, don't create a layout whose layout is itself.
- Don't allow an end user to violate recursion invariants (rules) through malicious data entry or JavaScript interop calls.

Infinite loops during rendering:

- Causes the rendering process to continue forever.
- Is equivalent to creating an unterminated loop.

In these scenarios, the Blazor fails and usually attempts to:

- Consume as much CPU time as permitted by the operating system, indefinitely.
- Consume an unlimited amount of memory. Consuming unlimited memory is equivalent to the scenario where an unterminated loop adds entries to a collection on every iteration.

To avoid infinite recursion patterns, ensure that recursive rendering code contains suitable stopping conditions.

Custom render tree logic

Most Razor components are implemented as Razor component files (`.razor`) and are compiled by the framework to produce logic that operates on a RenderTreeBuilder to render their output. However, a developer may manually implement RenderTreeBuilder logic using procedural C# code. For more information, see ASP.NET Core Blazor advanced scenarios (render tree construction).

> ⚠ **Warning**
>
> Use of manual render tree builder logic is considered an advanced and unsafe scenario, not recommended for general component development.

If RenderTreeBuilder code is written, the developer must guarantee the correctness of the code. For example, the developer must ensure that:

- Calls to OpenElement and CloseElement are correctly balanced.
- Attributes are only added in the correct places.

Incorrect manual render tree builder logic can cause arbitrary undefined behavior, including crashes, the app or server to stop responding, and security vulnerabilities.

Consider manual render tree builder logic on the same level of complexity and with the same level of *danger* as writing assembly code or Microsoft Intermediate Language (MSIL) instructions by hand.

ASP.NET Core Blazor SignalR guidance

Article • 09/27/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article explains how to configure and manage SignalR connections in Blazor apps.

For general guidance on ASP.NET Core SignalR configuration, see the topics in the Overview of ASP.NET Core SignalR area of the documentation, especially ASP.NET Core SignalR configuration.

Server-side apps use ASP.NET Core SignalR to communicate with the browser. SignalR's hosting and scaling conditions apply to server-side apps.

Blazor works best when using WebSockets as the SignalR transport due to lower latency, reliability, and security. Long Polling is used by SignalR when WebSockets isn't available or when the app is explicitly configured to use Long Polling.

Azure SignalR Service with stateful reconnect

Stateful reconnect (WithStatefulReconnect) was released with .NET 8 but isn't currently supported for the Azure SignalR Service. For more information, see Stateful Reconnect Support? (Azure/azure-signalr #1878).

WebSocket compression for Interactive Server components

By default, Interactive Server components:

- Enable compression for WebSocket connections. `ConfigureWebsocketOptions` controls WebSocket compression.
- Adopt a `frame-ancestors` Content Security Policy (CSP) directive set to `'self'`, which only permits embedding the app in an `<iframe>` of the origin from which

the app is served when compression is enabled or when a configuration for the WebSocket context is provided. `ContentSecurityFrameAncestorPolicy` controls the `frame-ancestors` CSP.

The `frame-ancestors` CSP can be removed manually by setting the value of `ConfigureWebSocketOptions` to `null`, as you may want to configure the CSP in a centralized way. When the `frame-ancestors` CSP is managed in a centralized fashion, care must be taken to apply a policy whenever the first document is rendered. We don't recommend removing the policy completely, as it might make the app vulnerable to attack.

Usage examples:

Disable compression by setting `ConfigureWebSocketOptions` to `null`, which reduces the vulnerability of the app to attack but may result in reduced performance:

```
C#

builder.MapRazorComponents<App>()
    .AddInteractiveServerRenderMode(o => o.ConfigureWebSocketOptions = null)
```

When compression is enabled, configure a stricter `frame-ancestors` CSP with a value of `'none'` (single quotes required), which allows WebSocket compression but prevents browsers from embedding the app into any `<iframe>`:

```
C#

builder.MapRazorComponents<App>()
    .AddInteractiveServerRenderMode(o =>
o.ContentSecurityFrameAncestorsPolicy = "'none'")
```

When compression is enabled, remove the `frame-ancestors` CSP by setting `ContentSecurityFrameAncestorsPolicy` to `null`. This scenario is only recommended for apps that set the CSP in a centralized way:

```
C#

builder.MapRazorComponents<App>()
    .AddInteractiveServerRenderMode(o =>
o.ContentSecurityFrameAncestorsPolicy = null)
```

ⓘ Important

Browsers apply CSP directives from multiple CSP headers using the strictest policy directive value. Therefore, a developer can't add a weaker `frame-ancestors` policy than `'self'` on purpose or by mistake.

Single quotes are required on the string value passed to `ContentSecurityFrameAncestorsPolicy`:

❌ `none`, `self`

✔ `'none'`, `'self'`

Additional options include specifying one or more host sources and scheme sources.

For security implications, see Threat mitigation guidance for ASP.NET Core Blazor interactive server-side rendering. For more information on the `frame-ancestors` directive, see CSP: frame-ancestors (MDN documentation).

Disable response compression for Hot Reload

When using Hot Reload, disable Response Compression Middleware in the `Development` environment. Whether or not the default code from a project template is used, always call UseResponseCompression first in the request processing pipeline.

In the `Program` file:

C#

```
if (!app.Environment.IsDevelopment())
{
    app.UseResponseCompression();
}
```

Client-side SignalR cross-origin negotiation for authentication

This section explains how to configure SignalR's underlying client to send credentials, such as cookies or HTTP authentication headers.

Use SetBrowserRequestCredentials to set Include on cross-origin fetch requests.

`IncludeRequestCredentialsMessageHandler.cs`:

C#

```
using System.Net.Http;
using System.Threading;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Components.WebAssembly.Http;

public class IncludeRequestCredentialsMessageHandler : DelegatingHandler
{
    protected override Task<HttpResponseMessage> SendAsync(
        HttpRequestMessage request, CancellationToken cancellationToken)
    {

request.SetBrowserRequestCredentials(BrowserRequestCredentials.Include);
        return base.SendAsync(request, cancellationToken);
    }
}
```

Where a hub connection is built, assign the HttpMessageHandler to the HttpMessageHandlerFactory option:

C#

```
private HubConnectionBuilder? hubConnection;

...

hubConnection = new HubConnectionBuilder()
    .WithUrl(new Uri(Navigation.ToAbsoluteUri("/chathub")), options =>
    {
        options.HttpMessageHandlerFactory = innerHandler =>
            new IncludeRequestCredentialsMessageHandler { InnerHandler =
innerHandler };
    }).Build();
```

The preceding example configures the hub connection URL to the absolute URI address at `/chathub`. The URI can also be set via a string, for example `https://signalr.example.com`, or via configuration. `Navigation` is an injected NavigationManager.

For more information, see ASP.NET Core SignalR configuration.

Client-side rendering

If prerendering is configured, prerendering occurs before the client connection to the server is established. For more information, see Prerender ASP.NET Core Razor components.

Prerendered state size and SignalR message size limit

A large prerendered state size may exceed the SignalR circuit message size limit, which results in the following:

- The SignalR circuit fails to initialize with an error on the client: Circuit host not initialized.
- The reconnection UI on the client appears when the circuit fails. Recovery isn't possible.

To resolve the problem, use ***either*** of the following approaches:

- Reduce the amount of data that you are putting into the prerendered state.
- Increase the SignalR message size limit. ***WARNING***: Increasing the limit may increase the risk of Denial of Service (DoS) attacks.

Additional client-side resources

- Secure a SignalR hub
- Overview of ASP.NET Core SignalR
- ASP.NET Core SignalR configuration
- Blazor samples GitHub repository (dotnet/blazor-samples) (how to download)

Use session affinity (sticky sessions) for server-side webfarm hosting

When more than one backend server is in use, the app must implement session affinity, also called *sticky sessions*. Session affinity ensures that a client's circuit reconnects to the same server if the connection is dropped, which is important because client state is only held in the memory of the server that first established the client's circuit.

The following error is thrown by an app that hasn't enabled session affinity in a webfarm:

> Uncaught (in promise) Error: Invocation canceled due to the underlying connection being closed.

For more information on session affinity with Azure App Service hosting, see Host and deploy ASP.NET Core server-side Blazor apps.

Azure SignalR Service

The optional Azure SignalR Service works in conjunction with the app's SignalR hub for scaling up a server-side app to a large number of concurrent connections. In addition, the service's global reach and high-performance data centers significantly aid in reducing latency due to geography.

The service isn't required for Blazor apps hosted in Azure App Service or Azure Container Apps but can be helpful in other hosting environments:

- To facilitate connection scale out.
- Handle global distribution.

For more information, see Host and deploy ASP.NET Core server-side Blazor apps.

Server-side circuit handler options

Configure the circuit with CircuitOptions. View default values in the reference source.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Read or set the options in the `Program` file with an options delegate to AddInteractiveServerComponents. The `{OPTION}` placeholder represents the option, and the `{VALUE}` placeholder is the value.

In the `Program` file:

C#

```
builder.Services.AddRazorComponents().AddInteractiveServerComponents(options
=>
{
    options.{OPTION} = {VALUE};
});
```

To configure the HubConnectionContext, use HubConnectionContextOptions with AddHubOptions. View the defaults for the hub connection context options in reference source. For option descriptions in the SignalR documentation, see ASP.NET Core SignalR configuration. The `{OPTION}` placeholder represents the option, and the `{VALUE}` placeholder is the value.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

In the `Program` file:

```
C#

builder.Services.AddRazorComponents().AddInteractiveServerComponents().AddHu
bOptions(options =>
{
    options.{OPTION} = {VALUE};
});
```

> **Warning**
>
> The default value of MaximumReceiveMessageSize is 32 KB. Increasing the value may increase the risk of Denial of Service (DoS) attacks.
>
> Blazor relies on MaximumParallelInvocationsPerClient set to 1, which is the default value. For more information, see MaximumParallelInvocationsPerClient > 1 breaks file upload in Blazor Server mode (dotnet/aspnetcore #53951).

For information on memory management, see Host and deploy ASP.NET Core server-side Blazor apps.

Blazor hub options

Configure MapBlazorHub options to control HttpConnectionDispatcherOptions of the Blazor hub. View the defaults for the hub connection dispatcher options in reference

source. The `{OPTION}` placeholder represents the option, and the `{VALUE}` placeholder is the value.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Place the call to `app.MapBlazorHub` after the call to `app.MapRazorComponents` in the app's `Program` file:

```
C#

app.MapBlazorHub(options =>
{
    options.{OPTION} = {VALUE};
});
```

Configuring the hub used by AddInteractiveServerRenderMode with MapBlazorHub fails with an `AmbiguousMatchException`:

> Microsoft.AspNetCore.Routing.Matching.AmbiguousMatchException: The request matched multiple endpoints.

To workaround the problem for apps targeting .NET 8, give the custom-configured Blazor hub higher precedence using the WithOrder method:

```
C#

app.MapBlazorHub(options =>
{
    options.CloseOnAuthenticationExpiration = true;
}).WithOrder(-1);
```

For more information, see the following resources:

- MapBlazorHub configuration in NET8 throws a The request matched multiple endpoints exception (dotnet/aspnetcore #51698)
- Attempts to map multiple blazor entry points with MapBlazorHub causes Ambiguous Route Error. This worked with net7 (dotnet/aspnetcore #52156)

Maximum receive message size

This section only applies to projects that implement SignalR.

The maximum incoming SignalR message size permitted for hub methods is limited by the HubOptions.MaximumReceiveMessageSize (default: 32 KB). SignalR messages larger than MaximumReceiveMessageSize throw an error. The framework doesn't impose a limit on the size of a SignalR message from the hub to a client.

When SignalR logging isn't set to Debug or Trace, a message size error only appears in the browser's developer tools console:

> Error: Connection disconnected with error 'Error: Server returned an error on close: Connection closed with an error.'.

When SignalR server-side logging is set to Debug or Trace, server-side logging surfaces an InvalidDataException for a message size error.

`appsettings.Development.json`:

JSON

```
{
  "DetailedErrors": true,
  "Logging": {
    "LogLevel": {
      ...
      "Microsoft.AspNetCore.SignalR": "Debug"
    }
  }
}
```

Error:

> System.IO.InvalidDataException: The maximum message size of 32768B was exceeded. The message size can be configured in AddHubOptions.

One approach involves increasing the limit by setting MaximumReceiveMessageSize in the `Program` file. The following example sets the maximum receive message size to 64 KB:

C#

```
builder.Services.AddRazorComponents().AddInteractiveServerComponents()
    .AddHubOptions(options => options.MaximumReceiveMessageSize = 64 *
```

```
1024);
```

Increasing the SignalR incoming message size limit comes at the cost of requiring more server resources, and it increases the risk of Denial of Service (DoS) attacks. Additionally, reading a large amount of content in to memory as strings or byte arrays can also result in allocations that work poorly with the garbage collector, resulting in additional performance penalties.

A better option for reading large payloads is to send the content in smaller chunks and process the payload as a Stream. This can be used when reading large JavaScript (JS) interop JSON payloads or if JS interop data is available as raw bytes. For an example that demonstrates sending large binary payloads in server-side apps that uses techniques similar to the InputFile component, see the Binary Submit sample app and the Blazor InputLargeTextArea Component Sample.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Forms that process large payloads over SignalR can also use streaming JS interop directly. For more information, see Call .NET methods from JavaScript functions in ASP.NET Core Blazor. For a forms example that streams `<textarea>` data to the server, see Troubleshoot ASP.NET Core Blazor forms.

Consider the following guidance when developing code that transfers a large amount of data:

- Leverage the native streaming JS interop support to transfer data larger than the SignalR incoming message size limit:
  - Call JavaScript functions from .NET methods in ASP.NET Core Blazor
  - Call .NET methods from JavaScript functions in ASP.NET Core Blazor
  - Form payload example: Troubleshoot ASP.NET Core Blazor forms
- General tips:
  - Don't allocate large objects in JS and C# code.
  - Free consumed memory when the process is completed or cancelled.
  - Enforce the following additional requirements for security purposes:
    - Declare the maximum file or data size that can be passed.

        - Declare the minimum upload rate from the client to the server.
    - After the data is received by the server, the data can be:
        - Temporarily stored in a memory buffer until all of the segments are collected.
        - Consumed immediately. For example, the data can be stored immediately in a database or written to disk as each segment is received.

Blazor server-side Hub endpoint route configuration

In the `Program` file, call MapBlazorHub to map the Blazor Hub to the app's default path. The Blazor script (`blazor.*.js`) automatically points to the endpoint created by MapBlazorHub.

Reflect the server-side connection state in the UI

When the client detects that the connection has been lost, a default UI is displayed to the user while the client attempts to reconnect. If reconnection fails, the user is provided the option to retry.

To customize the UI, define a single element with an `id` of `components-reconnect-modal`. The following example places the element in the `App` component.

`App.razor`:

CSHTML

```
<div id="components-reconnect-modal">
    There was a problem with the connection!
</div>
```

> ⓘ Note
>
> If more than one element with an `id` of `components-reconnect-modal` are rendered by the app, only the first rendered element receives CSS class changes to display or hide the element.

Add the following CSS styles to the site's stylesheet.

`wwwroot/app.css`:

```css
#components-reconnect-modal {
    display: none;
}

#components-reconnect-modal.components-reconnect-show,
#components-reconnect-modal.components-reconnect-failed,
#components-reconnect-modal.components-reconnect-rejected {
    display: block;
}
```

The following table describes the CSS classes applied to the `components-reconnect-modal` element by the Blazor framework.

Expand table

CSS class	Indicates...
`components-reconnect-show`	A lost connection. The client is attempting to reconnect. Show the modal.
`components-reconnect-hide`	An active connection is re-established to the server. Hide the modal.
`components-reconnect-failed`	Reconnection failed, probably due to a network failure. To attempt reconnection, call `window.Blazor.reconnect()` in JavaScript.
`components-reconnect-rejected`	Reconnection rejected. The server was reached but refused the connection, and the user's state on the server is lost. To reload the app, call `location.reload()` in JavaScript. This connection state may result when: • A crash in the server-side circuit occurs. • The client is disconnected long enough for the server to drop the user's state. Instances of the user's components are disposed. • The server is restarted, or the app's worker process is recycled.

Customize the delay before the reconnection UI appears by setting the `transition-delay` property in the site's CSS for the modal element. The following example sets the transition delay from 500 ms (default) to 1,000 ms (1 second).

`wwwroot/app.css`:

```css
#components-reconnect-modal {
    transition: visibility 0s linear 1000ms;
```

```
}
```

To display the current reconnect attempt, define an element with an `id` of `components-reconnect-current-attempt`. To display the maximum number of reconnect retries, define an element with an `id` of `components-reconnect-max-retries`. The following example places these elements inside a reconnect attempt modal element following the previous example.

CSHTML

```
<div id="components-reconnect-modal">
    There was a problem with the connection!
    (Current reconnect attempt:
    <span id="components-reconnect-current-attempt"></span> /
    <span id="components-reconnect-max-retries"></span>)
</div>
```

When the custom reconnect modal appears, it renders content similar to the following based on the preceding code:

HTML

```
There was a problem with the connection! (Current reconnect attempt: 3 / 8)
```

Server-side rendering

By default, components are prerendered on the server before the client connection to the server is established. For more information, see Prerender ASP.NET Core Razor components.

Monitor server-side circuit activity

Monitor inbound circuit activity using the CreateInboundActivityHandler method on CircuitHandler. Inbound circuit activity is any activity sent from the browser to the server, such as UI events or JavaScript-to-.NET interop calls.

For example, you can use a circuit activity handler to detect if the client is idle and log its circuit ID (Circuit.Id):

C#

```
using Microsoft.AspNetCore.Components.Server.Circuits;
using Microsoft.Extensions.Options;
```

```
using Timer = System.Timers.Timer;

public sealed class IdleCircuitHandler : CircuitHandler, IDisposable
{
    private Circuit? currentCircuit;
    private readonly ILogger logger;
    private readonly Timer timer;

    public IdleCircuitHandler(ILogger<IdleCircuitHandler> logger,
        IOptions<IdleCircuitOptions> options)
    {
        timer = new Timer
        {
            Interval = options.Value.IdleTimeout.TotalMilliseconds,
            AutoReset = false
        };

        timer.Elapsed += CircuitIdle;
        this.logger = logger;
    }

    private void CircuitIdle(object? sender, System.Timers.ElapsedEventArgs
e)
    {
        logger.LogInformation("{CircuitId} is idle", currentCircuit?.Id);
    }

    public override Task OnCircuitOpenedAsync(Circuit circuit,
        CancellationToken cancellationToken)
    {
        currentCircuit = circuit;

        return Task.CompletedTask;
    }

    public override Func<CircuitInboundActivityContext, Task>
CreateInboundActivityHandler(
        Func<CircuitInboundActivityContext, Task> next)
    {
        return context =>
        {
            timer.Stop();
            timer.Start();

            return next(context);
        };
    }

    public void Dispose() => timer.Dispose();
}

public class IdleCircuitOptions
{
    public TimeSpan IdleTimeout { get; set; } = TimeSpan.FromMinutes(5);
}
```

```
public static class IdleCircuitHandlerServiceCollectionExtensions
{
    public static IServiceCollection AddIdleCircuitHandler(
        this IServiceCollection services,
        Action<IdleCircuitOptions> configureOptions)
    {
        services.Configure(configureOptions);
        services.AddIdleCircuitHandler();

        return services;
    }

    public static IServiceCollection AddIdleCircuitHandler(
        this IServiceCollection services)
    {
        services.AddScoped<CircuitHandler, IdleCircuitHandler>();

        return services;
    }
}
```

Register the service in the `Program` file. The following example configures the default idle timeout of five minutes to five seconds in order to test the preceding `IdleCircuitHandler` implementation:

C#

```
builder.Services.AddIdleCircuitHandler(options =>
    options.IdleTimeout = TimeSpan.FromSeconds(5));
```

Circuit activity handlers also provide an approach for accessing scoped Blazor services from other non-Blazor dependency injection (DI) scopes. For more information and examples, see:

- ASP.NET Core Blazor dependency injection
- Server-side ASP.NET Core Blazor additional security scenarios

Blazor startup

Configure the manual start of a Blazor app's SignalR circuit in the `App.razor` file of a Blazor Web App:

- Add an `autostart="false"` attribute to the `<script>` tag for the `blazor.*.js` script.

- Place a script that calls `Blazor.start()` after the Blazor script is loaded and inside the closing `</body>` tag.

When `autostart` is disabled, any aspect of the app that doesn't depend on the circuit works normally. For example, client-side routing is operational. However, any aspect that depends on the circuit isn't operational until `Blazor.start()` is called. App behavior is unpredictable without an established circuit. For example, component methods fail to execute while the circuit is disconnected.

For more information, including how to initialize Blazor when the document is ready and how to chain to a JS Promise, see ASP.NET Core Blazor startup.

Configure SignalR timeouts and Keep-Alive on the client

Configure the following values for the client:

- `withServerTimeout`: Configures the server timeout in milliseconds. If this timeout elapses without receiving any messages from the server, the connection is terminated with an error. The default timeout value is 30 seconds. The server timeout should be at least double the value assigned to the Keep-Alive interval (`withKeepAliveInterval`).
- `withKeepAliveInterval`: Configures the Keep-Alive interval in milliseconds (default interval at which to ping the server). This setting allows the server to detect hard disconnects, such as when a client unplugs their computer from the network. The ping occurs at most as often as the server pings. If the server pings every five seconds, assigning a value lower than `5000` (5 seconds) pings every five seconds. The default value is 15 seconds. The Keep-Alive interval should be less than or equal to half the value assigned to the server timeout (`withServerTimeout`).

The following example for the `App.razor` file (Blazor Web App) shows the assignment of default values.

Blazor Web App:

HTML

```
<script src="{BLAZOR SCRIPT}" autostart="false"></script>
<script>
  Blazor.start({
    circuit: {
      configureSignalR: function (builder) {
        builder.withServerTimeout(30000).withKeepAliveInterval(15000);
```

```
      }
    }
  });
</script>
```

The following example for the `Pages/_Host.cshtml` file (Blazor Server, all versions except ASP.NET Core in .NET 6) or `Pages/_Layout.cshtml` file (Blazor Server, ASP.NET Core in .NET 6).

Blazor Server:

HTML

```
<script src="{BLAZOR SCRIPT}" autostart="false"></script>
<script>
  Blazor.start({
    configureSignalR: function (builder) {
      builder.withServerTimeout(30000).withKeepAliveInterval(15000);
    }
  });
</script>
```

In the preceding example, the `{BLAZOR SCRIPT}` placeholder is the Blazor script path and file name. For the location of the script and the path to use, see ASP.NET Core Blazor project structure.

When creating a hub connection in a component, set the ServerTimeout (default: 30 seconds) and KeepAliveInterval (default: 15 seconds) on the HubConnectionBuilder. Set the HandshakeTimeout (default: 15 seconds) on the built HubConnection. The following example shows the assignment of default values:

C#

```
protected override async Task OnInitializedAsync()
{
    hubConnection = new HubConnectionBuilder()
        .WithUrl(Navigation.ToAbsoluteUri("/chathub"))
        .WithServerTimeout(TimeSpan.FromSeconds(30))
        .WithKeepAliveInterval(TimeSpan.FromSeconds(15))
        .Build();

    hubConnection.HandshakeTimeout = TimeSpan.FromSeconds(15);

    hubConnection.On<string, string>("ReceiveMessage", (user, message) =>
...

    await hubConnection.StartAsync();
}
```

When changing the values of the server timeout (ServerTimeout) or the Keep-Alive interval (KeepAliveInterval):

- The server timeout should be at least double the value assigned to the Keep-Alive interval.
- The Keep-Alive interval should be less than or equal to half the value assigned to the server timeout.

For more information, see the *Global deployment and connection failures* sections of the following articles:

- Host and deploy ASP.NET Core server-side Blazor apps
- Host and deploy ASP.NET Core Blazor WebAssembly

Modify the server-side reconnection handler

The reconnection handler's circuit connection events can be modified for custom behaviors, such as:

- To notify the user if the connection is dropped.
- To perform logging (from the client) when a circuit is connected.

To modify the connection events, register callbacks for the following connection changes:

- Dropped connections use `onConnectionDown`.
- Established/re-established connections use `onConnectionUp`.

Both `onConnectionDown` and `onConnectionUp` must be specified.

Blazor Web App:

HTML

```
<script src="{BLAZOR SCRIPT}" autostart="false"></script>
<script>
  Blazor.start({
    circuit: {
      reconnectionHandler: {
        onConnectionDown: (options, error) => console.error(error),
        onConnectionUp: () => console.log("Up, up, and away!")
      }
    }
  });
</script>
```

Blazor Server:

```
HTML
<script src="{BLAZOR SCRIPT}" autostart="false"></script>
<script>
  Blazor.start({
    reconnectionHandler: {
      onConnectionDown: (options, error) => console.error(error),
      onConnectionUp: () => console.log("Up, up, and away!")
    }
  });
</script>
```

In the preceding example, the `{BLAZOR SCRIPT}` placeholder is the Blazor script path and file name. For the location of the script and the path to use, see ASP.NET Core Blazor project structure.

Automatically refresh the page when server-side reconnection fails

The default reconnection behavior requires the user to take manual action to refresh the page after reconnection fails. However, a custom reconnection handler can be used to automatically refresh the page:

`App.razor`:

```
HTML
<div id="reconnect-modal" style="display: none;"></div>
<script src="{BLAZOR SCRIPT}" autostart="false"></script>
<script src="boot.js"></script>
```

In the preceding example, the `{BLAZOR SCRIPT}` placeholder is the Blazor script path and file name. For the location of the script and the path to use, see ASP.NET Core Blazor project structure.

Create the following `wwwroot/boot.js` file.

Blazor Web App:

```
JavaScript
(() => {
  const maximumRetryCount = 3;
  const retryIntervalMilliseconds = 5000;
```

```
  const reconnectModal = document.getElementById('reconnect-modal');

  const startReconnectionProcess = () => {
    reconnectModal.style.display = 'block';

    let isCanceled = false;

    (async () => {
      for (let i = 0; i < maximumRetryCount; i++) {
        reconnectModal.innerText = `Attempting to reconnect: ${i + 1} of
${maximumRetryCount}`;

        await new Promise(resolve => setTimeout(resolve,
retryIntervalMilliseconds));

        if (isCanceled) {
          return;
        }

        try {
          const result = await Blazor.reconnect();
          if (!result) {
            // The server was reached, but the connection was rejected;
reload the page.
            location.reload();
            return;
          }

          // Successfully reconnected to the server.
          return;
        } catch {
          // Didn't reach the server; try again.
        }
      }

      // Retried too many times; reload the page.
      location.reload();
    })();

    return {
      cancel: () => {
        isCanceled = true;
        reconnectModal.style.display = 'none';
      },
    };
  };

  let currentReconnectionProcess = null;

  Blazor.start({
    circuit: {
      reconnectionHandler: {
        onConnectionDown: () => currentReconnectionProcess ??=
startReconnectionProcess(),
        onConnectionUp: () => {
```

```
          currentReconnectionProcess?.cancel();
          currentReconnectionProcess = null;
        }
      }
    }
  });
})();
```

Blazor Server:

JavaScript

```
(() => {
  const maximumRetryCount = 3;
  const retryIntervalMilliseconds = 5000;
  const reconnectModal = document.getElementById('reconnect-modal');

  const startReconnectionProcess = () => {
    reconnectModal.style.display = 'block';

    let isCanceled = false;

    (async () => {
      for (let i = 0; i < maximumRetryCount; i++) {
        reconnectModal.innerText = `Attempting to reconnect: ${i + 1} of
${maximumRetryCount}`;

        await new Promise(resolve => setTimeout(resolve,
retryIntervalMilliseconds));

        if (isCanceled) {
          return;
        }

        try {
          const result = await Blazor.reconnect();
          if (!result) {
            // The server was reached, but the connection was rejected;
reload the page.
            location.reload();
            return;
          }

          // Successfully reconnected to the server.
          return;
        } catch {
          // Didn't reach the server; try again.
        }
      }

      // Retried too many times; reload the page.
      location.reload();
    })();
```

```
    return {
      cancel: () => {
        isCanceled = true;
        reconnectModal.style.display = 'none';
      },
    };
  };

  let currentReconnectionProcess = null;

  Blazor.start({
    reconnectionHandler: {
      onConnectionDown: () => currentReconnectionProcess ??=
startReconnectionProcess(),
      onConnectionUp: () => {
        currentReconnectionProcess?.cancel();
        currentReconnectionProcess = null;
      }
    }
  });
})();
```

For more information on Blazor startup, see ASP.NET Core Blazor startup.

Adjust the server-side reconnection retry count and interval

To adjust the reconnection retry count and interval, set the number of retries (`maxRetries`) and period in milliseconds permitted for each retry attempt (`retryIntervalMilliseconds`).

Blazor Web App:

HTML

```
<script src="{BLAZOR SCRIPT}" autostart="false"></script>
<script>
  Blazor.start({
    circuit: {
      reconnectionOptions: {
        maxRetries: 3,
        retryIntervalMilliseconds: 2000
      }
    }
  });
</script>
```

Blazor Server:

```HTML
<script src="{BLAZOR SCRIPT}" autostart="false"></script>
<script>
  Blazor.start({
    reconnectionOptions: {
      maxRetries: 3,
      retryIntervalMilliseconds: 2000
    }
  });
</script>
```

In the preceding example, the `{BLAZOR SCRIPT}` placeholder is the Blazor script path and file name. For the location of the script and the path to use, see ASP.NET Core Blazor project structure.

When the user navigates back to an app with a disconnected circuit, reconnection is attempted immediately rather than waiting for the duration of the next reconnect interval. This behavior seeks to resume the connection as quickly as possible for the user.

The default reconnect timing uses a computed backoff strategy. The first several reconnection attempts occur in rapid succession before computed delays are introduced between attempts. The default logic for computing the retry interval is an implementation detail subject to change without notice, but you can find the default logic that the Blazor framework uses in the computeDefaultRetryInterval function (reference source).

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Customize the retry interval behavior by specifying a function to compute the retry interval. In the following exponential backoff example, the number of previous reconnection attempts is multiplied by 1,000 ms to calculate the retry interval. When the count of previous attempts to reconnect (`previousAttempts`) is greater than the

maximum retry limit (`maxRetries`), `null` is assigned to the retry interval (`retryIntervalMilliseconds`) to cease further reconnection attempts:

JavaScript

```
Blazor.start({
  circuit: {
    reconnectionOptions: {
      retryIntervalMilliseconds: (previousAttempts, maxRetries) =>
        previousAttempts >= maxRetries ? null : previousAttempts * 1000
    },
  },
});
```

An alternative is to specify the exact sequence of retry intervals. After the last specified retry interval, retries stop because the `retryIntervalMilliseconds` function returns `undefined`:

JavaScript

```
Blazor.start({
  circuit: {
    reconnectionOptions: {
      retryIntervalMilliseconds:
        Array.prototype.at.bind([0, 1000, 2000, 5000, 10000, 15000, 30000]),
    },
  },
});
```

For more information on Blazor startup, see ASP.NET Core Blazor startup.

Control when the reconnection UI appears

Controlling when the reconnection UI appears can be useful in the following situations:

- A deployed app frequently displays the reconnection UI due to ping timeouts caused by internal network or Internet latency, and you would like to increase the delay.
- An app should report to users that the connection has dropped sooner, and you would like to shorten the delay.

The timing of the appearance of the reconnection UI is influenced by adjusting the Keep-Alive interval and timeouts on the client. The reconnection UI appears when the server timeout is reached on the client (`withServerTimeout`, Client configuration section).

However, changing the value of `withServerTimeout` requires changes to other Keep-Alive, timeout, and handshake settings described in the following guidance.

As general recommendations for the guidance that follows:

- The Keep-Alive interval should match between client and server configurations.
- Timeouts should be at least double the value assigned to the Keep-Alive interval.

Server configuration

Set the following:

- ClientTimeoutInterval (default: 30 seconds): The time window clients have to send a message before the server closes the connection.
- HandshakeTimeout (default: 15 seconds): The interval used by the server to timeout incoming handshake requests by clients.
- KeepAliveInterval (default: 15 seconds): The interval used by the server to send keep alive pings to connected clients. Note that there is also a Keep-Alive interval setting on the client, which should match the server's value.

The ClientTimeoutInterval and HandshakeTimeout can be increased, and the KeepAliveInterval can remain the same. The important consideration is that if you change the values, make sure that the timeouts are at least double the value of the Keep-Alive interval and that the Keep-Alive interval matches between server and client. For more information, see the Configure SignalR timeouts and Keep-Alive on the client section.

In the following example:

- The ClientTimeoutInterval is increased to 60 seconds (default value: 30 seconds).
- The HandshakeTimeout is increased to 30 seconds (default value: 15 seconds).
- The KeepAliveInterval isn't set in developer code and uses its default value of 15 seconds. Decreasing the value of the Keep-Alive interval increases the frequency of communication pings, which increases the load on the app, server, and network. Care must be taken to avoid introducing poor performance when lowering the Keep-Alive interval.

Blazor Web App (.NET 8 or later) in the server project's `Program` file:

C#

```
builder.Services.AddRazorComponents().AddInteractiveServerComponents()
    .AddHubOptions(options =>
{
```

```
    options.ClientTimeoutInterval = TimeSpan.FromSeconds(60);
    options.HandshakeTimeout = TimeSpan.FromSeconds(30);
});
```

Blazor Server in the `Program` file:

C#

```
builder.Services.AddServerSideBlazor()
    .AddHubOptions(options =>
    {
        options.ClientTimeoutInterval = TimeSpan.FromSeconds(60);
        options.HandshakeTimeout = TimeSpan.FromSeconds(30);
    });
```

For more information, see the Server-side circuit handler options section.

Client configuration

Set the following:

- `withServerTimeout` (default: 30 seconds): Configures the server timeout, specified in milliseconds, for the circuit's hub connection.
- `withKeepAliveInterval` (default: 15 seconds): The interval, specified in milliseconds, at which the connection sends Keep-Alive messages.

The server timeout can be increased, and the Keep-Alive interval can remain the same. The important consideration is that if you change the values, make sure that the server timeout is at least double the value of the Keep-Alive interval and that the Keep-Alive interval values match between server and client. For more information, see the Configure SignalR timeouts and Keep-Alive on the client section.

In the following startup configuration example (location of the Blazor script), a custom value of 60 seconds is used for the server timeout. The Keep-Alive interval (`withKeepAliveInterval`) isn't set and uses its default value of 15 seconds.

Blazor Web App:

HTML

```
<script src="{BLAZOR SCRIPT}" autostart="false"></script>
<script>
  Blazor.start({
    circuit: {
      configureSignalR: function (builder) {
        builder.withServerTimeout(60000);
```

```
      }
    }
  });
</script>
```

Blazor Server:

HTML

```
<script src="{BLAZOR SCRIPT}" autostart="false"></script>
<script>
  Blazor.start({
    configureSignalR: function (builder) {
      builder.withServerTimeout(60000);
    }
  });
</script>
```

When creating a hub connection in a component, set the server timeout (WithServerTimeout, default: 30 seconds) on the HubConnectionBuilder. Set the HandshakeTimeout (default: 15 seconds) on the built HubConnection. Confirm that the timeouts are at least double the Keep-Alive interval (WithKeepAliveInterval/KeepAliveInterval) and that the Keep-Alive value matches between server and client.

The following example is based on the `Index` component in the SignalR with Blazor tutorial. The server timeout is increased to 60 seconds, and the handshake timeout is increased to 30 seconds. The Keep-Alive interval isn't set and uses its default value of 15 seconds.

C#

```
protected override async Task OnInitializedAsync()
{
    hubConnection = new HubConnectionBuilder()
        .WithUrl(Navigation.ToAbsoluteUri("/chathub"))
        .WithServerTimeout(TimeSpan.FromSeconds(60))
        .Build();

    hubConnection.HandshakeTimeout = TimeSpan.FromSeconds(30);

    hubConnection.On<string, string>("ReceiveMessage", (user, message) =>
...

    await hubConnection.StartAsync();
}
```

Disconnect the Blazor circuit from the client

A Blazor circuit is disconnected when the unload page event is triggered. To disconnect the circuit for other scenarios on the client, invoke `Blazor.disconnect` in the appropriate event handler. In the following example, the circuit is disconnected when the page is hidden (pagehide event):

JavaScript

```
window.addEventListener('pagehide', () => {
  Blazor.disconnect();
});
```

For more information on Blazor startup, see ASP.NET Core Blazor startup.

Server-side circuit handler

You can define a *circuit handler*, which allows running code on changes to the state of a user's circuit. A circuit handler is implemented by deriving from CircuitHandler and registering the class in the app's service container. The following example of a circuit handler tracks open SignalR connections.

`TrackingCircuitHandler.cs`:

C#

```
using Microsoft.AspNetCore.Components.Server.Circuits;

public class TrackingCircuitHandler : CircuitHandler
{
    private HashSet<Circuit> circuits = new();

    public override Task OnConnectionUpAsync(Circuit circuit,
        CancellationToken cancellationToken)
    {
        circuits.Add(circuit);

        return Task.CompletedTask;
    }

    public override Task OnConnectionDownAsync(Circuit circuit,
        CancellationToken cancellationToken)
    {
        circuits.Remove(circuit);

        return Task.CompletedTask;
    }
```

```
    public int ConnectedCircuits => circuits.Count;
}
```

Circuit handlers are registered using DI. Scoped instances are created per instance of a circuit. Using the `TrackingCircuitHandler` in the preceding example, a singleton service is created because the state of all circuits must be tracked.

In the `Program` file:

```
C#

builder.Services.AddSingleton<CircuitHandler, TrackingCircuitHandler>();
```

If a custom circuit handler's methods throw an unhandled exception, the exception is fatal to the circuit. To tolerate exceptions in a handler's code or called methods, wrap the code in one or more try-catch statements with error handling and logging.

When a circuit ends because a user has disconnected and the framework is cleaning up the circuit state, the framework disposes of the circuit's DI scope. Disposing the scope disposes any circuit-scoped DI services that implement System.IDisposable. If any DI service throws an unhandled exception during disposal, the framework logs the exception. For more information, see ASP.NET Core Blazor dependency injection.

Server-side circuit handler to capture users for custom services

Use a CircuitHandler to capture a user from the AuthenticationStateProvider and set that user in a service. For more information and example code, see Server-side ASP.NET Core Blazor additional security scenarios.

Closure of circuits when there are no remaining Interactive Server components

Interactive Server components handle web UI events using a real-time connection with the browser called a circuit. A circuit and its associated state are created when a root Interactive Server component is rendered. The circuit is closed when there are no remaining Interactive Server components on the page, which frees up server resources.

`IHttpContextAccessor` / `HttpContext` in Razor components

IHttpContextAccessor must be avoided with interactive rendering because there isn't a valid `HttpContext` available.

IHttpContextAccessor can be used for components that are statically rendered on the server. **However, we recommend avoiding it if possible.**

HttpContext can be used as a cascading parameter only in *statically-rendered root components* for general tasks, such as inspecting and modifying headers or other properties in the `App` component (`Components/App.razor`). The value is always `null` for interactive rendering.

C#

```
[CascadingParameter]
public HttpContext? HttpContext { get; set; }
```

For scenarios where the HttpContext is required in interactive components, we recommend flowing the data via persistent component state from the server. For more information, see Server-side ASP.NET Core Blazor additional security scenarios.

ASP.NET Core Blazor static files

Article • 11/05/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article describes Blazor app configuration for serving static files.

Static asset delivery in server-side Blazor apps

Serving static assets is managed by either routing endpoint conventions or a middleware described in the following table.

Expand table

Feature	API	.NET Version	Description
Map Static Assets routing endpoint conventions	MapStaticAssets	.NET 9 or later	Optimizes the delivery of static assets to clients.
Static Files Middleware	UseStaticFiles	All .NET versions	Serves static assets to clients without the optimizations of Map Static Assets but useful for some tasks that Map Static Assets isn't capable of managing.

Configure Map Static Assets by calling MapStaticAssets in the app's request processing pipeline, which performs the following:

- Sets the ETag and Last-Modified headers.
- Sets caching headers.
- Uses Caching Middleware.
- When possible, serves compressed static assets.
- Works with a Content Delivery Network (CDN) (for example, Azure CDN) to serve the app's static assets closer to the user.
- Fingerprinting assets to prevent reusing old versions of files.

Map Static Assets operates by combining build and publish processes to collect information about the static assets in the app. This information is utilized by the runtime library to efficiently serve the static assets to browsers.

Map Static Assets can replace UseStaticFiles in most situations. However, Map Static Assets is optimized for serving the assets from known locations in the app at build and publish time. If the app serves assets from other locations, such as disk or embedded resources, UseStaticFiles should be used.

Map Static Assets (MapStaticAssets) replaces calling UseBlazorFrameworkFiles in apps that serve Blazor WebAssembly framework files, and explicitly calling UseBlazorFrameworkFiles in a Blazor Web App isn't necessary because the API is automatically called when invoking AddInteractiveWebAssemblyComponents.

Map Static Assets provides the following benefits that aren't available when calling UseStaticFiles:

- Build-time compression for all the assets in the app, including JavaScript (JS) and stylesheets but excluding image and font assets that are already compressed. Gzip (`Content-Encoding: gz`) compression is used during development. Gzip with Brotli (`Content-Encoding: br`) compression is used during publish.
- Fingerprinting for all assets at build time with a Base64-encoded string of the SHA-256 hash of each file's content. This prevents reusing an old version of a file, even if the old file is cached. Fingerprinted assets are cached using the immutable directive, which results in the browser never requesting the asset again until it changes. For browsers that don't support the `immutable` directive, a max-age directive is added.
  - Even if an asset isn't fingerprinted, content based `ETags` are generated for each static asset using the fingerprint hash of the file as the `ETag` value. This ensures that the browser only downloads a file if its content changes (or the file is being downloaded for the first time).
  - Internally, Blazor maps physical assets to their fingerprints, which allows the app to:
    - Find automatically-generated Blazor assets, such as Razor component scoped CSS for Blazor's CSS isolation feature, and JS assets described by JS import maps.
    - Generate link tags in the `<head>` content of the page to preload assets.
- During Visual Studio Hot Reload development testing:
  - Integrity information is removed from the assets to avoid issues when a file is changed while the app is running.
  - Static assets aren't cached to ensure that the browser always retrieves current content.

When Interactive WebAssembly or Interactive Auto render modes are enabled:

- Blazor creates an endpoint to expose the resource collection as a JS module.
- The URL is emitted to the body of the request as persisted component state when a WebAssembly component is rendered into the page.
- During WebAssembly boot, Blazor retrieves the URL, imports the module, and calls a function to retrieve the asset collection and reconstruct it in memory. The URL is specific to the content and cached forever, so this overhead cost is only paid once per user until the app is updated.
- The resource collection is also exposed at a human-readable URL (`_framework/resource-collection.js`), so JS has access to the resource collection for enhanced navigation or to implement features of other frameworks and third-party components.

Map Static Assets doesn't provide features for minification or other file transformations. Minification is usually handled by custom code or third-party tooling.

Static File Middleware (UseStaticFiles) is useful in the following situations that Map Static Assets (MapStaticAssets) can't handle:

- Applying a path prefix to Blazor WebAssembly static asset files, which is covered in the Prefix for Blazor WebAssembly assets section.
- Configuring file mappings of extensions to specific content types and setting static file options, which is covered in the File mappings and static file options section.

For more information, see Static files in ASP.NET Core.

Deliver assets with Map Static Assets routing endpoint conventions

This section applies to server-side Blazor apps.

Assets are delivered via the ComponentBase.Assets property, which resolves the fingerprinted URL for a given asset. In the following example, Bootstrap, the Blazor project template app stylesheet (`app.css`), and the CSS isolation stylesheet (based on an app's namespace of `BlazorSample`) are linked in a root component, typically the `App` component (`Components/App.razor`):

razor

```
<link rel="stylesheet" href="@Assets["bootstrap/bootstrap.min.css"]" />
<link rel="stylesheet" href="@Assets["app.css"]" />
```

```
<link rel="stylesheet" href="@Assets["BlazorSample.styles.css"]" />
```

Import maps

This section applies to server-side Blazor apps.

The Import Map component (ImportMap) represents an import map element (`<script type="importmap"></script>`) that defines the import map for module scripts. The Import Map component is placed in `<head>` content of the root component, typically the `App` component (`Components/App.razor`).

razor

```
<ImportMap />
```

If a custom ImportMapDefinition isn't assigned to an Import Map component, the import map is generated based on the app's assets.

The following examples demonstrate custom import map definitions and the import maps that they create.

Basic import map:

C#

```
new ImportMapDefinition(
    new Dictionary<string, string>
    {
        { "jquery", "https://cdn.example.com/jquery.js" },
    },
    null,
    null);
```

The preceding code results in the following import map:

JSON

```
{
  "imports": {
    "jquery": "https://cdn.example.com/jquery.js"
  }
}
```

Scoped import map:

C#

```
new ImportMapDefinition(
    null,
    new Dictionary<string, IReadOnlyDictionary<string, string>>
    {
        ["/scoped/"] = new Dictionary<string, string>
        {
            { "jquery", "https://cdn.example.com/jquery.js" },
        }
    },
    null);
```

The preceding code results in the following import map:

JSON

```
{
  "scopes": {
    "/scoped/": {
      "jquery": "https://cdn.example.com/jquery.js"
    }
  }
}
```

Import map with integrity:

C#

```
new ImportMapDefinition(
    new Dictionary<string, string>
    {
        { "jquery", "https://cdn.example.com/jquery.js" },
    },
    null,
    new Dictionary<string, string>
    {
        { "https://cdn.example.com/jquery.js", "sha384-abc123" },
    });
```

The preceding code results in the following import map:

JSON

```
{
  "imports": {
    "jquery": "https://cdn.example.com/jquery.js"
  },
  "integrity": {
    "https://cdn.example.com/jquery.js": "sha384-abc123"
```

```
  }
}
```

Combine import map definitions (ImportMapDefinition) with ImportMapDefinition.Combine.

Import map created from a ResourceAssetCollection that maps static assets to their corresponding unique URLs:

C#

```
ImportMapDefinition.FromResourceCollection(
    new ResourceAssetCollection(
    [
        new ResourceAsset(
            "jquery.fingerprint.js",
            [
                new ResourceAssetProperty("integrity", "sha384-abc123"),
                new ResourceAssetProperty("label", "jquery.js"),
            ])
    ]));
```

The preceding code results in the following import map:

JSON

```
{
  "imports": {
    "./jquery.js": "./jquery.fingerprint.js"
  },
  "integrity": {
    "jquery.fingerprint.js": "sha384-abc123"
  }
}
```

In releases prior to .NET 8, Blazor framework static files, such as the Blazor script, are served via Static File Middleware. In .NET 8 or later, Blazor framework static files are mapped using endpoint routing, and Static File Middleware is no longer used.

Summary of static file `<link>` `href` formats

This section applies to all .NET releases and Blazor apps.

The following tables summarize static file `<link>` `href` formats by .NET release.

For the location of `<head>` content where static file links are placed, see ASP.NET Core Blazor project structure. Static asset links can also be supplied using <HeadContent> components in individual Razor components.

.NET 9 or later

Expand table

App type	`href` value	Examples
Blazor Web App	`@Assets["{PATH}"]`	`<link rel="stylesheet" href="@Assets["app.css"]" />` `<link href="@Assets["_content/ComponentLib/styles.css"]" rel="stylesheet" />`
Blazor Server†	`@Assets["{PATH}"]`	`<link href="@Assets["css/site.css"]" rel="stylesheet" />` `<link href="@Assets["_content/ComponentLib/styles.css"]" rel="stylesheet" />`
Standalone Blazor WebAssembly	`{PATH}`	`<link rel="stylesheet" href="css/app.css" />` `<link href="_content/ComponentLib/styles.css" rel="stylesheet" />`

.NET 8.x

Expand table

App type	`href` value	Examples
Blazor Web App	`{PATH}`	`<link rel="stylesheet" href="app.css" />` `<link href="_content/ComponentLib/styles.css" rel="stylesheet" />`
Blazor Server†	`{PATH}`	`<link href="css/site.css" rel="stylesheet" />` `<link href="_content/ComponentLib/styles.css" rel="stylesheet" />`
Standalone Blazor WebAssembly	`{PATH}`	`<link rel="stylesheet" href="css/app.css" />` `<link href="_content/ComponentLib/styles.css" rel="stylesheet" />`

.NET 7.x or earlier

Expand table

App type	`href` value	Examples
Blazor Server†	`{PATH}`	`<link href="css/site.css" rel="stylesheet" />` `<link href="_content/ComponentLib/styles.css" rel="stylesheet" />`
Hosted Blazor WebAssembly‡	`{PATH}`	`<link href="css/app.css" rel="stylesheet" />` `<link href="_content/ComponentLib/styles.css" rel="stylesheet" />`
Blazor WebAssembly	`{PATH}`	`<link href="css/app.css" rel="stylesheet" />` `<link href="_content/ComponentLib/styles.css" rel="stylesheet" />`

†Blazor Server is supported in .NET 8 or later but is no longer a project template after .NET 7.
‡We recommend updating Hosted Blazor WebAssembly apps to Blazor Web Apps when adopting .NET 8 or later.

Static Web Asset Project Mode

This section applies to the `.Client` project of a Blazor Web App.

The required `<StaticWebAssetProjectMode>Default</StaticWebAssetProjectMode>` setting in the `.Client` project of a Blazor Web App reverts Blazor WebAssembly static asset behaviors back to the defaults, so that the project behaves as part of the hosted project. The Blazor WebAssembly SDK (`Microsoft.NET.Sdk.BlazorWebAssembly`) configures static web assets in a specific way to work in "standalone" mode with a server simply consuming the outputs from the library. This isn't appropriate for a Blazor Web App, where the WebAssembly portion of the app is a logical part of the host and must behave more like a library. For example, the project doesn't expose the styles bundle (for example, `BlazorSample.Client.styles.css`) and instead only provides the host with the project bundle, so that the host can include it in its own styles bundle.

Changing the value (`Default`) of `<StaticWebAssetProjectMode>` or removing the property from the `.Client` project isn't supported.

Static files in non-`Development` environments

This section applies to server-side static files.

When running an app locally, static web assets are only enabled in the Development environment. To enable static files for environments other than Development during local development and testing (for example, Staging), call UseStaticWebAssets on the WebApplicationBuilder in the `Program` file.

> ⚠ **Warning**
>
> Call UseStaticWebAssets for the ***exact environment*** to prevent activating the feature in production, as it serves files from separate locations on disk *other than from the project* if called in a production environment. The example in this section checks for the Staging environment by calling IsStaging.

C#

```
if (builder.Environment.IsStaging())
{
    builder.WebHost.UseStaticWebAssets();
}
```

Prefix for Blazor WebAssembly assets

This section applies to Blazor Web Apps.

Use the WebAssemblyComponentsEndpointOptions.PathPrefix endpoint option to set the path string that indicates the prefix for Blazor WebAssembly assets. The path must correspond to a referenced Blazor WebAssembly application project.

C#

```
endpoints.MapRazorComponents<App>()
    .AddInteractiveWebAssemblyRenderMode(options =>
        options.PathPrefix = "{PATH PREFIX}");
```

In the preceding example, the `{PATH PREFIX}` placeholder is the path prefix and must start with a forward slash (`/`).

In the following example, the path prefix is set to `/path-prefix`:

C#

```
endpoints.MapRazorComponents<App>()
    .AddInteractiveWebAssemblyRenderMode(options =>
```

```
        options.PathPrefix = "/path-prefix");
```

Static web asset base path

This section applies to standalone Blazor WebAssembly apps.

Publishing the app places the app's static assets, including Blazor framework files (`_framework` folder assets), at the root path (`/`) in published output. The `<StaticWebAssetBasePath>` property specified in the project file (`.csproj`) sets the base path to a non-root path:

XML

```
<PropertyGroup>
  <StaticWebAssetBasePath>{PATH}</StaticWebAssetBasePath>
</PropertyGroup>
```

In the preceding example, the `{PATH}` placeholder is the path.

Without setting the `<StaticWebAssetBasePath>` property, a standalone app is published at `/BlazorStandaloneSample/bin/Release/{TFM}/publish/wwwroot/`.

In the preceding example, the `{TFM}` placeholder is the Target Framework Moniker (TFM) (for example, `net6.0`).

If the `<StaticWebAssetBasePath>` property in a standalone Blazor WebAssembly app sets the published static asset path to `app1`, the root path to the app in published output is `/app1`.

In the standalone Blazor WebAssembly app's project file (`.csproj`):

XML

```
<PropertyGroup>
  <StaticWebAssetBasePath>app1</StaticWebAssetBasePath>
</PropertyGroup>
```

In published output, the path to the standalone Blazor WebAssembly app is `/BlazorStandaloneSample/bin/Release/{TFM}/publish/wwwroot/app1/`.

In the preceding example, the `{TFM}` placeholder is the Target Framework Moniker (TFM) (for example, `net6.0`).

File mappings and static file options

This section applies to server-side static files.

To create additional file mappings with a FileExtensionContentTypeProvider or configure other StaticFileOptions, use **one** of the following approaches. In the following examples, the `{EXTENSION}` placeholder is the file extension, and the `{CONTENT TYPE}` placeholder is the content type. The namespace for the following API is Microsoft.AspNetCore.StaticFiles.

- Configure options through dependency injection (DI) in the `Program` file using StaticFileOptions:

  C#

  ```
  var provider = new FileExtensionContentTypeProvider();
  provider.Mappings["{EXTENSION}"] = "{CONTENT TYPE}";

  builder.Services.Configure<StaticFileOptions>(options =>
  {
      options.ContentTypeProvider = provider;
  });

  app.UseStaticFiles();
  ```

- Pass the StaticFileOptions directly to UseStaticFiles in the `Program` file:

  C#

  ```
  var provider = new FileExtensionContentTypeProvider();
  provider.Mappings["{EXTENSION}"] = "{CONTENT TYPE}";

  app.UseStaticFiles(new StaticFileOptions { ContentTypeProvider =
  provider });
  ```

Serve files from multiple locations

The guidance in this section only applies to Blazor Web Apps.

To serve files from multiple locations with a CompositeFileProvider:

- Add the namespace for Microsoft.Extensions.FileProviders to the top of the `Program` file of the server project.
- In the server project's `Program` file ***before*** the call to UseStaticFiles:
  - Create a PhysicalFileProvider with the path to the static assets.

- Create a CompositeFileProvider from the WebRootFileProvider and the PhysicalFileProvider. Assign the composite file provider back to the app's WebRootFileProvider.

Example:

Create a new folder in the server project named `AdditionalStaticAssets`. Place an image into the folder.

Add the following `using` statement to the top of the server project's `Program` file:

C#

```
using Microsoft.Extensions.FileProviders;
```

In the server project's `Program` file ***before*** the call to UseStaticFiles, add the following code:

C#

```
var secondaryProvider = new PhysicalFileProvider(
    Path.Combine(builder.Environment.ContentRootPath,
"AdditionalStaticAssets"));
app.Environment.WebRootFileProvider = new CompositeFileProvider(
    app.Environment.WebRootFileProvider, secondaryProvider);
```

In the app's `Home` component (`Home.razor`) markup, reference the image with an `<img>` tag:

razor

```
<img src="{IMAGE FILE NAME}" alt="{ALT TEXT}" />
```

In the preceding example:

- The `{IMAGE FILE NAME}` placeholder is the image file name. There's no need to provide a path segment if the image file is at the root of the `AdditionalStaticAssets` folder.
- The `{ALT TEXT}` placeholder is the image alternate text.

Run the app.

Additional resources

- App base path
- Avoid file capture in a route parameter

ASP.NET Core Razor components

Article • 10/18/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article explains how to create and use Razor components in Blazor apps, including guidance on Razor syntax, component naming, namespaces, and component parameters.

Razor components

Blazor apps are built using *Razor components*, informally known as *Blazor components* or only *components*. A component is a self-contained portion of user interface (UI) with processing logic to enable dynamic behavior. Components can be nested, reused, shared among projects, and used in MVC and Razor Pages apps.

Components render into an in-memory representation of the browser's Document Object Model (DOM) called a *render tree*, which is used to update the UI in a flexible and efficient way.

Although "Razor components" shares some naming with other ASP.NET Core content-rendering technologies, Razor components must be distinguished from the following different features in ASP.NET Core:

- Razor views, which are Razor-based markup pages for MVC apps.
- View components, which are for rendering chunks of content rather than whole responses in Razor Pages and MVC apps.

> **Important**
>
> When using a Blazor Web App, most of the Blazor documentation example components ***require*** interactivity to function and demonstrate the concepts covered by the articles. When you test an example component provided by an article, make sure that either the app adopts global interactivity or the component

adopts an interactive render mode. More information on this subject is provided by ASP.NET Core Blazor render modes, which is the next article in the table of contents after this article.

Component classes

Components are implemented using a combination of C# and HTML markup in Razor component files with the `.razor` file extension.

ComponentBase is the base class for components described by Razor component files. ComponentBase implements the lowest abstraction of components, the IComponent interface. ComponentBase defines component properties and methods for basic functionality, for example, to process a set of built-in component lifecycle events.

ComponentBase in dotnet/aspnetcore reference source : The reference source contains additional remarks on the built-in lifecycle events. However, keep in mind that the internal implementations of component features are subject to change at any time without notice.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205) .

Developers typically create Razor components from Razor component files (`.razor`) or base their components on ComponentBase, but components can also be built by implementing IComponent. Developer-built components that implement IComponent can take low-level control over rendering at the cost of having to manually trigger rendering with events and lifecycle methods that the developer must create and maintain.

Additional conventions adopted by Blazor documentation example code and sample apps is found in ASP.NET Core Blazor fundamentals.

Razor syntax

Components use Razor syntax. Two Razor features are extensively used by components, *directives* and *directive attributes*. These are reserved keywords prefixed with `@` that appear in Razor markup:

- Directives: Change the way component markup is compiled or functions. For example, the @page directive specifies a routable component with a route template that can be reached directly by a user's request in the browser at a specific URL.

  By convention, a component's directives at the top of a component definition (`.razor` file) are placed in a consistent order. For repeated directives, directives are placed alphabetically by namespace or type, except `@using` directives, which have special second-level ordering.

  The following order is adopted by Blazor sample apps and documentation. Components provided by a Blazor project template may differ from the following order and use a different format. For example, Blazor framework Identity components include blank lines between blocks of `@using` directives and blocks of `@inject` directives. You're free to use a custom ordering scheme and format in your own apps.

  Documentation and sample app Razor directive order:
  - `@page`
  - `@rendermode` (.NET 8 or later)
  - `@using`
    - `System` namespaces (alphabetical order)
    - `Microsoft` namespaces (alphabetical order)
    - Third-party API namespaces (alphabetical order)
    - App namespaces (alphabetical order)
  - Other directives (alphabetical order)

  No blank lines appear among the directives. One blank line appears between the directives and the first line of Razor markup.

  Example:

  razor

  ```
  @page "/doctor-who-episodes/{season:int}"
  @rendermode InteractiveWebAssembly
  @using System.Globalization
  @using System.Text.Json
  @using Microsoft.AspNetCore.Localization
  @using Mandrill
  ```

```
@using BlazorSample.Components.Layout
@attribute [Authorize]
@implements IAsyncDisposable
@inject IJSRuntime JS
@inject ILogger<DoctorWhoEpisodes> Logger

<PageTitle>Doctor Who Episode List</PageTitle>

...
```

- Directive attributes: Change the way a component element is compiled or functions.

  Example:

  ```
  razor

  <input @bind="episodeId" />
  ```

  You can prefix directive attribute values with the at symbol (`@`) for non-explicit Razor expressions (`@bind="@episodeId"`), but we don't recommend it, and the docs don't adopt the approach in examples.

Directives and directive attributes used in components are explained further in this article and other articles of the Blazor documentation set. For general information on Razor syntax, see Razor syntax reference for ASP.NET Core.

Component name, class name, and namespace

A component's name must start with an uppercase character:

✔ `ProductDetail.razor`

✘ `productDetail.razor`

Common Blazor naming conventions used throughout the Blazor documentation include:

- File paths and file names use Pascal case† and appear before showing code examples. If a path is present, it indicates the typical folder location. For example, `Components/Pages/ProductDetail.razor` indicates that the `ProductDetail` component has a file name of `ProductDetail.razor` and resides in the `Pages` folder of the `Components` folder of the app.
- Component file paths for routable components match their URLs in kebab case‡ with hyphens appearing between words in a component's route template. For

example, a `ProductDetail` component with a route template of `/product-detail` (`@page "/product-detail"`) is requested in a browser at the relative URL `/product-detail`.

†Pascal case (upper camel case) is a naming convention without spaces and punctuation and with the first letter of each word capitalized, including the first word.
‡Kebab case is a naming convention without spaces and punctuation that uses lowercase letters and dashes between words.

Components are ordinary C# classes and can be placed anywhere within a project. Components that produce webpages usually reside in the `Components/Pages` folder. Non-page components are frequently placed in the `Components` folder or a custom folder added to the project.

Typically, a component's namespace is derived from the app's root namespace and the component's location (folder) within the app. If the app's root namespace is `BlazorSample` and the `Counter` component resides in the `Components/Pages` folder:

- The `Counter` component's namespace is `BlazorSample.Components.Pages`.
- The fully qualified type name of the component is `BlazorSample.Components.Pages.Counter`.

For custom folders that hold components, add an @using directive to the parent component or to the app's `_Imports.razor` file. The following example makes components in the `AdminComponents` folder available:

razor

```
@using BlazorSample.AdminComponents
```

> **Note**
>
> @using directives in the `_Imports.razor` file are only applied to Razor files (`.razor`), not C# files (`.cs`).

Aliased using statements are supported. In the following example, the public `WeatherForecast` class of the `GridRendering` component is made available as `WeatherForecast` in a component elsewhere in the app:

razor

```
@using WeatherForecast = Components.Pages.GridRendering.WeatherForecast
```

Components can also be referenced using their fully qualified names, which doesn't require an @using directive. The following example directly references the `ProductDetail` component in the `AdminComponents/Pages` folder of the app:

razor

```
<BlazorSample.AdminComponents.Pages.ProductDetail />
```

The namespace of a component authored with Razor is based on the following (in priority order):

- The @namespace directive in the Razor file's markup (for example, `@namespace BlazorSample.CustomNamespace`).
- The project's `RootNamespace` in the project file (for example, `<RootNamespace>BlazorSample</RootNamespace>`).
- The project namespace and the path from the project root to the component. For example, the framework resolves `{PROJECT NAMESPACE}/Components/Pages/Home.razor` with a project namespace of `BlazorSample` to the namespace `BlazorSample.Components.Pages` for the `Home` component. `{PROJECT NAMESPACE}` is the project namespace. Components follow C# name binding rules. For the `Home` component in this example, the components in scope are all of the components:
  - In the same folder, `Components/Pages`.
  - The components in the project's root that don't explicitly specify a different namespace.

The following are **not** supported:

- The global:: qualification.
- Partially-qualified names. For example, you can't add `@using BlazorSample.Components` to a component and then reference the `NavMenu` component in the app's `Components/Layout` folder (`Components/Layout/NavMenu.razor`) with `<Layout.NavMenu></Layout.NavMenu>`.

Partial class support

Components are generated as C# partial classes and are authored using either of the following approaches:

- A single file contains C# code defined in one or more @code blocks, HTML markup, and Razor markup. Blazor project templates define their components using this single-file approach.
- HTML and Razor markup are placed in a Razor file (`.razor`). C# code is placed in a code-behind file defined as a partial class (`.cs`).

> **Note**
>
> A component stylesheet that defines component-specific styles is a separate file (`.css`). Blazor CSS isolation is described later in ASP.NET Core Blazor CSS isolation.

The following example shows the default `Counter` component with an @code block in an app generated from a Blazor project template. Markup and C# code are in the same file. This is the most common approach taken in component authoring.

`Counter.razor`:

```razor
@page "/counter"

<PageTitle>Counter</PageTitle>

<h1>Counter</h1>

<p role="status">Current count: @currentCount</p>

<button class="btn btn-primary" @onclick="IncrementCount">Click me</button>

@code {
    private int currentCount = 0;

    private void IncrementCount() => currentCount++;
}
```

The following `Counter` component splits presentation HTML and Razor markup from the C# code using a code-behind file with a partial class. Splitting the markup from the C# code is favored by some organizations and developers to organize their component code to suit how they prefer to work. For example, the organization's UI expert can work on the presentation layer independently of another developer working on the component's C# logic. The approach is also useful when working with automatically-generated code or source generators. For more information, see Partial Classes and Methods (C# Programming Guide).

`CounterPartialClass.razor`:

razor

```razor
@page "/counter-partial-class"

<PageTitle>Counter</PageTitle>

<h1>Counter</h1>

<p role="status">Current count: @currentCount</p>

<button class="btn btn-primary" @onclick="IncrementCount">Click me</button>
```

`CounterPartialClass.razor.cs`:

C#

```csharp
namespace BlazorSample.Components.Pages;

public partial class CounterPartialClass
{
    private int currentCount = 0;

    private void IncrementCount() => currentCount++;
}
```

@using directives in the `_Imports.razor` file are only applied to Razor files (`.razor`), not C# files (`.cs`). Add namespaces to a partial class file as needed.

Typical namespaces used by components:

C#

```csharp
using System.Net.Http;
using System.Net.Http.Json;
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Components.Authorization;
using Microsoft.AspNetCore.Components.Forms;
using Microsoft.AspNetCore.Components.Routing;
using Microsoft.AspNetCore.Components.Sections
using Microsoft.AspNetCore.Components.Web;
using static Microsoft.AspNetCore.Components.Web.RenderMode;
using Microsoft.AspNetCore.Components.Web.Virtualization;
using Microsoft.JSInterop;
```

Typical namespaces also include the namespace of the app and the namespace corresponding to the app's `Components` folder:

C#

```
using BlazorSample;
using BlazorSample.Components;
```

Additional folders can also be included, such as the `Layout` folder:

razor

```
using BlazorSample.Components.Layout;
```

Specify a base class

The @inherits directive is used to specify a base class for a component. Unlike using partial classes, which only split markup from C# logic, using a base class allows you to inherit C# code for use across a group of components that share the base class's properties and methods. Using base classes reduce code redundancy in apps and are useful when supplying base code from class libraries to multiple apps. For more information, see Inheritance in C# and .NET.

In the following example, the `BlazorRocksBase1` base class derives from ComponentBase.

`BlazorRocks1.razor`:

razor

```
@page "/blazor-rocks-1"
@inherits BlazorRocksBase1

<PageTitle>Blazor Rocks!</PageTitle>

<h1>Blazor Rocks! Example 1</h1>

<p>
    @BlazorRocksText
</p>
```

`BlazorRocksBase1.cs`:

C#

```
using Microsoft.AspNetCore.Components;

namespace BlazorSample;

public class BlazorRocksBase1 : ComponentBase
```

```
{
    public string BlazorRocksText { get; set; } = "Blazor rocks the
browser!";
}
```

Routing

Routing in Blazor is achieved by providing a route template to each accessible component in the app with an @page directive. When a Razor file with an @page directive is compiled, the generated class is given a RouteAttribute specifying the route template. At runtime, the router searches for component classes with a RouteAttribute and renders whichever component has a route template that matches the requested URL.

The following `HelloWorld` component uses a route template of `/hello-world`, and the rendered webpage for the component is reached at the relative URL `/hello-world`.

`HelloWorld.razor`:

razor

```
@page "/hello-world"

<PageTitle>Hello World!</PageTitle>

<h1>Hello World!</h1>
```

The preceding component loads in the browser at `/hello-world` regardless of whether or not you add the component to the app's UI navigation. Optionally, components can be added to the `NavMenu` component so that a link to the component appears in the app's UI-based navigation.

For the preceding `HelloWorld` component, you can add a `NavLink` component to the `NavMenu` component. For more information, including descriptions of the `NavLink` and `NavMenu` components, see ASP.NET Core Blazor routing and navigation.

Markup

A component's UI is defined using Razor syntax, which consists of Razor markup, C#, and HTML. When an app is compiled, the HTML markup and C# rendering logic are converted into a component class. The name of the generated class matches the name of the file.

Members of the component class are defined in one or more @code blocks. In @code blocks, component state is specified and processed with C#:

- Property and field initializers.
- Parameter values from arguments passed by parent components and route parameters.
- Methods for user event handling, lifecycle events, and custom component logic.

Component members are used in rendering logic using C# expressions that start with the `@` symbol. For example, a C# field is rendered by prefixing `@` to the field name. The following `Markup` component evaluates and renders:

- `headingFontStyle` for the CSS property value `font-style` of the heading element.
- `headingText` for the content of the heading element.

`Markup.razor`:

razor

```
@page "/markup"

<PageTitle>Markup</PageTitle>

<h1>Markup Example</h1>

<h2 style="font-style:@headingFontStyle">@headingText</h2>

@code {
    private string headingFontStyle = "italic";
    private string headingText = "Put on your new Blazor!";
}
```

> **Note**
>
> Examples throughout the Blazor documentation specify the private access modifier for private members. Private members are scoped to a component's class. However, C# assumes the `private` access modifier when no access modifier is present, so explicitly marking members "`private`" in your own code is optional. For more information on access modifiers, see Access Modifiers (C# Programming Guide).

The Blazor framework processes a component internally as a *render tree*, which is the combination of a component's DOM and Cascading Style Sheet Object Model (CSSOM). After the component is initially rendered, the component's render tree is regenerated in response to events. Blazor compares the new render tree against the

previous render tree and applies any modifications to the browser's DOM for display. For more information, see ASP.NET Core Razor component rendering.

Razor syntax for C# control structures, directives, and directive attributes are lowercase (examples: @if, @code, @bind). Property names are uppercase (example: `@Body` for LayoutComponentBase.Body).

Asynchronous methods (`async`) don't support returning `void`

The Blazor framework doesn't track `void`-returning asynchronous methods (`async`). As a result, exceptions aren't caught if `void` is returned. Always return a Task from asynchronous methods.

Nested components

Components can include other components by declaring them using HTML syntax. The markup for using a component looks like an HTML tag where the name of the tag is the component type.

Consider the following `Heading` component, which can be used by other components to display a heading.

`Heading.razor`:

razor

```razor
<h1 style="font-style:@headingFontStyle">Heading Example</h1>

@code {
    private string headingFontStyle = "italic";
}
```

The following markup in the `HeadingExample` component renders the preceding `Heading` component at the location where the `<Heading />` tag appears.

`HeadingExample.razor`:

razor

```razor
@page "/heading-example"

<PageTitle>Heading</PageTitle>
```

```
<h1>Heading Example</h1>

<Heading />
```

If a component contains an HTML element with an uppercase first letter that doesn't match a component name within the same namespace, a warning is emitted indicating that the element has an unexpected name. Adding an @using directive for the component's namespace makes the component available, which resolves the warning. For more information, see the Component name, class name, and namespace section.

The `Heading` component example shown in this section doesn't have an @page directive, so the `Heading` component isn't directly accessible to a user via a direct request in the browser. However, any component with an @page directive can be nested in another component. If the `Heading` component was directly accessible by including `@page "/heading"` at the top of its Razor file, then the component would be rendered for browser requests at both `/heading` and `/heading-example`.

Component parameters

Component parameters pass data to components and are defined using public C# properties on the component class with the [Parameter] attribute. In the following example, a built-in reference type (System.String) and a user-defined reference type (`PanelBody`) are passed as component parameters.

`PanelBody.cs`:

C#

```
namespace BlazorSample;

public class PanelBody
{
    public string? Text { get; set; }
    public string? Style { get; set; }
}
```

`ParameterChild.razor`:

razor

```
<div class="card w-25" style="margin-bottom:15px">
    <div class="card-header font-weight-bold">@Title</div>
    <div class="card-body" style="font-style:@Body.Style">
        @Body.Text
```

```
    </div>
</div>

@code {
    [Parameter]
    public string Title { get; set; } = "Set By Child";

    [Parameter]
    public PanelBody Body { get; set; } =
        new()
        {
            Text = "Card content set by child.",
            Style = "normal"
        };
}
```

> ⚠ **Warning**
>
> Providing initial values for component parameters is supported, but don't create a component that writes to its own parameters after the component is rendered for the first time. For more information, see Avoid overwriting parameters in ASP.NET Core Blazor.

The `Title` and `Body` component parameters of the `ParameterChild` component are set by arguments in the HTML tag that renders the instance of the component. The following `ParameterParent` component renders two `ParameterChild` components:

- The first `ParameterChild` component is rendered without supplying parameter arguments.
- The second `ParameterChild` component receives values for `Title` and `Body` from the `ParameterParent` component, which uses an explicit C# expression to set the values of the `PanelBody`'s properties.

`Parameter1.razor`:

razor

```
@page "/parameter-1"

<PageTitle>Parameter 1</PageTitle>

<h1>Parameter Example 1</h1>

<h1>Child component (without attribute values)</h1>

<ParameterChild />
```

```
<h1>Child component (with attribute values)</h1>

<ParameterChild Title="Set by Parent"
    Body="@(new PanelBody() { Text = "Set by parent.", Style = "italic" })"
/>
```

The following rendered HTML markup from the `ParameterParent` component shows `ParameterChild` component default values when the `ParameterParent` component doesn't supply component parameter values. When the `ParameterParent` component provides component parameter values, they replace the `ParameterChild` component's default values.

> **Note**
>
> For clarity, rendered CSS style classes aren't shown in the following rendered HTML markup.

HTML

```
<h1>Child component (without attribute values)</h1>

<div>
    <div>Set By Child</div>
    <div>Set by child.</div>
</div>

<h1>Child component (with attribute values)</h1>

<div>
    <div>Set by Parent</div>
    <div>Set by parent.</div>
</div>
```

Assign a C# field, property, or result of a method to a component parameter as an HTML attribute value. The value of the attribute can typically be any C# expression that matches the type of the parameter. The value of the attribute can optionally lead with a Razor reserved @ symbol, but it isn't required.

If the component parameter is of type string, then the attribute value is instead treated as a C# string literal. If you want to specify a C# expression instead, then use the `@` prefix.

The following `ParameterParent2` component displays four instances of the preceding `ParameterChild` component and sets their `Title` parameter values to:

- The value of the `title` field.
- The result of the `GetTitle` C# method.
- The current local date in long format with ToLongDateString, which uses an implicit C# expression.
- The `panelData` object's `Title` property.

Quotes around parameter attribute values are optional in most cases per the HTML5 specification. For example, `Value=this` is supported, instead of `Value="this"`. However, we recommend using quotes because it's easier to remember and widely adopted across web-based technologies.

Throughout the documentation, code examples:

- Always use quotes. Example: `Value="this"`.
- Don't use the `@` prefix with nonliterals unless required. Example: `Count="ct"`, where `ct` is a number-typed variable. `Count="@ct"` is a valid stylistic approach, but the documentation and examples don't adopt the convention.
- Always avoid `@` for literals, outside of Razor expressions. Example: `IsFixed="true"`. This includes keywords (for example, `this`) and `null`, but you can choose to use them if you wish. For example, `IsFixed="@true"` is uncommon but supported.

`Parameter2.razor`:

razor

```
@page "/parameter-2"

<PageTitle>Parameter 2</PageTitle>

<h1>Parameter Example 2</h1>

<ParameterChild Title="@title" />

<ParameterChild Title="@GetTitle()" />

<ParameterChild Title="@DateTime.Now.ToLongDateString()" />

<ParameterChild Title="@panelData.Title" />

@code {
    private string title = "From Parent field";
    private PanelData panelData = new();

    private string GetTitle() => "From Parent method";

    private class PanelData
    {
        public string Title { get; set; } = "From Parent object";
```

```
    }
}
```

> **Note**
>
> When assigning a C# member to a component parameter, don't prefix the parameter's HTML attribute with `@`.
>
> Correct (`Title` is a string parameter, `Count` is a number-typed parameter):
>
> ```razor
> <ParameterChild Title="@title" Count="ct" />
> ```
>
> ```razor
> <ParameterChild Title="@title" Count="@ct" />
> ```
>
> Incorrect:
>
> ```razor
> <ParameterChild @Title="@title" @Count="ct" />
> ```
>
> ```razor
> <ParameterChild @Title="@title" @Count="@ct" />
> ```

Unlike in Razor pages (`.cshtml`), Blazor can't perform asynchronous work in a Razor expression while rendering a component. This is because Blazor is designed for rendering interactive UIs. In an interactive UI, the screen must always display something, so it doesn't make sense to block the rendering flow. Instead, asynchronous work is performed during one of the asynchronous lifecycle events. After each asynchronous lifecycle event, the component may render again. The following Razor syntax is **not** supported:

```razor
<ParameterChild Title="await ..." />
<ParameterChild Title="@await ..." />
```

The code in the preceding example generates a *compiler error* when the app is built:

> The 'await' operator can only be used within an async method. Consider marking this method with the 'async' modifier and changing its return type to 'Task'.

To obtain a value for the `Title` parameter in the preceding example asynchronously, the component can use the OnInitializedAsync lifecycle event, as the following example demonstrates:

razor

```
<ParameterChild Title="@title" />

@code {
    private string? title;

    protected override async Task OnInitializedAsync()
    {
        title = await ...;
    }
}
```

For more information, see ASP.NET Core Razor component lifecycle.

Use of an explicit Razor expression to concatenate text with an expression result for assignment to a parameter is **not** supported. The following example seeks to concatenate the text "`Set by `" with an object's property value. Although this syntax is supported in a Razor page (`.cshtml`), it isn't valid for assignment to the child's `Title` parameter in a component. The following Razor syntax is **not** supported:

razor

```
<ParameterChild Title="Set by @(panelData.Title)" />
```

The code in the preceding example generates a *compiler error* when the app is built:

> Component attributes do not support complex content (mixed C# and markup).

To support the assignment of a composed value, use a method, field, or property. The following example performs the concatenation of "`Set by `" and an object's property value in the C# method `GetTitle`:

`Parameter3.razor`:

razor

```razor
@page "/parameter-3"

<PageTitle>Parameter 3</PageTitle>

<h1>Parameter Example 3</h1>

<ParameterChild Title="@GetTitle()" />

@code {
    private PanelData panelData = new();

    private string GetTitle() => $"Set by {panelData.Title}";

    private class PanelData
    {
        public string Title { get; set; } = "Parent";
    }
}
```

For more information, see Razor syntax reference for ASP.NET Core.

> ⚠ **Warning**
>
> Providing initial values for component parameters is supported, but don't create a component that writes to its own parameters after the component is rendered for the first time. For more information, see **Avoid overwriting parameters in ASP.NET Core Blazor**.

Component parameters should be declared as *auto-properties*, meaning that they shouldn't contain custom logic in their `get` or `set` accessors. For example, the following `StartData` property is an auto-property:

C#

```
[Parameter]
public DateTime StartData { get; set; }
```

Don't place custom logic in the `get` or `set` accessor because component parameters are purely intended for use as a channel for a parent component to flow information to a child component. If a `set` accessor of a child component property contains logic that causes rerendering of the parent component, an infinite rendering loop results.

To transform a received parameter value:

- Leave the parameter property as an auto-property to represent the supplied raw data.
- Create a different property or method to supply the transformed data based on the parameter property.

Override OnParametersSetAsync to transform a received parameter each time new data is received.

Writing an initial value to a component parameter is supported because initial value assignments don't interfere with the Blazor's automatic component rendering. The following assignment of the current local DateTime with DateTime.Now to `StartData` is valid syntax in a component:

C#

```
[Parameter]
public DateTime StartData { get; set; } = DateTime.Now;
```

After the initial assignment of DateTime.Now, do **not** assign a value to `StartData` in developer code. For more information, see Avoid overwriting parameters in ASP.NET Core Blazor.

Apply the [EditorRequired] attribute to specify a required component parameter. If a parameter value isn't provided, editors or build tools may display warnings to the user. This attribute is only valid on properties also marked with the [Parameter] attribute. The EditorRequiredAttribute is enforced at design-time and when the app is built. The attribute isn't enforced at runtime, and it doesn't guarantee a non-`null` parameter value.

C#

```
[Parameter]
[EditorRequired]
public string? Title { get; set; }
```

Single-line attribute lists are also supported:

C#

```
[Parameter, EditorRequired]
public string? Title { get; set; }
```

Don't use the required modifier or init accessor on component parameter properties. Components are usually instantiated and assigned parameter values using reflection,

which bypasses the guarantees that `init` and `required` are designed to make. Instead, use the [EditorRequired] attribute to specify a required component parameter.

Tuples (API documentation) are supported for component parameters and RenderFragment types. The following component parameter example passes three values in a `Tuple`:

`RenderTupleChild.razor`:

razor

```razor
<div class="card w-50" style="margin-bottom:15px">
    <div class="card-header font-weight-bold">Tuple Card</div>
    <div class="card-body">
        <ul>
            <li>Integer: @Data?.Item1</li>
            <li>String: @Data?.Item2</li>
            <li>Boolean: @Data?.Item3</li>
        </ul>
    </div>
</div>

@code {
    [Parameter]
    public (int, string, bool)? Data { get; set; }
}
```

`RenderTupleParent.razor`:

razor

```razor
@page "/render-tuple-parent"

<PageTitle>Render Tuple Parent</PageTitle>

<h1>Render Tuple Parent Example</h1>

<RenderTupleChild Data="data" />

@code {
    private (int, string, bool) data = new(999, "I aim to misbehave.",
true);
}
```

Named tuples are supported, as seen in the following example:

`NamedTupleChild.razor`:

razor

```
<div class="card w-50" style="margin-bottom:15px">
    <div class="card-header font-weight-bold">Tuple Card</div>
    <div class="card-body">
        <ul>
            <li>Integer: @Data?.TheInteger</li>
            <li>String: @Data?.TheString</li>
            <li>Boolean: @Data?.TheBoolean</li>
        </ul>
    </div>
</div>

@code {
    [Parameter]
    public (int TheInteger, string TheString, bool TheBoolean)? Data { get;
set; }
}
```

`NamedTuples.razor`:

razor

```
@page "/named-tuples"

<PageTitle>Named Tuples</PageTitle>

<h1>Named Tuples Example</h1>

<NamedTupleChild Data="data" />

@code {
    private (int TheInteger, string TheString, bool TheBoolean) data =
        new(999, "I aim to misbehave.", true);
}
```

Quote ©2005 Universal Pictures: Serenity (Nathan Fillion)

Route parameters

Components can specify route parameters in the route template of the @page directive. The Blazor router uses route parameters to populate corresponding component parameters.

`RouteParameter1.razor`:

razor

```
@page "/route-parameter-1/{text}"
```

```razor
<PageTitle>Route Parameter 1</PageTitle>

<h1>Route Parameter Example 1</h1>

<p>Blazor is @Text!</p>

@code {
    [Parameter]
    public string? Text { get; set; }
}
```

For more information, see the *Route parameters* section of ASP.NET Core Blazor routing and navigation. Optional route parameters are also supported and covered in the same section. For information on catch-all route parameters (`{*pageRoute}`), which capture paths across multiple folder boundaries, see the *Catch-all route parameters* section of ASP.NET Core Blazor routing and navigation.

> ⚠ **Warning**
>
> With compression, which is enabled by default, avoid creating secure (authenticated/authorized) interactive server-side components that render data from untrusted sources. Untrusted sources include route parameters, query strings, data from JS interop, and any other source of data that a third-party user can control (databases, external services). For more information, see **ASP.NET Core Blazor SignalR guidance** and **Threat mitigation guidance for ASP.NET Core Blazor interactive server-side rendering**.

Child content render fragments

Components can set the content of another component. The assigning component provides the content between the child component's opening and closing tags.

In the following example, the `RenderFragmentChild` component has a `ChildContent` component parameter that represents a segment of the UI to render as a RenderFragment. The position of `ChildContent` in the component's Razor markup is where the content is rendered in the final HTML output.

`RenderFragmentChild.razor`:

razor

```razor
<div class="card w-25" style="margin-bottom:15px">
    <div class="card-header font-weight-bold">Child content</div>
    <div class="card-body">@ChildContent</div>
```

```
</div>

@code {
    [Parameter]
    public RenderFragment? ChildContent { get; set; }
}
```

> **Important**
>
> The property receiving the RenderFragment content must be named `ChildContent` by convention.
>
> Event callbacks aren't supported for RenderFragment.

The following component provides content for rendering the `RenderFragmentChild` by placing the content inside the child component's opening and closing tags.

`RenderFragments.razor`:

razor

```
@page "/render-fragments"

<PageTitle>Render Fragments</PageTitle>

<h1>Render Fragments Example</h1>

<RenderFragmentChild>
    Content of the child component is supplied
    by the parent component.
</RenderFragmentChild>
```

Render fragments are used to render child content throughout Blazor apps and are described with examples in the following articles and article sections:

- Blazor layouts
- Pass data across a component hierarchy
- Templated components
- Global exception handling

> **Note**
>
> Blazor framework's built-in Razor components use the same `ChildContent` component parameter convention to set their content. You can see the components that set child content by searching for the component parameter

property name `ChildContent` in the API documentation (filters API with the search term "ChildContent").

Render fragments for reusable rendering logic

You can factor out child components purely as a way of reusing rendering logic. In any component's `@code` block, define a RenderFragment and render the fragment from any location as many times as needed:

razor

```
@RenderWelcomeInfo

<p>Render the welcome info a second time:</p>

@RenderWelcomeInfo

@code {
    private RenderFragment RenderWelcomeInfo =  @<p>Welcome to your new app!
</p>;
}
```

For more information, see Reuse rendering logic.

Loop variables with component parameters and child content

Rendering components inside a for loop requires a local index variable if the incrementing loop variable is used by the component's parameters or RenderFragment child content.

Consider the following `RenderFragmentChild2` component that has both a component parameter (`Id`) and a render fragment to display child content (`ChildContent`).

`RenderFragmentChild2.razor`:

razor

```
<div class="card w-25" style="margin-bottom:15px">
    <div class="card-header font-weight-bold">Child content (@Id)</div>
    <div class="card-body">@ChildContent</div>
</div>

@code {
```

```
    [Parameter]
    public string? Id { get; set; }

    [Parameter]
    public RenderFragment? ChildContent { get; set; }
}
```

When rendering the `RenderFragmentChild2` component in a parent component, use a local index variable (`ct` in the following example) instead of the loop variable (`c`) when assigning the component parameter value and providing the child component's content:

razor

```
@for (int c = 1; c < 4; c++)
{
    var ct = c;

    <RenderFragmentChild2 Id="@($"Child{ct}")">
        Count: @ct
    </RenderFragmentChild2>
}
```

Alternatively, use a foreach loop with Enumerable.Range instead of a for loop:

razor

```
@foreach (var c in Enumerable.Range(1, 3))
{
    <RenderFragmentChild2 Id="@($"Child{c}")">
        Count: @c
    </RenderFragmentChild2>
}
```

Capture references to components

Component references provide a way to reference a component instance for issuing commands. To capture a component reference:

- Add an @ref attribute to the child component.
- Define a field with the same type as the child component.

When the component is rendered, the field is populated with the component instance. You can then invoke .NET methods on the instance.

Consider the following `ReferenceChild` component that logs a message when its `ChildMethod` is called.

`ReferenceChild.razor`:

razor

```razor
@inject ILogger<ReferenceChild> Logger

@if (value > 0)
{
    <p>
        <code>value</code>: @value
    </p>
}

@code {
    private int value;

    public void ChildMethod(int value)
    {
        Logger.LogInformation("Received {Value} in ChildMethod", value);

        this.value = value;
        StateHasChanged();
    }
}
```

A component reference is only populated after the component is rendered and its output includes `ReferenceChild`'s element. Until the component is rendered, there's nothing to reference. Don't attempt to call a referenced component method to an event handler directly (for example, `@onclick="childComponent!.ChildMethod(5)"`) because the reference variable may not be assigned at the time the click event is assigned.

To manipulate component references after the component has finished rendering, use the OnAfterRender or OnAfterRenderAsync methods.

The following example uses the preceding `ReferenceChild` component.

`ReferenceParent.razor`:

razor

```razor
@page "/reference-parent"

<div>
    <button @onclick="@(() => childComponent1!.ChildMethod(5))">
        Call <code>ReferenceChild.ChildMethod</code> (first instance)
        with an argument of 5
```

```
    </button>

    <ReferenceChild @ref="childComponent1" />
</div>

<div>
    <button @onclick="CallChildMethod">
        Call <code>ReferenceChild.ChildMethod</code> (second instance)
        with an argument of 5
    </button>

    <ReferenceChild @ref="childComponent2" />
</div>

@code {
    private ReferenceChild? childComponent1;
    private ReferenceChild? childComponent2;

    private void CallChildMethod() => childComponent2!.ChildMethod(5);
}
```

While capturing component references use a similar syntax to capturing element references, capturing component references isn't a JavaScript interop feature. Component references aren't passed to JavaScript code. Component references are only used in .NET code.

> **Important**
>
> Do **not** use component references to mutate the state of child components. Instead, use normal declarative component parameters to pass data to child components. Use of component parameters result in child components that rerender at the correct times automatically. For more information, see the component parameters section and the ASP.NET Core Blazor data binding article.

Apply an attribute

Attributes can be applied to components with the @attribute directive. The following example applies the [Authorize] attribute to the component's class:

razor

```
@page "/"
@attribute [Authorize]
```

Conditional HTML element attributes and DOM properties

Blazor adopts the following general behaviors:

- For HTML attributes, Blazor sets or removes the attribute conditionally based on the .NET value. If the .NET value is `false` or `null`, the attribute isn't set or is removed if it was previously set.
- For DOM properties, such as `checked` or `value`, Blazor sets the DOM property based on the .NET value. If the .NET value is `false` or `null`, the DOM property is reset to a default value.

Which Razor syntax attributes correspond to HTML attributes and which ones correspond to DOM properties remains undocumented because this is a framework implementation detail that might change without notice.

> ⚠ **Warning**
>
> Some HTML attributes, such as aria-pressed, must have a string value of either "true" or "false". Since they require a string value and not a boolean, you must use a .NET `string` and not a `bool` for their value. This is a requirement set by browser DOM APIs.

Raw HTML

Strings are normally rendered using DOM text nodes, which means that any markup they may contain is ignored and treated as literal text. To render raw HTML, wrap the HTML content in a MarkupString value. The value is parsed as HTML or SVG and inserted into the DOM.

> ⚠ **Warning**
>
> Rendering raw HTML constructed from any untrusted source is a **security risk** and should **always** be avoided.

The following example shows using the MarkupString type to add a block of static HTML content to the rendered output of a component.

`MarkupStrings.razor`:

razor

```razor
@page "/markup-strings"

<PageTitle>Markup Strings</PageTitle>

<h1>Markup Strings Example</h1>

@((MarkupString)myMarkup)

@code {
    private string myMarkup =
        "<p class=\"text-danger\">This is a dangerous <em>markup
string</em>.</p>";
}
```

Razor templates

Render fragments can be defined using Razor template syntax to define a UI snippet. Razor templates use the following format:

razor

```razor
@<{HTML tag}>...</{HTML tag}>
```

The following example illustrates how to specify RenderFragment and RenderFragment<TValue> values and render templates directly in a component. Render fragments can also be passed as arguments to templated components.

`RazorTemplate.razor`:

razor

```razor
@page "/razor-template"

<PageTitle>Razor Template</PageTitle>

<h1>Razor Template Example</h1>

@timeTemplate

@petTemplate(new Pet { Name = "Nutty Rex" })

@code {
    private RenderFragment timeTemplate = @<p>The time is @DateTime.Now.
</p>;
    private RenderFragment<Pet> petTemplate = (pet) => @<p>Pet:
@pet.Name</p>;
```

```
    private class Pet
    {
        public string? Name { get; set; }
    }
}
```

Rendered output of the preceding code:

HTML

```
<p>The time is 4/19/2021 8:54:46 AM.</p>
<p>Pet: Nutty Rex</p>
```

Static assets

Blazor follows the convention of ASP.NET Core apps for static assets. Static assets are located in the project's web root (wwwroot) folder or folders under the `wwwroot` folder.

Use a base-relative path (`/`) to refer to the web root for a static asset. In the following example, `logo.png` is physically located in the `{PROJECT ROOT}/wwwroot/images` folder. `{PROJECT ROOT}` is the app's project root.

razor

```
<img alt="Company logo" src="/images/logo.png" />
```

Components do **not** support tilde-slash notation (`~/`).

For information on setting an app's base path, see Host and deploy ASP.NET Core Blazor.

Tag Helpers aren't supported in components

Tag Helpers aren't supported in components. To provide Tag Helper-like functionality in Blazor, create a component with the same functionality as the Tag Helper and use the component instead.

Scalable Vector Graphics (SVG) images

Since Blazor renders HTML, browser-supported images, including Scalable Vector Graphics (SVG) images (.svg), are supported via the `<img>` tag:

HTML

```
<img alt="Example image" src="image.svg" />
```

Similarly, SVG images are supported in the CSS rules of a stylesheet file (`.css`):

css

```
.element-class {
    background-image: url("image.svg");
}
```

Blazor supports the <foreignObject> element to display arbitrary HTML within an SVG. The markup can represent arbitrary HTML, a RenderFragment, or a Razor component.

The following example demonstrates:

- Display of a `string` (`@message`).
- Two-way binding with an `<input>` element and a `value` field.
- A `Robot` component.

razor

```
<svg width="200" height="200" xmlns="http://www.w3.org/2000/svg">
    <rect x="0" y="0" rx="10" ry="10" width="200" height="200"
stroke="black"
        fill="none" />
    <foreignObject x="20" y="20" width="160" height="160">
        <p>@message</p>
    </foreignObject>
</svg>

<svg xmlns="http://www.w3.org/2000/svg">
    <foreignObject width="200" height="200">
        <label>
            Two-way binding:
            <input @bind="value" @bind:event="oninput" />
        </label>
    </foreignObject>
</svg>

<svg xmlns="http://www.w3.org/2000/svg">
    <foreignObject>
        <Robot />
    </foreignObject>
</svg>

@code {
```

```
    private string message = "Lorem ipsum dolor sit amet, consectetur
adipiscing " +
        "elit, sed do eiusmod tempor incididunt ut labore et dolore magna
aliqua.";

    private string? value;
}
```

Whitespace rendering behavior

Unless the @preservewhitespace directive is used with a value of `true`, extra whitespace is removed if:

- Leading or trailing within an element.
- Leading or trailing within a RenderFragment/RenderFragment<TValue> parameter (for example, child content passed to another component).
- It precedes or follows a C# code block, such as `@if` or `@foreach`.

Whitespace removal might affect the rendered output when using a CSS rule, such as `white-space: pre`. To disable this performance optimization and preserve the whitespace, take one of the following actions:

- Add the `@preservewhitespace true` directive at the top of the Razor file (`.razor`) to apply the preference to a specific component.
- Add the `@preservewhitespace true` directive inside an `_Imports.razor` file to apply the preference to a subdirectory or to the entire project.

In most cases, no action is required, as apps typically continue to behave normally (but faster). If stripping whitespace causes a rendering problem for a particular component, use `@preservewhitespace true` in that component to disable this optimization.

Root component

A *root Razor component* (*root component*) is the first component loaded of any component hierarchy created by the app.

In an app created from the Blazor Web App project template, the `App` component (`App.razor`) is specified as the default root component by the type parameter declared for the call to MapRazorComponents<TRootComponent> in the server-side `Program` file. The following example shows the use of the `App` component as the root component, which is the default for an app created from the Blazor project template:

```
```

C#

```
app.MapRazorComponents<App>();
```

> **Note**
>
> Making a root component interactive, such as the `App` component, isn't supported.

In an app created from the Blazor WebAssembly project template, the `App` component (`App.razor`) is specified as the default root component in the `Program` file:

C#

```
builder.RootComponents.Add<App>("#app");
```

In the preceding code, the CSS selector, `#app`, indicates that the `App` component is specified for the `<div>` in `wwwroot/index.html` with an `id` of `app`:

HTML

```
<div id="app">...</app>
```

MVC and Razor Pages apps can also use the Component Tag Helper to register statically-rendered Blazor WebAssembly root components:

CSHTML

```
<component type="typeof(App)" render-mode="WebAssemblyPrerendered" />
```

Statically-rendered components can only be added to the app. They can't be removed or updated afterwards.

- Component Tag Helper in ASP.NET Core
- Integrate ASP.NET Core Razor components into ASP.NET Core apps

ASP.NET Core Blazor render modes

Article • 11/06/2024

This article explains control of Razor component rendering in Blazor Web Apps, either at compile time or runtime.

This guidance doesn't apply to standalone Blazor WebAssembly apps. Blazor WebAssembly apps only render on the client via a client-side WebAssembly-based runtime and have no concept of a *render mode*. If a render mode is applied to a component in a Blazor WebAssembly app, the render mode designation has no influence on rendering the component.

Render modes

Every component in a Blazor Web App adopts a *render mode* to determine the hosting model that it uses, where it's rendered, and whether or not it's interactive.

The following table shows the available render modes for rendering Razor components in a Blazor Web App. To apply a render mode to a component use the `@rendermode` directive on the component instance or on the component definition. Later in this article, examples are shown for each render mode scenario.

Expand table

Name	Description	Render location	Interactive
Static Server	Static server-side rendering (static SSR)	Server	✗
Interactive Server	Interactive server-side rendering (interactive SSR) using Blazor Server.	Server	✓
Interactive WebAssembly	Client-side rendering (CSR) using Blazor WebAssembly†.	Client	✓
Interactive Auto	Interactive SSR using Blazor Server initially and then CSR on subsequent visits after the Blazor bundle is downloaded.	Server, then client	✓

†Client-side rendering (CSR) is assumed to be interactive. "*Interactive* client-side rendering" and "*interactive* CSR" aren't used by the industry or in the Blazor documentation.

Prerendering is enabled by default for interactive components. Guidance on controlling prerendering is provided later in this article. For general industry terminology on client and server rendering concepts, see ASP.NET Core Blazor fundamentals.

The following examples demonstrate setting the component's render mode with a few basic Razor component features.

To test the render mode behaviors locally, you can place the following components in an app created from the *Blazor Web App* project template. When you create the app, select options from dropdown menus (Visual Studio) or apply the CLI options (.NET CLI) to enable both server-side and client-side interactivity. For guidance on how to create a Blazor Web App, see Tooling for ASP.NET Core Blazor.

Enable support for interactive render modes

A Blazor Web App must be configured to support interactive render modes. The following extensions are automatically applied to apps created from the *Blazor Web App* project template during app creation. Individual components are still required to declare their render mode per the *Render modes* section after the component services and endpoints are configured in the app's `Program` file.

Services for Razor components are added by calling AddRazorComponents.

Component builder extensions:

- AddInteractiveServerComponents adds services to support rendering Interactive Server components.
- AddInteractiveWebAssemblyComponents adds services to support rendering Interactive WebAssembly components.

MapRazorComponents discovers available components and specifies the root component for the app (the first component loaded), which by default is the `App` component (`App.razor`).

Endpoint convention builder extensions:

- AddInteractiveServerRenderMode configures interactive server-side rendering (interactive SSR) for the app.
- AddInteractiveWebAssemblyRenderMode configures the Interactive WebAssembly render mode for the app.

> ⓘ **Note**

For orientation on the placement of the API in the following examples, inspect the `Program` file of an app generated from the Blazor Web App project template. For guidance on how to create a Blazor Web App, see Tooling for ASP.NET Core Blazor.

Example 1: The following `Program` file API adds services and configuration for enabling interactive SSR:

C#

```
builder.Services.AddRazorComponents()
    .AddInteractiveServerComponents();
```

C#

```
app.MapRazorComponents<App>()
    .AddInteractiveServerRenderMode();
```

Example 2: The following `Program` file API adds services and configuration for enabling the Interactive WebAssembly render mode:

C#

```
builder.Services.AddRazorComponents()
    .AddInteractiveWebAssemblyComponents();
```

C#

```
app.MapRazorComponents<App>()
    .AddInteractiveWebAssemblyRenderMode();
```

Example 3: The following `Program` file API adds services and configuration for enabling the Interactive Server, Interactive WebAssembly, and Interactive Auto render modes:

C#

```
builder.Services.AddRazorComponents()
    .AddInteractiveServerComponents()
    .AddInteractiveWebAssemblyComponents();
```

C#

```
app.MapRazorComponents<App>()
    .AddInteractiveServerRenderMode()
```

```
    .AddInteractiveWebAssemblyRenderMode();
```

Blazor uses the Blazor WebAssembly hosting model to download and execute components that use the Interactive WebAssembly render mode. A separate client project is required to set up Blazor WebAssembly hosting for these components. The client project contains the startup code for the Blazor WebAssembly host and sets up the .NET runtime for running in a browser. The Blazor Web App template adds this client project for you when you select the option to enable WebAssembly interactivity. Any components using the Interactive WebAssembly render mode should be built from the client project, so they get included in the downloaded app bundle.

Apply a render mode to a component instance

To apply a render mode to a component instance use the @rendermode Razor directive attribute where the component is used.

In the following example, interactive server-side rendering (interactive SSR) is applied to the `Dialog` component instance:

```razor
<Dialog @rendermode="InteractiveServer" />
```

> **Note**
>
> Blazor templates include a static `using` directive for RenderMode in the app's `_Imports` file (`Components/_Imports.razor`) for shorter `@rendermode` syntax:
>
> ```razor
> @using static Microsoft.AspNetCore.Components.Web.RenderMode
> ```
>
> Without the preceding directive, components must specify the static RenderMode class in `@rendermode` syntax:
>
> ```razor
> <Dialog @rendermode="RenderMode.InteractiveServer" />
> ```

You can also reference custom render mode instances instantiated directly with custom configuration. For more information, see the Custom shorthand render modes section later in this article.

Apply a render mode to a component definition

To specify the render mode for a component as part of its definition, use the @rendermode Razor directive and the corresponding render mode attribute.

razor

```
@page "..."
@rendermode InteractiveServer
```

Applying a render mode to a component definition is commonly used when applying a render mode to a specific page. Routable pages use the same render mode as the Router component that rendered the page.

Technically, `@rendermode` is both a Razor *directive* and a Razor *directive attribute*. The semantics are similar, but there are differences. The `@rendermode` directive is on the component definition, so the referenced render mode instance must be static. The `@rendermode` directive attribute can take any render mode instance.

> **Note**
>
> Component authors should avoid coupling a component's implementation to a specific render mode. Instead, component authors should typically design components to support any render mode or hosting model. A component's implementation should avoid assumptions on where it's running (server or client) and should degrade gracefully when rendered statically. Specifying the render mode in the component definition may be needed if the component isn't instantiated directly (such as with a routable page component) or to specify a render mode for all component instances.

Apply a render mode to the entire app

To set the render mode for the entire app, indicate the render mode at the highest-level interactive component in the app's component hierarchy that isn't a root component.

> **Note**
>
> Making a root component interactive, such as the `App` component, isn't supported. Therefore, the render mode for the entire app can't be set directly by the `App` component.

For apps based on the Blazor Web App project template, a render mode assigned to the entire app is typically specified where the `Routes` component is used in the `App` component (`Components/App.razor`):

```razor
<Routes @rendermode="InteractiveServer" />
```

The Router component propagates its render mode to the pages it routes.

You also typically must set the same interactive render mode on the HeadOutlet component, which is also found in the `App` component of a Blazor Web App generated from the project template:

```
<HeadOutlet @rendermode="InteractiveServer" />
```

For apps that adopt an interactive client-side (WebAssembly or Auto) rendering mode and enable the render mode for the entire app via the `Routes` component:

- Place or move the layout and navigation files of the server app's `Components/Layout` folder into the `.Client` project's `Layout` folder. Create a `Layout` folder in the `.Client` project if it doesn't exist.
- Place or move the components of the server app's `Components/Pages` folder into the `.Client` project's `Pages` folder. Create a `Pages` folder in the `.Client` project if it doesn't exist.
- Place or move the `Routes` component of the server app's `Components` folder into the `.Client` project's root folder.

To enable global interactivity when creating a Blazor Web App:

- Visual Studio: Set the **Interactivity location** dropdown list to **Global**.
- .NET CLI: Use the `-ai|--all-interactive` option.

For more information, see Tooling for ASP.NET Core Blazor.

Apply a render mode programatically

Properties and fields can assign a render mode.

The second approach described in this section, setting the render mode by component instance, is especially useful when your app specification calls for one or more components to adopt static SSR in a globally-interactive app. This scenario is covered in the Static SSR pages in a globally-interactive app section later in this article.

Set the render mode by component definition

A component definition can define a render mode via a private field:

razor

```
@rendermode pageRenderMode

...

@code {
    private static IComponentRenderMode pageRenderMode = InteractiveServer;
}
```

Set the render mode by component instance

The following example applies interactive server-side rendering (interactive SSR) to any request.

razor

```
<Routes @rendermode="PageRenderMode" />

...

@code {
    private IComponentRenderMode? PageRenderMode => InteractiveServer;
}
```

Additional information on render mode propagation is provided in the Render mode propagation section later in this article. The Static SSR pages in a globally-interactive app section shows how to use the preceding approach to adopt static SSR in a globally-interactive app.

Detect rendering location, interactivity, and assigned render mode at runtime

The `ComponentBase.RendererInfo` and `ComponentBase.AssignedRenderMode` properties permit the app to detect details about the location, interactivity, and assigned render mode of a component:

- `RendererInfo.Name` returns the location where the component is executing:
  - `Static`: On the server (SSR) and incapable of interactivity.
  - `Server`: On the server (SSR) and capable of interactivity after prerendering.
  - `WebAssembly`: On the client (CSR) and capable of interactivity after prerendering.
  - `WebView`: On the native device and capable of interactivity after prerendering.
- `RendererInfo.IsInteractive` indicates if the component supports interactivity at the time of rendering. The value is `true` when rendering interactively or `false` when prerendering or for static SSR (`Platform.Name` of `Static`).
- `ComponentBase.AssignedRenderMode` exposes the component's assigned render mode:
  - `InteractiveServer` for Interactive Server.
  - `InteractiveAuto` for Interactive Auto.
  - `InteractiveWebAssembly` for Interactive WebAssembly.

Components use these properties to render content depending on their location or interactivity status. For example, a form can be disabled during prerendering and enabled when the component becomes interactive:

razor

```razor
<EditForm Model="Movie" ...>
    <fieldset disabled="@disabled">

        ...

        <button type="submit" >Save</button>
    </fieldset>
</EditForm>

@code {
    private bool disabled = true;

    [SupplyParameterFromForm]
    private Movie? Movie { get; set; }

    protected override async Task OnInitializedAsync()
    {
        Movie ??= await ...;
```

```
        if (RendererInfo.IsInteractive)
        {
            disabled = false;
        }
    }
}
```

The next example shows how to render markup to support performing a regular HTML action if the component is statically rendered:

razor

```razor
@if (AssignedRenderMode is null)
{
    // The render mode is Static Server
    <form action="/movies">
        <input type="text" name="titleFilter" />
        <input type="submit" value="Search" />
    </form>
}
else
{
    // The render mode is Interactive Server, WebAssembly, or Auto
    <input @bind="titleFilter" />
    <button @onclick="FilterMovies">Search</button>
}
```

In the preceding example:

- When the value of `AssignedRenderMode` is `null`, the component adopts static SSR. Blazor event handling isn't functional in a browser with static SSR, so the component submits a form (GET request) with a `titleFilter` query string set to the user's `<input>` value. The `Movie` component (`/movie`) can read the query string and process the value of `titleFilter` to render the component with the filtered results.
- Otherwise, the render mode is any of `InteractiveServer`, `InteractiveWebAssembly`, or `InteractiveAuto`. The component is capable of using an event handler delegate (`FilterMovies`) and the value bound to the `<input>` element (`titleFilter`) to filter movies interactively over the background SignalR connection.

Blazor documentation examples for Blazor Web Apps

When using a Blazor Web App, most of the Blazor documentation example components ***require*** interactivity to function and demonstrate the concepts covered by the articles. When you test an example component provided by an article, make sure that either the app adopts global interactivity or the component adopts an interactive render mode.

Prerendering

Prerendering is the process of initially rendering page content on the server without enabling event handlers for rendered controls. The server outputs the HTML UI of the page as soon as possible in response to the initial request, which makes the app feel more responsive to users. Prerendering can also improve Search Engine Optimization (SEO) by rendering content for the initial HTTP response that search engines use to calculate page rank.

Prerendering is enabled by default for interactive components.

Internal navigation for interactive routing doesn't involve requesting new page content from the server. Therefore, prerendering doesn't occur for internal page requests, including for enhanced navigation. For more information, see Static versus interactive routing, Interactive routing and prerendering, and Enhanced navigation and form handling.

Disabling prerendering using the following techniques only takes effect for top-level render modes. If a parent component specifies a render mode, the prerendering settings of its children are ignored. This behavior is under investigation for possible changes with the release of .NET 10 in November, 2025.

To disable prerendering for a *component instance*, pass the `prerender` flag with a value of `false` to the render mode:

- `<... @rendermode="new InteractiveServerRenderMode(prerender: false)" />`
- `<... @rendermode="new InteractiveWebAssemblyRenderMode(prerender: false)" />`
- `<... @rendermode="new InteractiveAutoRenderMode(prerender: false)" />`

To disable prerendering in a *component definition*:

- `@rendermode @(new InteractiveServerRenderMode(prerender: false))`
- `@rendermode @(new InteractiveWebAssemblyRenderMode(prerender: false))`
- `@rendermode @(new InteractiveAutoRenderMode(prerender: false))`

To disable prerendering for the entire app, indicate the render mode at the highest-level interactive component in the app's component hierarchy that isn't a root component.

For apps based on the Blazor Web App project template, a render mode assigned to the entire app is specified where the `Routes` component is used in the `App` component (`Components/App.razor`). The following example sets the app's render mode to Interactive Server with prerendering disabled:

```razor
<Routes @rendermode="new InteractiveServerRenderMode(prerender: false)" />
```

Also, disable prerendering for the HeadOutlet component in the `App` component:

```razor
<HeadOutlet @rendermode="new InteractiveServerRenderMode(prerender: false)"
/>
```

Making a root component, such as the `App` component, interactive with the `@rendermode` directive at the top of the root component's definition file (`.razor`) isn't supported. Therefore, prerendering can't be disabled directly by the `App` component.

Static server-side rendering (static SSR)

Components use static server-side rendering (static SSR). The component renders to the response stream and interactivity isn't enabled.

In the following example, there's no designation for the component's render mode, so the component inherits its render mode from its parent. Since no ancestor component specifies a render mode, the following component is *statically rendered* on the server. The button isn't interactive and doesn't call the `UpdateMessage` method when selected. The value of `message` doesn't change, and the component isn't rerendered in response to UI events.

`RenderMode1.razor`:

```razor
@page "/render-mode-1"

<button @onclick="UpdateMessage">Click me</button> @message

@code {
    private string message = "Not updated yet.";

    private void UpdateMessage()
```

```
    {
        message = "Somebody updated me!";
    }
}
```

If using the preceding component locally in a Blazor Web App, place the component in the server project's `Components/Pages` folder. The server project is the solution's project with a name that doesn't end in `.Client`. When the app is running, navigate to `/render-mode-1` in the browser's address bar.

During static SSR, Razor component page requests are processed by server-side ASP.NET Core middleware pipeline request processing for routing and authorization. Dedicated Blazor features for routing and authorization aren't operational because Razor components aren't rendered during server-side request processing. Blazor router features in the `Routes` component that aren't available during static SSR include displaying:

- Not authorized content (<NotAuthorized>...</NotAuthorized>) (NotAuthorized): Blazor Web Apps typically process unauthorized requests on the server by customizing the behavior of Authorization Middleware.
- Not found content (<NotFound>...</NotFound>) (NotFound): Blazor Web Apps typically process bad URL requests on the server by either displaying the browser's built-in 404 UI or returning a custom 404 page (or other response) via ASP.NET Core middleware (for example, UseStatusCodePagesWithRedirects / API documentation).

If the app exhibits root-level interactivity, server-side ASP.NET Core request processing isn't involved after the initial static SSR, which means that the preceding Blazor features work as expected.

Enhanced navigation with static SSR requires special attention when loading JavaScript. For more information, see ASP.NET Core Blazor JavaScript with static server-side rendering (static SSR).

Interactive server-side rendering (interactive SSR)

Interactive server-side rendering (interactive SSR) renders the component interactively from the server using Blazor Server. User interactions are handled over a real-time connection with the browser. The circuit connection is established when the Server component is rendered.

In the following example, the render mode is set interactive SSR by adding `@rendermode InteractiveServer` to the component definition. The button calls the `UpdateMessage` method when selected. The value of `message` changes, and the component is rerendered to update the message in the UI.

`RenderMode2.razor`:

razor

```razor
@page "/render-mode-2"
@rendermode InteractiveServer

<button @onclick="UpdateMessage">Click me</button> @message

@code {
    private string message = "Not updated yet.";

    private void UpdateMessage()
    {
        message = "Somebody updated me!";
    }
}
```

If using the preceding component in a Blazor Web App, place the component in the server project's `Components/Pages` folder. The server project is the solution's project with a name that doesn't end in `.Client`. When the app is running, navigate to `/render-mode-2` in the browser's address bar.

Client-side rendering (CSR)

Client-side rendering (CSR) renders the component interactively on the client using Blazor WebAssembly. The .NET runtime and app bundle are downloaded and cached when the WebAssembly component is initially rendered. Components using CSR must be built from a separate client project that sets up the Blazor WebAssembly host.

In the following example, the render mode is set to CSR with `@rendermode InteractiveWebAssembly`. The button calls the `UpdateMessage` method when selected. The value of `message` changes, and the component is rerendered to update the message in the UI.

`RenderMode3.razor`:

razor

```
@page "/render-mode-3"
@rendermode InteractiveWebAssembly

<button @onclick="UpdateMessage">Click me</button> @message

@code {
    private string message = "Not updated yet.";

    private void UpdateMessage()
    {
        message = "Somebody updated me!";
    }
}
```

If using the preceding component locally in a Blazor Web App, place the component in the client project's `Pages` folder. The client project is the solution's project with a name that ends in `.Client`. When the app is running, navigate to `/render-mode-3` in the browser's address bar.

Automatic (Auto) rendering

Automatic (Auto) rendering determines how to render the component at runtime. The component is initially rendered with interactive server-side rendering (interactive SSR) using the Blazor Server hosting model. The .NET runtime and app bundle are downloaded to the client in the background and cached so that they can be used on future visits.

The Auto render mode never dynamically changes the render mode of a component already on the page. The Auto render mode makes an initial decision about which type of interactivity to use for a component, then the component keeps that type of interactivity for as long as it's on the page. One factor in this initial decision is considering whether components already exist on the page with WebAssembly/Server interactivity. Auto mode prefers to select a render mode that matches the render mode of existing interactive components. The reason that the Auto mode prefers to use an existing interactivity mode is to avoid introducing a new interactive runtime that doesn't share state with the existing runtime.

Components using the Auto render mode must be built from a separate client project that sets up the Blazor WebAssembly host.

In the following example, the component is interactive throughout the process. The button calls the `UpdateMessage` method when selected. The value of `message` changes, and the component is rerendered to update the message in the UI. Initially, the

component is rendered interactively from the server, but on subsequent visits it's rendered from the client after the .NET runtime and app bundle are downloaded and cached.

`RenderMode4.razor`:

razor

```razor
@page "/render-mode-4"
@rendermode InteractiveAuto

<button @onclick="UpdateMessage">Click me</button> @message

@code {
    private string message = "Not updated yet.";

    private void UpdateMessage()
    {
        message = "Somebody updated me!";
    }
}
```

If using the preceding component locally in a Blazor Web App, place the component in the client project's `Pages` folder. The client project is the solution's project with a name that ends in `.Client`. When the app is running, navigate to `/render-mode-4` in the browser's address bar.

Render mode propagation

Render modes propagate down the component hierarchy.

Rules for applying render modes:

- The default render mode is Static.
- The Interactive Server (InteractiveServer), Interactive WebAssembly (InteractiveWebAssembly), and Interactive Auto (InteractiveAuto) render modes can be used from a component, including using different render modes for sibling components.
- You can't switch to a different interactive render mode in a child component. For example, a Server component can't be a child of a WebAssembly component.
- Parameters passed to an interactive child component from a Static parent must be JSON serializable. This means that you can't pass render fragments or child content from a Static parent component to an interactive child component.

The following examples use a non-routable, non-page `SharedMessage` component. The render mode agnostic `SharedMessage` component doesn't apply a render mode with an @attribute directive. If you're testing these scenarios with a Blazor Web App, place the following component in the app's `Components` folder.

`SharedMessage.razor`:

razor

```razor
<p>@Greeting</p>

<button @onclick="UpdateMessage">Click me</button> @message

<p>@ChildContent</p>

@code {
    private string message = "Not updated yet.";

    [Parameter]
    public RenderFragment? ChildContent { get; set; }

    [Parameter]
    public string Greeting { get; set; } = "Hello!";

    private void UpdateMessage()
    {
        message = "Somebody updated me!";
    }
}
```

Render mode inheritance

If the `SharedMessage` component is placed in a statically-rendered parent component, the `SharedMessage` component is also rendered statically and isn't interactive. The button doesn't call `UpdateMessage`, and the message isn't updated.

`RenderMode5.razor`:

razor

```razor
@page "/render-mode-5"

<SharedMessage />
```

If the `SharedMessage` component is placed in a component that defines the render mode, it inherits the applied render mode.

In the following example, the `SharedMessage` component is interactive over a SignalR connection to the client. The button calls `UpdateMessage`, and the message is updated.

`RenderMode6.razor`:

```razor
@page "/render-mode-6"
@rendermode InteractiveServer

<SharedMessage />
```

Child components with different render modes

In the following example, both `SharedMessage` components are prerendered and appear when the page is displayed in the browser.

- The first `SharedMessage` component with interactive server-side rendering (interactive SSR) is interactive after the SignalR circuit is established.
- The second `SharedMessage` component with client-side rendering (CSR) is interactive *after* the Blazor app bundle is downloaded and the .NET runtime is active on the client.

`RenderMode7.razor`:

```razor
@page "/render-mode-7"

<SharedMessage @rendermode="InteractiveServer" />
<SharedMessage @rendermode="InteractiveWebAssembly" />
```

Child component with a serializable parameter

The following example demonstrates an interactive child component that takes a parameter. Parameters must be serializable.

`RenderMode8.razor`:

```razor
@page "/render-mode-8"
```

```razor
<SharedMessage @rendermode="InteractiveServer" Greeting="Welcome!" />
```

Non-serializable component parameters, such as child content or a render fragment, aren't supported. In the following example, passing child content to the `SharedMessage` component results in a runtime error.

`RenderMode9.razor`:

```razor
@page "/render-mode-9"

<SharedMessage @rendermode="InteractiveServer">
    Child content
</SharedMessage>
```

❌ **Error**:

> System.InvalidOperationException: Cannot pass the parameter 'ChildContent' to component 'SharedMessage' with rendermode 'InteractiveServerRenderMode'. This is because the parameter is of the delegate type 'Microsoft.AspNetCore.Components.RenderFragment', which is arbitrary code and cannot be serialized.

To circumvent the preceding limitation, wrap the child component in another component that doesn't have the parameter. This is the approach taken in the Blazor Web App project template with the `Routes` component (`Components/Routes.razor`) to wrap the Router component.

`WrapperComponent.razor`:

```razor
<SharedMessage>
    Child content
</SharedMessage>
```

`RenderMode10.razor`:

```razor
@page "/render-mode-10"

<WrapperComponent @rendermode="InteractiveServer" />
```

In the preceding example:

- The child content is passed to the `SharedMessage` component without generating a runtime error.
- The `SharedMessage` component renders interactively on the server.

Child component with a different render mode than its parent

Don't try to apply a different interactive render mode to a child component than its parent's render mode.

The following component results in a runtime error when the component is rendered:

`RenderMode11.razor`:

razor

```razor
@page "/render-mode-11"
@rendermode InteractiveServer

<SharedMessage @rendermode="InteractiveWebAssembly" />
```

❌ **Error**:

> Cannot create a component of type 'BlazorSample.Components.SharedMessage' because its render mode 'Microsoft.AspNetCore.Components.Web.InteractiveWebAssemblyRenderMode' is not supported by Interactive Server rendering.

Static SSR pages in a globally-interactive app

There are cases where the app's specification calls for components to adopt static server-side rendering (static SSR) and only run on the server, while the rest of the app uses an interactive render mode.

This approach is only useful when the app has specific pages that can't work with interactive Server or WebAssembly rendering. For example, adopt this approach for pages that depend on reading/writing HTTP cookies and can only work in a request/response cycle instead of interactive rendering. For pages that work with interactive rendering, you shouldn't force them to use static SSR rendering, as it's less efficient and less responsive for the end user.

Mark any Razor component page with the `[ExcludeFromInteractiveRouting]` attribute assigned with the `@attribute` Razor directive:

razor

```razor
@attribute [ExcludeFromInteractiveRouting]
```

Applying the attribute causes navigation to the page to exit from interactive routing. Inbound navigation is forced to perform a full-page reload instead resolving the page via interactive routing. The full-page reload forces the top-level root component, typically the `App` component (`App.razor`), to rerender from the server, allowing the app to switch to a different top-level render mode.

The `HttpContext.AcceptsInteractiveRouting` extension method allows the component to detect whether `[ExcludeFromInteractiveRouting]` is applied to the current page.

In the `App` component, use the pattern in the following example:

- Pages that aren't annotated with `[ExcludeFromInteractiveRouting]` default to the `InteractiveServer` render mode with global interactivity. You can replace `InteractiveServer` with `InteractiveWebAssembly` or `InteractiveAuto` to specify a different default global render mode.
- Pages annotated with `[ExcludeFromInteractiveRouting]` adopt static SSR (`PageRenderMode` is assigned `null`).

razor

```razor
<!DOCTYPE html>
<html>
<head>
    ...
    <HeadOutlet @rendermode="@PageRenderMode" />
</head>
<body>
    <Routes @rendermode="@PageRenderMode" />
    ...
</body>
</html>

@code {
    [CascadingParameter]
    private HttpContext HttpContext { get; set; } = default!;

    private IComponentRenderMode? PageRenderMode
        => HttpContext.AcceptsInteractiveRouting() ? InteractiveServer :
```

```
null;
}
```

An alternative to using the `HttpContext.AcceptsInteractiveRouting` extension method is to read endpoint metadata manually using `HttpContext.GetEndpoint()?.Metadata`.

Client-side services fail to resolve during prerendering

Assuming that prerendering isn't disabled for a component or for the app, a component in the `.Client` project is prerendered on the server. Because the server doesn't have access to registered client-side Blazor services, it isn't possible to inject these services into a component without receiving an error that the service can't be found during prerendering.

For example, consider the following `Home` component in the `.Client` project in a Blazor Web App with global Interactive WebAssembly or Interactive Auto rendering. The component attempts to inject IWebAssemblyHostEnvironment to obtain the environment's name.

razor

```
@page "/"
@inject IWebAssemblyHostEnvironment Environment

<PageTitle>Home</PageTitle>

<h1>Home</h1>

<p>
    Environment: @Environment.Environment
</p>
```

No compile time error occurs, but a runtime error occurs during prerendering:

> Cannot provide a value for property 'Environment' on type 'BlazorSample.Client.Pages.Home'. There is no registered service of type 'Microsoft.AspNetCore.Components.WebAssembly.Hosting.IWebAssemblyHostEnvironment'.

This error occurs because the component must compile and execute on the server during prerendering, but IWebAssemblyHostEnvironment isn't a registered service on the server.

If the app doesn't require the value during prerendering, this problem can be solved by injecting IServiceProvider to obtain the service instead of the service type itself:

razor

```
@page "/"
@using Microsoft.AspNetCore.Components.WebAssembly.Hosting
@inject IServiceProvider Services

<PageTitle>Home</PageTitle>

<h1>Home</h1>

<p>
    <b>Environment:</b> @environmentName
</p>

@code {
    private string? environmentName;

    protected override void OnInitialized()
    {
        if (Services.GetService<IWebAssemblyHostEnvironment>() is { } env)
        {
            environmentName = env.Environment;
        }
    }
}
```

However, the preceding approach isn't useful if your logic requires a value during prerendering.

You can also avoid the problem if you disable prerendering for the component, but that's an extreme measure to take in many cases that may not meet your component's specifications.

There are a three approaches that you can take to address this scenario. The following are listed from most recommended to least recommended:

- *Recommended* for shared framework services: For shared framework services that merely aren't registered server-side in the main project, register the services in the main project, which makes them available during prerendering. For an example of this scenario, see the guidance for HttpClient services in Call a web API from an ASP.NET Core Blazor app.

- *Recommended* for services outside of the shared framework: Create a custom service implementation for the service on the server. Use the service normally in

interactive components of the `.Client` project. For a demonstration of this approach, see ASP.NET Core Blazor environments.

- Create a service abstraction and create implementations for the service in the `.Client` and server projects. Register the services in each project. Inject the custom service in the component.
- You might be able to add a `.Client` project package reference to a server-side package and fall back to using the server-side API when prerendering on the server.

Discover components from additional assemblies

Additional assemblies must be disclosed to the Blazor framework to discover routable Razor components in referenced projects. For more information, see ASP.NET Core Blazor routing and navigation.

Closure of circuits when there are no remaining Interactive Server components

Interactive Server components handle web UI events using a real-time connection with the browser called a circuit. A circuit and its associated state are created when a root Interactive Server component is rendered. The circuit is closed when there are no remaining Interactive Server components on the page, which frees up server resources.

Custom shorthand render modes

The `@rendermode` directive takes a single parameter that's a static instance of type IComponentRenderMode. The `@rendermode` directive attribute can take any render mode instance, static or not. The Blazor framework provides the RenderMode static class with some predefined render modes for convenience, but you can create your own.

Normally, a component uses the following `@rendermode` directive to disable prerendering:

razor

```
@rendermode @(new InteractiveServerRenderMode(prerender: false))
```

However, consider the following example that creates a shorthand interactive server-side render mode without prerendering via the app's `_Imports` file (`Components/_Imports.razor`):

C#

```
public static IComponentRenderMode InteractiveServerWithoutPrerendering {
get; } =
    new InteractiveServerRenderMode(prerender: false);
```

Use the shorthand render mode in components throughout the `Components` folder:

razor

```
@rendermode InteractiveServerWithoutPrerendering
```

Alternatively, a single component instance can define a custom render mode via a private field:

razor

```
@rendermode interactiveServerWithoutPrerendering

...

@code {
    private static IComponentRenderMode interactiveServerWithoutPrerendering
=
        new InteractiveServerRenderMode(prerender: false);
}
```

At the moment, the shorthand render mode approach is probably only useful for reducing the verbosity of specifying the `prerender` flag. The shorthand approach might be more useful in the future if additional flags become available for interactive rendering and you would like to create shorthand render modes with different combinations of flags.

Service injection via a top-level imports file (`_Imports.razor`)

This section only applies to Blazor Web Apps.

A top-level imports file in the `Components` folder (`Components/_Imports.razor`) injects its references into all of the components in the folder hierarchy, which includes the `App` component (`App.razor`). The `App` component is always rendered statically even if prerendering of a page component is disabled. Therefore, injecting services via the top-level imports file results in resolving *two instances* of the service in page components.

To address this scenario, inject the service in a new imports file placed in the `Pages` folder (`Components/Pages/_Imports.razor`). From that location, the service is only resolved once in page components.

Prerender ASP.NET Core Razor components

Article • 10/08/2024

This article explains Razor component prerendering scenarios for server-rendered components in Blazor Web Apps.

Prerendering is the process of initially rendering page content on the server without enabling event handlers for rendered controls. The server outputs the HTML UI of the page as soon as possible in response to the initial request, which makes the app feel more responsive to users. Prerendering can also improve Search Engine Optimization (SEO) by rendering content for the initial HTTP response that search engines use to calculate page rank.

Persist prerendered state

Without persisting prerendered state, state used during prerendering is lost and must be recreated when the app is fully loaded. If any state is created asynchronously, the UI may flicker as the prerendered UI is replaced when the component is rerendered.

Consider the following `PrerenderedCounter1` counter component. The component sets an initial random counter value during prerendering in OnInitialized lifecycle method. After the SignalR connection to the client is established, the component rerenders, and the initial count value is replaced when `OnInitialized` executes a second time.

`PrerenderedCounter1.razor`:

razor

```razor
@page "/prerendered-counter-1"
@rendermode @(new InteractiveServerRenderMode(prerender: true))
@inject ILogger<PrerenderedCounter1> Logger

<PageTitle>Prerendered Counter 1</PageTitle>

<h1>Prerendered Counter 1</h1>

<p role="status">Current count: @currentCount</p>

<button class="btn btn-primary" @onclick="IncrementCount">Click me</button>

@code {
    private int currentCount;
```

```
    protected override void OnInitialized()
    {
        currentCount = Random.Shared.Next(100);
        Logger.LogInformation("currentCount set to {Count}", currentCount);
    }

    private void IncrementCount() => currentCount++;
}
```

Run the app and inspect logging from the component. The following is example output.

> **Note**
>
> If the app adopts interactive (enhanced) routing and the page is reached via an internal navigation, prerendering doesn't occur. Therefore, you must perform a full page reload for the `PrerenderedCounter1` component to see the following output.

```
info: BlazorSample.Components.Pages.PrerenderedCounter1[0]
currentCount set to 41
info: BlazorSample.Components.Pages.PrerenderedCounter1[0]
currentCount set to 92
```

The first logged count occurs during prerendering. The count is set again after prerendering when the component is rerendered. There's also a flicker in the UI when the count updates from 41 to 92.

To retain the initial value of the counter during prerendering, Blazor supports persisting state in a prerendered page using the PersistentComponentState service (and for components embedded into pages or views of Razor Pages or MVC apps, the Persist Component State Tag Helper).

To preserve prerendered state, decide what state to persist using the PersistentComponentState service. PersistentComponentState.RegisterOnPersisting registers a callback to persist the component state before the app is paused. The state is retrieved when the app resumes.

The following example demonstrates the general pattern:

- The `{TYPE}` placeholder represents the type of data to persist.
- The `{TOKEN}` placeholder is a state identifier string. Consider using `nameof({VARIABLE})`, where the `{VARIABLE}` placeholder is the name of the variable that holds the state. Using nameof() for the state identifier avoids the use of a quoted string.

razor

```razor
@implements IDisposable
@inject PersistentComponentState ApplicationState

...

@code {
    private {TYPE} data;
    private PersistingComponentStateSubscription persistingSubscription;

    protected override async Task OnInitializedAsync()
    {
        persistingSubscription =
            ApplicationState.RegisterOnPersisting(PersistData);

        if (!ApplicationState.TryTakeFromJson<{TYPE}>(
            "{TOKEN}", out var restored))
        {
            data = await ...;
        }
        else
        {
            data = restored!;
        }
    }

    private Task PersistData()
    {
        ApplicationState.PersistAsJson("{TOKEN}", data);

        return Task.CompletedTask;
    }

    void IDisposable.Dispose()
    {
        persistingSubscription.Dispose();
    }
}
```

The following counter component example persists counter state during prerendering and retrieves the state to initialize the component.

`PrerenderedCounter2.razor`:

razor

```razor
@page "/prerendered-counter-2"
@implements IDisposable
@inject ILogger<PrerenderedCounter2> Logger
@inject PersistentComponentState ApplicationState
```

```
<PageTitle>Prerendered Counter 2</PageTitle>

<h1>Prerendered Counter 2</h1>

<p role="status">Current count: @currentCount</p>

<button class="btn btn-primary" @onclick="IncrementCount">Click me</button>

@code {
    private int currentCount;
    private PersistingComponentStateSubscription persistingSubscription;

    protected override void OnInitialized()
    {
        persistingSubscription =
            ApplicationState.RegisterOnPersisting(PersistCount);

        if (!ApplicationState.TryTakeFromJson<int>(
            nameof(currentCount), out var restoredCount))
        {
            currentCount = Random.Shared.Next(100);
            Logger.LogInformation("currentCount set to {Count}",
currentCount);
        }
        else
        {
            currentCount = restoredCount!;
            Logger.LogInformation("currentCount restored to {Count}",
currentCount);
        }
    }

    private Task PersistCount()
    {
        ApplicationState.PersistAsJson(nameof(currentCount), currentCount);

        return Task.CompletedTask;
    }

    void IDisposable.Dispose() => persistingSubscription.Dispose();

    private void IncrementCount() => currentCount++;
}
```

When the component executes, `currentCount` is only set once during prerendering. The value is restored when the component is rerendered. The following is example output.

> ⓘ Note
>
> If the app adopts interactive routing and the page is reached via an internal navigation, prerendering doesn't occur. Therefore, you must perform a full page

reload for the `PrerenderedCounter2` component to see the following output.

```
info: BlazorSample.Components.Pages.PrerenderedCounter2[0]
currentCount set to 96
info: BlazorSample.Components.Pages.PrerenderedCounter2[0]
currentCount restored to 96
```

By initializing components with the same state used during prerendering, any expensive initialization steps are only executed once. The rendered UI also matches the prerendered UI, so no flicker occurs in the browser.

The persisted prerendered state is transferred to the client, where it's used to restore the component state. During client-side rendering (CSR, `InteractiveWebAssembly`), the data is exposed to the browser and must not contain sensitive, private information. During interactive server-side rendering (interactive SSR, `InteractiveServer`), ASP.NET Core Data Protection ensures that the data is transferred securely. The `InteractiveAuto` render mode combines WebAssembly and Server interactivity, so it's necessary to consider data exposure to the browser, as in the CSR case.

Components embedded into pages and views (Razor Pages/MVC)

For components embedded into a page or view of a Razor Pages or MVC app, you must add the Persist Component State Tag Helper with the `<persist-component-state />` HTML tag inside the closing `</body>` tag of the app's layout. **This is only required for Razor Pages and MVC apps.** For more information, see Persist Component State Tag Helper in ASP.NET Core.

`Pages/Shared/_Layout.cshtml`:

CSHTML

```
<body>
    ...

    <persist-component-state />
</body>
```

Interactive routing and prerendering

Internal navigation for interactive routing doesn't involve requesting new page content from the server. Therefore, prerendering doesn't occur for internal page requests.

The PersistentComponentState service only works on the initial page load and not across enhanced page navigation events. If the app performs a full (non-enhanced) navigation to a page utilizing persistent component state, the persisted state is made available for the app to use when it becomes interactive. But if an interactive circuit has already been established and an enhanced navigation is performed to a page that renders persisted component state, that state isn't made available in the existing circuit. The PersistentComponentState service isn't aware of enhanced navigation, and there's no mechanism to deliver state updates to components that are already running.

Prerendering guidance

Prerendering guidance is organized in the Blazor documentation by subject matter. The following links cover all of the prerendering guidance throughout the documentation set by subject:

- Fundamentals
  - OnNavigateAsync is executed *twice* when prerendering: Handle asynchronous navigation events with OnNavigateAsync
  - Startup: Control headers in C# code
  - Handle Errors: Prerendering
  - SignalR: Prerendered state size and SignalR message size limit
- Render modes: Prerendering
- Components
  - Control <head> content during prerendering
  - Razor component lifecycle subjects that pertain to prerendering
    - Component initialization (OnInitialized{Async})
    - After component render (OnAfterRender{Async})
    - Stateful reconnection after prerendering
    - Prerendering with JavaScript interop: This section also appears in the two JS interop articles on calling JavaScript from .NET and calling .NET from JavaScript.
  - QuickGrid component sample app: The **QuickGrid for Blazor** sample app is hosted on GitHub Pages. The site loads fast thanks to static prerendering using the community-maintained BlazorWasmPrerendering.Build GitHub project.
  - Prerendering when integrating components into Razor Pages and MVC apps
- Authentication and authorization

    - Server-side threat mitigation: Cross-site scripting (XSS)
    - Server-side unauthorized content display while prerendering with a custom AuthenticationStateProvider
    - Blazor WebAssembly rendered component authentication with prerendering

- State management: Handle prerendering: Besides the *Handle prerendering* section, several of the article's other sections include remarks on prerendering.

ASP.NET Core Razor component generic type support

Article • 10/18/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article describes generic type support in Razor components.

If you're new to generic types, see Generic classes and methods (C# Guide) for general guidance on the use of generics before reading this article.

The example code in this article is only available for the latest .NET release in the Blazor sample apps.

Generic type parameter support

The @typeparam directive declares a generic type parameter for the generated component class:

```razor
@typeparam TItem
```

C# syntax with where type constraints is supported:

```razor
@typeparam TEntity where TEntity : IEntity
```

A RenderFragment generic type is supported, but components aren't supported as the generic type. To render components by type, consider using a DynamicComponent. For more information, see Dynamically-rendered ASP.NET Core Razor components.

In the following example, the `ListItems1` component is generically typed as `TExample`, which represents the type of the `ExampleList` collection.

`ListItems1.razor`:

razor

```
@typeparam TExample

<h2>List Items 1</h2>

@if (ExampleList is not null)
{
    <ul style="color:@Color">
        @foreach (var item in ExampleList)
        {
            <li>@item</li>
        }
    </ul>

    <p>
        Type of <code>TExample</code>: @typeof(TExample)
    </p>
}

@code {
    [Parameter]
    public string? Color { get; set; }

    [Parameter]
    public IEnumerable<TExample>? ExampleList { get; set; }
}
```

The following component renders two `ListItems1` components:

- String or integer data is assigned to the `ExampleList` parameter of each component.
- Type `string` or `int` that matches the type of the assigned data is set for the type parameter (`TExample`) of each component.

`Generics1.razor`:

razor

```
@page "/generics-1"

<PageTitle>Generics 1</PageTitle>

<h1>Generic Type Example 1</h1>
```

```
<ListItems1 Color="blue"
            ExampleList="@(new List<string> { "Item 1", "Item 2" })"
            TExample="string" />

<ListItems1 Color="red"
            ExampleList="@(new List<int> { 1, 2 })"
            TExample="int" />
```

For more information, see Razor syntax reference for ASP.NET Core. For an example of generic typing with templated components, see ASP.NET Core Blazor templated components.

Cascaded generic type support

An ancestor component can cascade a type parameter by name to descendants using the [CascadingTypeParameter] attribute. This attribute allows a generic type inference to use the specified type parameter automatically with descendants that have a type parameter with the same name.

By adding `@attribute [CascadingTypeParameter(...)]` to a component, the specified generic type argument is automatically used by descendants that:

- Are nested as child content for the component in the same `.razor` document.
- Also declare a @typeparam with the exact same name.
- Don't have another value explicitly supplied or implicitly inferred for the type parameter. If another value is supplied or inferred, it takes precedence over the cascaded generic type.

When receiving a cascaded type parameter, components obtain the parameter value from the closest ancestor that has a [CascadingTypeParameter] attribute with a matching name. Cascaded generic type parameters are overridden within a particular subtree.

Matching is only performed by name. Therefore, we recommend avoiding a cascaded generic type parameter with a generic name, for example `T` or `TItem`. If a developer opts into cascading a type parameter, they're implicitly promising that its name is unique enough not to clash with other cascaded type parameters from unrelated components.

Generic types can be cascaded to child components with either of the following approaches for ancestor (parent) components, which are demonstrated in the following two sub-sections:

- Explicitly set the cascaded generic type.

- Infer the cascaded generic type.

The following subsections provide examples of the preceding approaches using the following `ListDisplay1` component. The component receives and renders list data generically typed as `TExample`. To make each instance of `ListDisplay1` stand out, an additional component parameter controls the color of the list.

`ListDisplay1.razor`:

razor

```razor
@typeparam TExample

@if (ExampleList is not null)
{
    <ul style="color:@Color">
        @foreach (var item in ExampleList)
        {
            <li>@item</li>
        }
    </ul>
}

@code {
    [Parameter]
    public string? Color { get; set; }

    [Parameter]
    public IEnumerable<TExample>? ExampleList { get; set; }
}
```

Explicit generic types based on ancestor components

The demonstration in this section cascades a type explicitly for `TExample`.

> ⓘ Note
>
> This section uses the preceding `ListDisplay1` component in the Cascaded generic type support section.

The following `ListItems2` component receives data and cascades a generic type parameter named `TExample` to its descendent components. In the upcoming parent component, the `ListItems2` component is used to display list data with the preceding `ListDisplay1` component.

`ListItems2.razor`:

```razor
@attribute [CascadingTypeParameter(nameof(TExample))]
@typeparam TExample

<h2>List Items 2</h2>

@ChildContent

<p>
    Type of <code>TExample</code>: @typeof(TExample)
</p>

@code {
    [Parameter]
    public RenderFragment? ChildContent { get; set; }
}
```

The following parent component sets the child content (RenderFragment) of two `ListItems2` components specifying the `ListItems2` types (`TExample`), which are cascaded to child components. `ListDisplay1` components are rendered with the list item data shown in the example. String data is used with the first `ListItems2` component, and integer data is used with the second `ListItems2` component.

`Generics2.razor`:

```razor
@page "/generics-2"

<PageTitle>Generics 2</PageTitle>

<h1>Generic Type Example 2</h1>

<ListItems2 TExample="string">
    <ListDisplay1 Color="blue"
                  ExampleList="@(new List<string> { "Item 1", "Item 2" })"
/>
    <ListDisplay1 Color="red"
                  ExampleList="@(new List<string> { "Item 3", "Item 4" })"
/>
</ListItems2>

<ListItems2 TExample="int">
    <ListDisplay1 Color="blue"
                  ExampleList="@(new List<int> { 1, 2 })" />
    <ListDisplay1 Color="red"
```

```
                    ExampleList="@(new List<int> { 3, 4 })" />
</ListItems2>
```

Specifying the type explicitly also allows the use of cascading values and parameters to provide data to child components, as the following demonstration shows.

`ListDisplay2.razor`:

razor

```razor
@typeparam TExample

@if (ExampleList is not null)
{
    <ul style="color:@Color">
        @foreach (var item in ExampleList)
        {
            <li>@item</li>
        }
    </ul>
}

@code {
    [Parameter]
    public string? Color { get; set; }

    [CascadingParameter]
    protected IEnumerable<TExample>? ExampleList { get; set; }
}
```

`ListItems3.razor`:

razor

```razor
@attribute [CascadingTypeParameter(nameof(TExample))]
@typeparam TExample

<h2>List Items 3</h2>

@ChildContent

@if (ExampleList is not null)
{
    <ul style="color:green">
        @foreach (var item in ExampleList)
        {
            <li>@item</li>
        }
    </ul>

    <p>
```

```
        Type of <code>TExample</code>: @typeof(TExample)
    </p>
}

@code {
    [CascadingParameter]
    protected IEnumerable<TExample>? ExampleList { get; set; }

    [Parameter]
    public RenderFragment? ChildContent { get; set; }
}
```

When cascading the data in the following example, the type must be provided to the component.

`Generics3.razor`:

razor

```
@page "/generics-3"

<PageTitle>Generics 3</PageTitle>

<h1>Generic Type Example 3</h1>

<CascadingValue Value="stringData">
    <ListItems3 TExample="string">
        <ListDisplay2 Color="blue" />
        <ListDisplay2 Color="red" />
    </ListItems3>
</CascadingValue>

<CascadingValue Value="integerData">
    <ListItems3 TExample="int">
        <ListDisplay2 Color="blue" />
        <ListDisplay2 Color="red" />
    </ListItems3>
</CascadingValue>

@code {
    private List<string> stringData = new() { "Item 1", "Item 2" };
    private List<int> integerData = new() { 1, 2 };
}
```

When multiple generic types are cascaded, values for all generic types in the set must be passed. In the following example, `TItem`, `TValue`, and `TEdit` are `GridColumn` generic types, but the parent component that places `GridColumn` doesn't specify the `TItem` type:

razor

```
<GridColumn TValue="string" TEdit="TextEdit" />
```

The preceding example generates a compile-time error that the `GridColumn` component is missing the `TItem` type parameter. Valid code specifies all of the types:

razor

```
<GridColumn TValue="string" TEdit="TextEdit" TItem="User" />
```

Infer generic types based on ancestor components

The demonstration in this section cascades a type inferred for `TExample`.

> **Note**
>
> This section uses the `ListDisplay` component in the Cascaded generic type support section.

`ListItems4.razor`:

razor

```
@attribute [CascadingTypeParameter(nameof(TExample))]
@typeparam TExample

<h2>List Items 4</h2>

@ChildContent

@if (ExampleList is not null)
{
    <ul style="color:green">
        @foreach (var item in ExampleList)
        {
            <li>@item</li>
        }
    </ul>

    <p>
        Type of <code>TExample</code>: @typeof(TExample)
    </p>
}

@code {
    [Parameter]
    public IEnumerable<TExample>? ExampleList { get; set; }
```

```
    [Parameter]
    public RenderFragment? ChildContent { get; set; }
}
```

The following component with inferred cascaded types provides different data for display.

`Generics4.razor`:

razor

```
@page "/generics-4"

<PageTitle>Generics 4</PageTitle>

<h1>Generic Type Example 4</h1>

<ListItems4 ExampleList="@(new List<string> { "Item 5", "Item 6" })">
    <ListDisplay1 Color="blue"
                  ExampleList="@(new List<string> { "Item 1", "Item 2" })"
/>
    <ListDisplay1 Color="red"
                  ExampleList="@(new List<string> { "Item 3", "Item 4" })"
/>
</ListItems4>

<ListItems4 ExampleList="@(new List<int> { 5, 6 })">
    <ListDisplay1 Color="blue"
                  ExampleList="@(new List<int> { 1, 2 })" />
    <ListDisplay1 Color="red"
                  ExampleList="@(new List<int> { 3, 4 })" />
</ListItems4>
```

The following component with inferred cascaded types provides the same data for display. The following example directly assigns the data to the components.

`Generics5.razor`:

razor

```
@page "/generics-5"

<PageTitle>Generics 5</PageTitle>

<h1>Generic Type Example 5</h1>

<ListItems4 ExampleList="stringData">
    <ListDisplay1 Color="blue" ExampleList="stringData" />
    <ListDisplay1 Color="red" ExampleList="stringData" />
```

```
</ListItems4>

<ListItems4 ExampleList="integerData">
    <ListDisplay1 Color="blue" ExampleList="integerData" />
    <ListDisplay1 Color="red" ExampleList="integerData" />
</ListItems4>

@code {
    private List<string> stringData = new() { "Item 1", "Item 2" };
    private List<int> integerData = new() { 1, 2 };
}
```

ASP.NET Core Blazor synchronization context

Article • 10/18/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

Blazor uses a synchronization context (SynchronizationContext) to enforce a single logical thread of execution. A component's lifecycle methods and event callbacks raised by Blazor are executed on the synchronization context.

Blazor's server-side synchronization context attempts to emulate a single-threaded environment so that it closely matches the WebAssembly model in the browser, which is single threaded. This emulation is scoped only to an individual circuit, meaning two different circuits can run in parallel. At any given point in time within a circuit, work is performed on exactly one thread, which yields the impression of a single logical thread. No two operations execute concurrently within the same circuit.

Avoid thread-blocking calls

Generally, don't call the following methods in components. The following methods block the execution thread and thus block the app from resuming work until the underlying Task is complete:

- Result
- Wait
- WaitAny
- WaitAll
- Sleep
- GetResult

> **Note**

Blazor documentation examples that use the thread-blocking methods mentioned in this section are only using the methods for demonstration purposes, not as recommended coding guidance. For example, a few component code demonstrations simulate a long-running process by calling Thread.Sleep.

Invoke component methods externally to update state

In the event a component must be updated based on an external event, such as a timer or other notification, use the `InvokeAsync` method, which dispatches code execution to Blazor's synchronization context. For example, consider the following *notifier service* that can notify any listening component about updated state. The `Update` method can be called from anywhere in the app.

`TimerService.cs`:

C#

```
namespace BlazorSample;

public class TimerService(NotifierService notifier,
    ILogger<TimerService> logger) : IDisposable
{
    private int elapsedCount;
    private readonly static TimeSpan heartbeatTickRate =
TimeSpan.FromSeconds(5);
    private readonly ILogger<TimerService> logger = logger;
    private readonly NotifierService notifier = notifier;
    private PeriodicTimer? timer;

    public async Task Start()
    {
        if (timer is null)
        {
            timer = new(heartbeatTickRate);
            logger.LogInformation("Started");

            using (timer)
            {
                while (await timer.WaitForNextTickAsync())
                {
                    elapsedCount += 1;
                    await notifier.Update("elapsedCount", elapsedCount);
                    logger.LogInformation("ElapsedCount {Count}",
elapsedCount);
                }
            }
```

```
        }
    }

    public void Dispose()
    {
        timer?.Dispose();

        // The following prevents derived types that introduce a
        // finalizer from needing to re-implement IDisposable.
        GC.SuppressFinalize(this);
    }
}
```

`NotifierService.cs`:

C#

```
namespace BlazorSample;

public class NotifierService
{
    public async Task Update(string key, int value)
    {
        if (Notify != null)
        {
            await Notify.Invoke(key, value);
        }
    }

    public event Func<string, int, Task>? Notify;
}
```

Register the services:

- For client-side development, register the services as singletons in the client-side `Program` file:

  C#

  ```
  builder.Services.AddSingleton<NotifierService>();
  builder.Services.AddSingleton<TimerService>();
  ```

- For server-side development, register the services as scoped in the server `Program` file:

  C#

  ```
  builder.Services.AddScoped<NotifierService>();
  ```

```
builder.Services.AddScoped<TimerService>();
```

Use the `NotifierService` to update a component.

`Notifications.razor`:

razor

```razor
@page "/notifications"
@implements IDisposable
@inject NotifierService Notifier
@inject TimerService Timer

<PageTitle>Notifications</PageTitle>

<h1>Notifications Example</h1>

<h2>Timer Service</h2>

<button @onclick="StartTimer">Start Timer</button>

<h2>Notifications</h2>

<p>
    Status:
    @if (lastNotification.key is not null)
    {
        <span>@lastNotification.key = @lastNotification.value</span>
    }
    else
    {
        <span>Awaiting notification</span>
    }
</p>

@code {
    private (string key, int value) lastNotification;

    protected override void OnInitialized() => Notifier.Notify += OnNotify;

    public async Task OnNotify(string key, int value)
    {
        await InvokeAsync(() =>
        {
            lastNotification = (key, value);
            StateHasChanged();
        });
    }

    private void StartTimer() => _ = Task.Run(Timer.Start);
```

```
    public void Dispose() => Notifier.Notify -= OnNotify;
}
```

In the preceding example:

- The timer is initiated outside of Blazor's synchronization context with `_ = Task.Run(Timer.Start)`.
- `NotifierService` invokes the component's `OnNotify` method. `InvokeAsync` is used to switch to the correct context and enqueue a rerender. For more information, see ASP.NET Core Razor component rendering.
- The component implements IDisposable. The `OnNotify` delegate is unsubscribed in the `Dispose` method, which is called by the framework when the component is disposed. For more information, see ASP.NET Core Razor component lifecycle.

> **Important**
>
> If a Razor component defines an event that's triggered from a background thread, the component might be required to capture and restore the execution context (ExecutionContext) at the time the handler is registered. For more information, see Calling InvokeAsync(StateHasChanged) causes page to fallback to default culture (dotnet/aspnetcore #28521).

To dispatch caught exceptions from the background `TimerService` to the component to treat the exceptions like normal lifecycle event exceptions, see the Handle caught exceptions outside of a Razor component's lifecycle section.

Handle caught exceptions outside of a Razor component's lifecycle

Use ComponentBase.DispatchExceptionAsync in a Razor component to process exceptions thrown outside of the component's lifecycle call stack. This permits the component's code to treat exceptions as though they're lifecycle method exceptions. Thereafter, Blazor's error handling mechanisms, such as error boundaries, can process the exceptions.

> **Note**

ComponentBase.DispatchExceptionAsync is used in Razor component files (`.razor`) that inherit from ComponentBase. When creating components that implement IComponent directly, use RenderHandle.DispatchExceptionAsync.

To handle caught exceptions outside of a Razor component's lifecycle, pass the exception to DispatchExceptionAsync and await the result:

C#

```
try
{
    ...
}
catch (Exception ex)
{
    await DispatchExceptionAsync(ex);
}
```

A common scenario for the preceding approach is when a component starts an asynchronous operation but doesn't await a Task, often called the *fire and forget* pattern because the method is *fired* (started) and the result of the method is *forgotten* (thrown away). If the operation fails, you may want the component to treat the failure as a component lifecycle exception for any of the following goals:

- Put the component into a faulted state, for example, to trigger an error boundary.
- Terminate the circuit if there's no error boundary.
- Trigger the same logging that occurs for lifecycle exceptions.

In the following example, the user selects the **Send report** button to trigger a background method, `ReportSender.SendAsync`, that sends a report. In most cases, a component awaits the Task of an asynchronous call and updates the UI to indicate the operation completed. In the following example, the `SendReport` method doesn't await a Task and doesn't report the result to the user. Because the component intentionally discards the Task in `SendReport`, any asynchronous failures occur off of the normal lifecycle call stack, hence aren't seen by Blazor:

razor

```
<button @onclick="SendReport">Send report</button>

@code {
    private void SendReport()
    {
        _ = ReportSender.SendAsync();
```

```
    }
}
```

To treat failures like lifecycle method exceptions, explicitly dispatch exceptions back to the component with DispatchExceptionAsync, as the following example demonstrates:

razor

```
<button @onclick="SendReport">Send report</button>

@code {
    private void SendReport()
    {
        _ = SendReportAsync();
    }

    private async Task SendReportAsync()
    {
        try
        {
            await ReportSender.SendAsync();
        }
        catch (Exception ex)
        {
            await DispatchExceptionAsync(ex);
        }
    }
}
```

An alternative approach leverages Task.Run:

C#

```
private void SendReport()
{
    _ = Task.Run(async () =>
    {
        try
        {
            await ReportSender.SendAsync();
        }
        catch (Exception ex)
        {
            await DispatchExceptionAsync(ex);
        }
    });
}
```

For a working demonstration, implement the timer notification example in Invoke component methods externally to update state. In a Blazor app, add the following files

from the timer notification example and register the services in the `Program` file as the section explains:

- `TimerService.cs`
- `NotifierService.cs`
- `Notifications.razor`

The example uses a timer outside of a Razor component's lifecycle, where an unhandled exception normally isn't processed by Blazor's error handling mechanisms, such as an error boundary.

First, change the code in `TimerService.cs` to create an artificial exception outside of the component's lifecycle. In the `while` loop of `TimerService.cs`, throw an exception when the `elapsedCount` reaches a value of two:

C#

```
if (elapsedCount == 2)
{
    throw new Exception("I threw an exception! Somebody help me!");
}
```

Place an error boundary in the app's main layout. Replace the `<article>...</article>` markup with the following markup.

In `MainLayout.razor`:

razor

```
<article class="content px-4">
    <ErrorBoundary>
        <ChildContent>
            @Body
        </ChildContent>
        <ErrorContent>
            <p class="alert alert-danger" role="alert">
                Oh, dear! Oh, my! - George Takei
            </p>
        </ErrorContent>
    </ErrorBoundary>
</article>
```

In Blazor Web Apps with the error boundary only applied to a static `MainLayout` component, the boundary is only active during the static server-side rendering (static SSR) phase. The boundary doesn't activate just because a component further down the component hierarchy is interactive. To enable interactivity broadly for the `MainLayout`

component and the rest of the components further down the component hierarchy, enable interactive rendering for the `HeadOutlet` and `Routes` component instances in the `App` component (`Components/App.razor`). The following example adopts the Interactive Server (`InteractiveServer`) render mode:

razor

```razor
<HeadOutlet @rendermode="InteractiveServer" />

...

<Routes @rendermode="InteractiveServer" />
```

If you run the app at this point, the exception is thrown when the elapsed count reaches a value of two. However, the UI doesn't change. The error boundary doesn't show the error content.

To dispatch exceptions from the timer service back to the `Notifications` component, the following changes are made to the component:

- Start the timer in a try-catch statement. In the `catch` clause of the `try-catch` block, exceptions are dispatched back to the component by passing the Exception to DispatchExceptionAsync and awaiting the result.
- In the `StartTimer` method, start the asynchronous timer service in the Action delegate of Task.Run and intentionally discard the returned Task.

The `StartTimer` method of the `Notifications` component (`Notifications.razor`):

C#

```
private void StartTimer()
{
    _ = Task.Run(async () =>
    {
        try
        {
            await Timer.Start();
        }
        catch (Exception ex)
        {
            await DispatchExceptionAsync(ex);
        }
    });
}
```

When the timer service executes and reaches a count of two, the exception is dispatched to the Razor component, which in turn triggers the error boundary to display the error content of the `<ErrorBoundary>` in the `MainLayout` component:

> Oh, dear! Oh, my! - George Takei

Retain element, component, and model relationships in ASP.NET Core Blazor

Article • 10/18/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article explains how to use the `@key` directive attribute to retain element, component, and model relationships when rendering and the elements or components subsequently change.

Use of the `@key` directive attribute

When rendering a list of elements or components and the elements or components subsequently change, Blazor must decide which of the previous elements or components are retained and how model objects should map to them. Normally, this process is automatic and sufficient for general rendering, but there are often cases where controlling the process using the @key directive attribute is required.

Consider the following example that demonstrates a collection mapping problem that's solved by using @key.

For the following components:

- The `Details` component receives data (`Data`) from the parent component, which is displayed in an `<input>` element. Any given displayed `<input>` element can receive the focus of the page from the user when they select one of the `<input>` elements.
- The parent component creates a list of person objects for display using the `Details` component. Every three seconds, a new person is added to the collection.

This demonstration allows you to:

- Select an `<input>` from among several rendered `Details` components.
- Study the behavior of the page's focus as the people collection automatically grows.

`Details.razor`:

```razor
<input value="@Data" />

@code {
    [Parameter]
    public string? Data { get; set; }
}
```

In the following parent component, each iteration of adding a person in `OnTimerCallback` results in Blazor rebuilding the entire collection. The page's focus remains on the *same index* position of `<input>` elements, so the focus shifts each time a person is added. *Shifting the focus away from what the user selected isn't desirable behavior.* After demonstrating the poor behavior with the following component, the @key directive attribute is used to improve the user's experience.

`People.razor`:

```razor
@page "/people"
@using System.Timers
@implements IDisposable

<PageTitle>People</PageTitle>

<h1>People Example</h1>

@foreach (var person in people)
{
    <Details Data="@person.Data" />
}

@code {
    private Timer timer = new Timer(3000);

    public List<Person> people =
        new()
        {
            { new Person { Data = "Person 1" } },
            { new Person { Data = "Person 2" } },
            { new Person { Data = "Person 3" } }
        };

    protected override void OnInitialized()
    {
        timer.Elapsed += (sender, eventArgs) => OnTimerCallback();
        timer.Start();
```

```
    }

    private void OnTimerCallback()
    {
        _ = InvokeAsync(() =>
        {
            people.Insert(0,
                new Person
                {
                    Data = $"INSERTED {DateTime.Now.ToString("hh:mm:ss
tt")}"
                });
            StateHasChanged();
        });
    }

    public void Dispose() => timer.Dispose();

    public class Person
    {
        public string? Data { get; set; }
    }
}
```

The contents of the `people` collection changes with inserted, deleted, or re-ordered entries. Rerendering can lead to visible behavior differences. For example, each time a person is inserted into the `people` collection, the user's focus is lost.

The mapping process of elements or components to a collection can be controlled with the @key directive attribute. Use of @key guarantees the preservation of elements or components based on the key's value. If the `Details` component in the preceding example is keyed on the `person` item, Blazor ignores rerendering `Details` components that haven't changed.

To modify the parent component to use the @key directive attribute with the `people` collection, update the `<Details>` element to the following:

razor

```
<Details @key="person" Data="@person.Data" />
```

When the `people` collection changes, the association between `Details` instances and `person` instances is retained. When a `Person` is inserted at the beginning of the collection, one new `Details` instance is inserted at that corresponding position. Other instances are left unchanged. Therefore, the user's focus isn't lost as people are added to the collection.

Other collection updates exhibit the same behavior when the @key directive attribute is used:

- If an instance is deleted from the collection, only the corresponding component instance is removed from the UI. Other instances are left unchanged.
- If collection entries are re-ordered, the corresponding component instances are preserved and re-ordered in the UI.

> **ⓘ Important**
>
> Keys are local to each container element or component. Keys aren't compared globally across the document.

When to use `@key`

Typically, it makes sense to use @key whenever a list is rendered (for example, in a foreach block) and a suitable value exists to define the @key.

You can also use @key to preserve an element or component subtree when an object doesn't change, as the following examples show.

Example 1:

razor

```razor
<li @key="person">
    <input value="@person.Data" />
</li>
```

Example 2:

razor

```razor
<div @key="person">
    @* other HTML elements *@
</div>
```

If an `person` instance changes, the @key attribute directive forces Blazor to:

- Discard the entire `<li>` or `<div>` and their descendants.
- Rebuild the subtree within the UI with new elements and components.

This is useful to guarantee that no UI state is preserved when the collection changes within a subtree.

Scope of `@key`

The @key attribute directive is scoped to its own siblings within its parent.

Consider the following example. The `first` and `second` keys are compared against each other within the same scope of the outer `<div>` element:

razor

```
<div>
    <div @key="first">...</div>
    <div @key="second">...</div>
</div>
```

The following example demonstrates `first` and `second` keys in their own scopes, unrelated to each other and without influence on each other. Each @key scope only applies to its parent `<div>` element, not across the parent `<div>` elements:

razor

```
<div>
    <div @key="first">...</div>
</div>
<div>
    <div @key="second">...</div>
</div>
```

For the `Details` component shown earlier, the following examples render `person` data within the same @key scope and demonstrate typical use cases for @key:

razor

```
<div>
    @foreach (var person in people)
    {
        <Details @key="person" Data="@person.Data" />
    }
</div>
```

razor

```razor
@foreach (var person in people)
{
    <div @key="person">
        <Details Data="@person.Data" />
    </div>
}
```

razor

```razor
<ol>
    @foreach (var person in people)
    {
        <li @key="person">
            <Details Data="@person.Data" />
        </li>
    }
</ol>
```

The following examples only scope @key to the `<div>` or `<li>` element that surrounds each `Details` component instance. Therefore, `person` data for each member of the `people` collection is **not** keyed on each `person` instance across the rendered `Details` components. Avoid the following patterns when using @key:

razor

```razor
@foreach (var person in people)
{
    <div>
        <Details @key="person" Data="@person.Data" />
    </div>
}
```

razor

```razor
<ol>
    @foreach (var person in people)
    {
        <li>
            <Details @key="person" Data="@person.Data" />
        </li>
    }
</ol>
```

When not to use `@key`

There's a performance cost when rendering with @key. The performance cost isn't large, but only specify @key if preserving the element or component benefits the app.

Even if @key isn't used, Blazor preserves child element and component instances as much as possible. The only advantage to using @key is control over *how* model instances are mapped to the preserved component instances, instead of Blazor selecting the mapping.

Values to use for `@key`

Generally, it makes sense to supply one of the following values for @key:

- Model object instances. For example, the `Person` instance (`person`) was used in the earlier example. This ensures preservation based on object reference equality.
- Unique identifiers. For example, unique identifiers can be based on primary key values of type `int`, `string`, or `Guid`.

Ensure that values used for @key don't clash. If clashing values are detected within the same parent element, Blazor throws an exception because it can't deterministically map old elements or components to new elements or components. Only use distinct values, such as object instances or primary key values.

Avoid overwriting parameters in ASP.NET Core Blazor

Article • 10/18/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Robert Haken

This article explains how to avoid overwriting parameters in Blazor apps during rerendering.

Overwritten parameters

The Blazor framework generally imposes safe parent-to-child parameter assignment:

- Parameters aren't overwritten unexpectedly.
- Side effects are minimized. For example, additional renders are avoided because they may create infinite rendering loops.

A child component receives new parameter values that possibly overwrite existing values when the parent component rerenders. Accidentally overwriting parameter values in a child component often occurs when developing the component with one or more data-bound parameters and the developer writes directly to a parameter in the child:

- The child component is rendered with one or more parameter values from the parent component.
- The child writes directly to the value of a parameter.
- The parent component rerenders and overwrites the value of the child's parameter.

The potential for overwriting parameter values extends into the child component's property `set` accessors, too.

> **Important**

> Our general guidance is not to create components that directly write to their own parameters after the component is rendered for the first time.

Consider the following `ShowMoreExpander` component that:

- Renders the title.
- Shows the child content when selected.
- Allows you to set initial state with a component parameter (`InitiallyExpanded`).

After the following `ShowMoreExpander` component demonstrates an overwritten parameter, a modified `ShowMoreExpander` component is shown to demonstrate the correct approach for this scenario. The following examples can be placed in a local sample app to experience the behaviors described.

`ShowMoreExpander.razor`:

```
<div @onclick="ShowMore" class="card bg-light mb-3" style="width:30rem">
    <div class="card-header">
        <h2 class="card-title">Show more (<code>Expanded</code> =
@InitiallyExpanded)</h2>
    </div>
    @if (InitiallyExpanded)
    {
        <div class="card-body">
            <p class="card-text">@ChildContent</p>
        </div>
    }
</div>

@code {
    [Parameter]
    public bool InitiallyExpanded { get; set; }

    [Parameter]
    public RenderFragment? ChildContent { get; set; }

    private void ShowMore() => InitiallyExpanded = true;
}
```

The `ShowMoreExpander` component is added to the following `Expanders` parent component that may call StateHasChanged:

- Calling StateHasChanged in developer code notifies a component that its state has changed and typically enqueues component rerendering to update the UI. StateHasChanged is covered in more detail later in ASP.NET Core Razor component lifecycle and ASP.NET Core Razor component rendering.

- The button's `@onclick` directive attribute attaches an event handler to the button's `onclick` event. Event handling is covered in more detail later in ASP.NET Core Blazor event handling.

`Expanders.razor`:

```
@page "/expanders"

<PageTitle>Expanders</PageTitle>

<h1>Expanders Example</h1>

<ShowMoreExpander InitiallyExpanded="false">
    Expander 1 content
</ShowMoreExpander>

<ShowMoreExpander InitiallyExpanded="false" />

<button @onclick="StateHasChanged">Call StateHasChanged</button>
```

Initially, the `ShowMoreExpander` components behave independently when their `InitiallyExpanded` properties are set. The child components maintain their states as expected.

If StateHasChanged is called in a parent component, the Blazor framework rerenders child components if their parameters might have changed:

- For a group of parameter types that Blazor explicitly checks, Blazor rerenders a child component if it detects that any of the parameters have changed.
- For unchecked parameter types, Blazor rerenders the child component *regardless of whether or not the parameters have changed*. Child content falls into this category of parameter types because child content is of type RenderFragment, which is a delegate that refers to other mutable objects.

For the `Expanders` component:

- The first `ShowMoreExpander` component sets child content in a potentially mutable RenderFragment, so a call to StateHasChanged in the parent component automatically rerenders the component and potentially overwrites the value of `InitiallyExpanded` to its initial value of `false`.
- The second `ShowMoreExpander` component doesn't set child content. Therefore, a potentially mutable RenderFragment doesn't exist. A call to StateHasChanged in the parent component doesn't automatically rerender the child component, so the component's `InitiallyExpanded` value isn't overwritten.

To maintain state in the preceding scenario, use a *private field* in the `ShowMoreExpander` component to maintain its state.

The following revised `ShowMoreExpander` component:

- Accepts the `InitiallyExpanded` component parameter value from the parent.
- Assigns the component parameter value to a *private field* (`expanded`) in the OnInitialized event.
- Uses the private field to maintain its internal toggle state, which demonstrates how to avoid writing directly to a parameter.

> **Note**
>
> The advice in this section extends to similar logic in component parameter `set` accessors, which can result in similar undesirable side effects.

`ShowMoreExpander.razor`:

```
<div @onclick="Expand" class="card bg-light mb-3" style="width:30rem">
    <div class="card-header">
        <h2 class="card-title">Show more (<code>Expanded</code> = @expanded)
</h2>
    </div>
    @if (expanded)
    {
        <div class="card-body">
            <p class="card-text">@ChildContent</p>
        </div>
    }
</div>

@code {
    private bool expanded;

    [Parameter]
    public bool InitiallyExpanded { get; set; }

    [Parameter]
    public RenderFragment? ChildContent { get; set; }

    protected override void OnInitialized() => expanded = InitiallyExpanded;

    private void Expand() => expanded = true;
}
```

> **Note**

The revised `ShowMoreExpander` doesn't reflect changes to the `InitiallyExpanded` parameter after initialization (`OnInitialized`). In certain scenarios, an already initialized component might receive new parameter values. This can happen, for example, in a primary-subordinate view where the same component is used to render different detail views or when the `/item/{id}` route parameter changes to display a different item.

Consider following `ToggleExpander` component that:

- Allows you to change the state both from inside and outside.
- Handles new parameter values even if the same component instance is reused.

`ToggleExpander.razor`:

```
<div class="card bg-light mb-3" style="width:30rem">
    <div @onclick="Toggle" class="card-header">
        <h2 class="card-title">Toggle (<code>Expanded</code> = @expanded)
</h2>
    </div>
    @if (expanded)
    {
        <div class="card-body">
            <p class="card-text">@ChildContent</p>
        </div>
    }
</div>

@code {
    [Parameter]
    public bool Expanded { get; set; }

    [Parameter]
    public EventCallback<bool> ExpandedChanged { get; set; }

    [Parameter]
    public RenderFragment? ChildContent { get; set; }

    private bool expanded;

    protected override void OnParametersSet() => expanded = Expanded;

    private async void Toggle()
    {
        expanded = !expanded;
        await ExpandedChanged.InvokeAsync(expanded);
    }
}
```

The `ToggleExpander` component should be used with the `@bind-Expanded="{field}"` binding syntax, allowing two-way synchronization of the parameter.

`ExpandersToggle.razor`:

```
@page "/expanders-toggle"

<PageTitle>Expanders Toggle</PageTitle>

<h1>Expanders Toggle</h1>

<ToggleExpander @bind-Expanded="expanded">
    Expander content
</ToggleExpander>

<button @onclick="Toggle">Toggle</button>

<button @onclick="StateHasChanged">Call StateHasChanged</button>

@code {
    private bool expanded;

    private void Toggle() => expanded = !expanded;
}
```

For more information on parent-child binding, see the following resources:

- Binding with component parameters
- Bind across more than two components
- Blazor Two Way Binding Error (dotnet/aspnetcore #24599)

For more information on change detection, including information on the exact types that Blazor checks, see ASP.NET Core Razor component rendering.

ASP.NET Core Blazor attribute splatting and arbitrary parameters

Article • 10/18/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

Components can capture and render additional attributes in addition to the component's declared parameters. Additional attributes can be captured in a dictionary and then *splatted* onto an element when the component is rendered using the `@attributes` Razor directive attribute. This scenario is useful for defining a component that produces a markup element that supports a variety of customizations. For example, it can be tedious to define attributes separately for an `<input>` that supports many parameters.

Attribute splatting

In the following `Splat` component:

- The first `<input>` element (`id="useIndividualParams"`) uses individual component parameters.
- The second `<input>` element (`id="useAttributesDict"`) uses attribute splatting.

`Splat.razor`:

razor

```
@page "/splat"

<PageTitle>SPLAT!</PageTitle>

<h1>Splat Parameters Example</h1>

<input id="useIndividualParams"
       maxlength="@maxlength"
       placeholder="@placeholder"
       required="@required"
```

```
        size="@size" />

<input id="useAttributesDict"
       @attributes="InputAttributes" />

@code {
    private string maxlength = "10";
    private string placeholder = "Input placeholder text";
    private string required = "required";
    private string size = "50";

    private Dictionary<string, object> InputAttributes { get; set; } =
        new()
        {
            { "maxlength", "10" },
            { "placeholder", "Input placeholder text" },
            { "required", "required" },
            { "size", "50" }
        };
}
```

The rendered `<input>` elements in the webpage are identical:

HTML

```
<input id="useIndividualParams"
       maxlength="10"
       placeholder="Input placeholder text"
       required="required"
       size="50">

<input id="useAttributesDict"
       maxlength="10"
       placeholder="Input placeholder text"
       required="required"
       size="50">
```

Arbitrary attributes

To accept arbitrary attributes, define a component parameter with the CaptureUnmatchedValues property set to `true`:

razor

```
@code {
    [Parameter(CaptureUnmatchedValues = true)]
    public Dictionary<string, object>? InputAttributes { get; set; }
}
```

The CaptureUnmatchedValues property on [Parameter] allows the parameter to match all attributes that don't match any other parameter. A component can only define a single parameter with CaptureUnmatchedValues. The property type used with CaptureUnmatchedValues must be assignable from Dictionary<string, object> with string keys. Use of IEnumerable<KeyValuePair<string, object>> or IReadOnlyDictionary<string, object> are also options in this scenario.

The position of @attributes relative to the position of element attributes is important. When @attributes are splatted on the element, the attributes are processed from right to left (last to first). Consider the following example of a parent component that consumes a child component:

`AttributeOrderChild1.razor`:

razor

```razor
<div @attributes="AdditionalAttributes" extra="5" />

@code {
    [Parameter(CaptureUnmatchedValues = true)]
    public IDictionary<string, object>? AdditionalAttributes { get; set; }
}
```

`AttributeOrder1.razor`:

razor

```razor
@page "/attribute-order-1"

<PageTitle>Attribute Order 1</PageTitle>

<h1>Attribute Order Example 1</h1>

<AttributeOrderChild1 extra="10" />

<p>
    View the HTML markup in your browser to inspect the attributes on
    the AttributeOrderChild1 component.
</p>
```

The `AttributeOrderChild1` component's `extra` attribute is set to the right of @attributes. The `AttributeOrderParent1` component's rendered `<div>` contains `extra="5"` when passed through the additional attribute because the attributes are processed right to left (last to first):

HTML

```
<div extra="5" />
```

In the following example, the order of `extra` and @attributes is reversed in the child component's `<div>`:

`AttributeOrderChild2.razor`:

razor

```
<div extra="5" @attributes="AdditionalAttributes" />

@code {
    [Parameter(CaptureUnmatchedValues = true)]
    public IDictionary<string, object>? AdditionalAttributes { get; set; }
}
```

`AttributeOrder2.razor`:

razor

```
@page "/attribute-order-2"

<PageTitle>Attribute Order 2</PageTitle>

<h1>Attribute Order Example 2</h1>

<AttributeOrderChild2 extra="10" />

<p>
    View the HTML markup in your browser to inspect the attributes on
    the AttributeOrderChild2 component.
</p>
```

The `<div>` in the parent component's rendered webpage contains `extra="10"` when passed through the additional attribute:

HTML

```
<div extra="10" />
```

ASP.NET Core Blazor layouts

Article • 11/06/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article explains how to create reusable layout components for Blazor apps.

Usefulness of Blazor layouts

Some app elements, such as menus, copyright messages, and company logos, are usually part of app's overall presentation. Placing a copy of the markup for these elements into all of the components of an app isn't efficient. Every time that one of these elements is updated, every component that uses the element must be updated. This approach is costly to maintain and can lead to inconsistent content if an update is missed. *Layouts* solve these problems.

A Blazor layout is a Razor component that shares markup with components that reference it. Layouts can use data binding, dependency injection, and other features of components.

Layout components

Create a layout component

To create a layout component:

- Create a Razor component defined by a Razor template or C# code. Layout components based on a Razor template use the `.razor` file extension just like ordinary Razor components. Because layout components are shared across an app's components, they're usually placed in the app's `Shared` or `Layout` folder. However, layouts can be placed in any location accessible to the components that use it. For example, a layout can be placed in the same folder as the components that use it.

- Inherit the component from LayoutComponentBase. The LayoutComponentBase defines a Body property (RenderFragment type) for the rendered content inside the layout.
- Use the Razor syntax `@Body` to specify the location in the layout markup where the content is rendered.

> **Note**
>
> For more information on RenderFragment, see ASP.NET Core Razor components.

The following `DoctorWhoLayout` component shows the Razor template of a layout component. The layout inherits LayoutComponentBase and sets the `@Body` between the navigation bar (`<nav>...</nav>`) and the footer (`<footer>...</footer>`).

`DoctorWhoLayout.razor`:

razor

```
@inherits LayoutComponentBase

<PageTitle>Doctor Who® Database</PageTitle>

<header>
    <h1>Doctor Who® Database</h1>
</header>

<nav>
    <a href="main-list">Main Episode List</a>
    <a href="search">Search</a>
    <a href="new">Add Episode</a>
</nav>

@Body

<footer>
    @TrademarkMessage
</footer>

@code {
    public string TrademarkMessage { get; set; } =
        "Doctor Who is a registered trademark of the BBC. " +
        "https://www.doctorwho.tv/ https://www.bbc.com";
}
```

`MainLayout` component

In an app created from a Blazor project template, the `MainLayout` component is the app's default layout. Blazor's layout adopts the Flexbox layout model (MDN documentation) (W3C specification).

Blazor's CSS isolation feature applies isolated CSS styles to the `MainLayout` component. By convention, the styles are provided by the accompanying stylesheet of the same name, `MainLayout.razor.css`. The ASP.NET Core framework implementation of the stylesheet is available for inspection in the ASP.NET Core reference source (`dotnet/aspnetcore` GitHub repository):

- Blazor Web App MainLayout.razor.css
- Blazor WebAssembly MainLayout.razor.css

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Apply a layout

Make the layout namespace available

Layout file locations and namespaces changed over time for the Blazor framework. Depending on the version of Blazor and type of Blazor app that you're building, you may need to indicate the layout's namespace when using it. When referencing a layout implementation and the layout isn't found without indicating the layout's namespace, take any of the following approaches:

- Add an `@using` directive to the `_Imports.razor` file for the location of the layouts. In the following example, a folder of layouts with the name `Layout` is inside a `Components` folder, and the app's namespace is `BlazorSample`:

  ```razor
  @using BlazorSample.Components.Layout
  ```

- Add an `@using` directive at the top of the component definition where the layout is used:

  razor

  ```
  @using BlazorSample.Components.Layout
  @layout DoctorWhoLayout
  ```

- Fully qualify the namespace of the layout where it's used:

  razor

  ```
  @layout BlazorSample.Components.Layout.DoctorWhoLayout
  ```

Apply a layout to a component

Use the @layout Razor directive to apply a layout to a routable Razor component that has an @page directive. The compiler converts `@layout` into a LayoutAttribute and applies the attribute to the component class.

The content of the following `Episodes` component is inserted into the `DoctorWhoLayout` at the position of `@Body`.

`Episodes.razor`:

razor

```
@page "/episodes"
@layout DoctorWhoLayout

<h2>Doctor Who® Episodes</h2>

<ul>
    <li>
        <a href="https://www.bbc.co.uk/programmes/p00vfknq">
            <em>The Ribos Operation</em>
        </a>
    </li>
    <li>
        <a href="https://www.bbc.co.uk/programmes/p00vfdsb">
            <em>The Sunmakers</em>
        </a>
    </li>
    <li>
        <a href="https://www.bbc.co.uk/programmes/p00vhc26">
            <em>Nightmare of Eden</em>
        </a>
```

```
    </li>
</ul>
```

The following rendered HTML markup is produced by the preceding `DoctorWhoLayout` and `Episodes` component. Extraneous markup doesn't appear in order to focus on the content provided by the two components involved:

- The H1 "database" heading (`<h1>...</h1>`) in the header (`<header>...</header>`), navigation bar (`<nav>...</nav>`), and trademark information in the footer (`<footer>...</footer>`) come from the `DoctorWhoLayout` component.
- The H2 "episodes" heading (`<h2>...</h2>`) and episode list (`<ul>...</ul>`) come from the `Episodes` component.

HTML

```
<header>
    <h1 ...>...</h1>
</header>

<nav>
    ...
</nav>

<h2>...</h2>

<ul>
    <li>...</li>
    <li>...</li>
    <li>...</li>
</ul>

<footer>
    ...
</footer>
```

Specifying the layout directly in a component overrides a *default layout*:

- Set by an `@layout` directive imported from an `_Imports.razor` file, as described in the following Apply a layout to a folder of components section.
- Set as the app's default layout, as described in the Apply a default layout to an app section later in this article.

Apply a layout to a folder of components

Every folder of an app can optionally contain a template file named `_Imports.razor`. The compiler includes the directives specified in the imports file in all of the Razor templates

in the same folder and recursively in all of its subfolders. Therefore, an `_Imports.razor` file containing `@layout DoctorWhoLayout` ensures that all of the components in a folder use the `DoctorWhoLayout` component. There's no need to repeatedly add `@layout DoctorWhoLayout` to all of the Razor components (`.razor`) within the folder and subfolders.

`_Imports.razor`:

```razor
@layout DoctorWhoLayout
...
```

The `_Imports.razor` file is similar to the _ViewImports.cshtml file for Razor views and pages but applied specifically to Razor component files.

Specifying a layout in `_Imports.razor` overrides a layout specified as the router's default app layout, which is described in the following section.

> ⚠ **Warning**
>
> Do **not** add a Razor `@layout` directive to the root `_Imports.razor` file, which results in an infinite loop of layouts. To control the default app layout, specify the layout in the Router component. For more information, see the following Apply a default layout to an app section.

> ⓘ **Note**
>
> The @layout Razor directive only applies a layout to routable Razor components with an @page directive.

Apply a default layout to an app

Specify the default app layout in the Router component's RouteView component. Use the DefaultLayout parameter to set the layout type:

```razor
<RouteView RouteData="routeData" DefaultLayout="typeof({LAYOUT})" />
```

In the preceding example, the `{LAYOUT}` placeholder is the layout (for example, `DoctorWhoLayout` if the layout file name is `DoctorWhoLayout.razor`). You may need to idenfity the layout's namespace depending on the .NET version and type of Blazor app. For more information, see the Make the layout namespace available section.

Specifying the layout as a default layout in the Router component's RouteView is a useful practice because you can override the layout on a per-component or per-folder basis, as described in the preceding sections of this article. We recommend using the Router component to set the app's default layout because it's the most general and flexible approach for using layouts.

Apply a layout to arbitrary content (`LayoutView` component)

To set a layout for arbitrary Razor template content, specify the layout with a LayoutView component. You can use a LayoutView in any Razor component. The following example sets a layout component named `ErrorLayout` for the `MainLayout` component's NotFound template (`<NotFound>...</NotFound>`).

razor

```razor
<Router ...>
    <Found ...>
        ...
    </Found>
    <NotFound>
        <LayoutView Layout="typeof(ErrorLayout)">
            <h1>Page not found</h1>
            <p>Sorry, there's nothing at this address.</p>
        </LayoutView>
    </NotFound>
</Router>
```

You may need to identity the layout's namespace depending on the .NET version and type of Blazor app. For more information, see the Make the layout namespace available section.

> **ⓘ Important**
>
> Blazor Web Apps don't use the **NotFound** parameter (`<NotFound>...</NotFound>` markup), but the parameter is supported for backward compatibility to avoid a breaking change in the framework. The server-side ASP.NET Core middleware

pipeline processes requests on the server. Use server-side techniques to handle bad requests. For more information, see ASP.NET Core Blazor render modes.

Nested layouts

A component can reference a layout that in turn references another layout. For example, nested layouts are used to create a multi-level menu structures.

The following example shows how to use nested layouts. The `Episodes` component shown in the Apply a layout to a component section is the component to display. The component references the `DoctorWhoLayout` component.

The following `DoctorWhoLayout` component is a modified version of the example shown earlier in this article. The header and footer elements are removed, and the layout references another layout, `ProductionsLayout`. The `Episodes` component is rendered where `@Body` appears in the `DoctorWhoLayout`.

`DoctorWhoLayout.razor`:

razor

```
@inherits LayoutComponentBase
@layout ProductionsLayout

<PageTitle>Doctor Who® Database</PageTitle>

<h1>Doctor Who® Database</h1>

<nav>
    <a href="main-episode-list">Main Episode List</a>
    <a href="episode-search">Search</a>
    <a href="new-episode">Add Episode</a>
</nav>

@Body

<div>
    @TrademarkMessage
</div>

@code {
    public string TrademarkMessage { get; set; } =
        "Doctor Who is a registered trademark of the BBC. " +
        "https://www.doctorwho.tv/ https://www.bbc.com";
}
```

The `ProductionsLayout` component contains the top-level layout elements, where the header (`<header>...</header>`) and footer (`<footer>...</footer>`) elements now reside. The `DoctorWhoLayout` with the `Episodes` component is rendered where `@Body` appears.

`ProductionsLayout.razor`:

razor

```razor
@inherits LayoutComponentBase

<header>
    <h1>Productions</h1>
</header>

<nav>
    <a href="main-production-list">Main Production List</a>
    <a href="production-search">Search</a>
    <a href="new-production">Add Production</a>
</nav>

@Body

<footer>
    Footer of Productions Layout
</footer>
```

The following rendered HTML markup is produced by the preceding nested layout. Extraneous markup doesn't appear in order to focus on the nested content provided by the three components involved:

- The header (`<header>...</header>`), production navigation bar (`<nav>...</nav>`), and footer (`<footer>...</footer>`) elements and their content come from the `ProductionsLayout` component.
- The H1 "database" heading (`<h1>...</h1>`), episode navigation bar (`<nav>...</nav>`), and trademark information (`<div>...</div>`) come from the `DoctorWhoLayout` component.
- The H2 "episodes" heading (`<h2>...</h2>`) and episode list (`<ul>...</ul>`) come from the `Episodes` component.

HTML

```html
<header>
    ...
</header>

<nav>
    <a href="main-production-list">Main Production List</a>
```

```
    <a href="production-search">Search</a>
    <a href="new-production">Add Production</a>
</nav>

<h1>...</h1>

<nav>
    <a href="main-episode-list">Main Episode List</a>
    <a href="episode-search">Search</a>
    <a href="new-episode">Add Episode</a>
</nav>

<h2>...</h2>

<ul>
    <li>...</li>
    <li>...</li>
    <li>...</li>
</ul>

<div>
    ...
</div>

<footer>
    ...
</footer>
```

Share a Razor Pages layout with integrated components

When routable components are integrated into a Razor Pages app, the app's shared layout can be used with the components. For more information, see Integrate ASP.NET Core Razor components into ASP.NET Core apps.

Sections

To control the content in a layout from a child Razor component, see ASP.NET Core Blazor sections.

- Layout in ASP.NET Core
- Blazor samples GitHub repository (dotnet/blazor-samples) (how to download)

ASP.NET Core Blazor sections

Article • 03/01/2024

This article explains how to control the content in a Razor component from a child Razor component.

Blazor sections

To control the content in a Razor component from a child Razor component, Blazor supports *sections* using the following built-in components:

- SectionOutlet: Renders content provided by SectionContent components with matching SectionName or SectionId arguments. Two or more SectionOutlet components can't have the same SectionName or SectionId.
- SectionContent: Provides content as a RenderFragment to SectionOutlet components with a matching SectionName or SectionId. If several SectionContent components have the same SectionName or SectionId, the matching SectionOutlet component renders the content of the last rendered SectionContent.

Sections can be used in both layouts and across nested parent-child components.

Although the argument passed to SectionName can use any type of casing, the documentation adopts kebab casing (for example, `top-bar`), which is a common casing choice for HTML element IDs. SectionId receives a static `object` field, and we always recommend Pascal casing for C# field names (for example, `TopbarSection`).

In the following example, the app's main layout component implements an increment counter button for the app's `Counter` component.

If the namespace for sections isn't in the `_Imports.razor` file, add it:

razor

```
@using Microsoft.AspNetCore.Components.Sections
```

In the `MainLayout` component (`MainLayout.razor`), place a SectionOutlet component and pass a string to the SectionName parameter to indicate the section's name. The following example uses the section name `top-bar`:

razor

```razor
<SectionOutlet SectionName="top-bar" />
```

In the `Counter` component (`Counter.razor`), create a SectionContent component and pass the matching string (`top-bar`) to its SectionName parameter:

razor

```razor
<SectionContent SectionName="top-bar">
    <button class="btn btn-primary" @onclick="IncrementCount">Click
me</button>
</SectionContent>
```

When the `Counter` component is accessed at `/counter`, the `MainLayout` component renders the increment count button from the `Counter` component where the SectionOutlet component is placed. When any other component is accessed, the increment count button isn't rendered.

Instead of using a named section, you can pass a static `object` with the SectionId parameter to identify the section. The following example also implements an increment counter button for the app's `Counter` component in the app's main layout.

If you don't want other SectionContent components to accidentally match the name of a SectionOutlet, pass an object SectionId parameter to identify the section. This can be useful when designing a Razor class library (RCL). When a SectionOutlet in the RCL uses an object reference with SectionId and the consumer places a SectionContent component with a matching SectionId object, an accidental match by name isn't possible when consumers of the RCL implement other SectionContent components.

The following example also implements an increment counter button for the app's `Counter` component in the app's main layout, using an object reference instead of a section name.

Add a `TopbarSection` static `object` to the `MainLayout` component in an `@code` block:

razor

```razor
@code {
    internal static object TopbarSection = new();
}
```

In the `MainLayout` component's Razor markup, place a SectionOutlet component and pass `TopbarSection` to the SectionId parameter to indicate the section:

razor

```razor
<SectionOutlet SectionId="TopbarSection" />
```

Add a SectionContent component to the app's `Counter` component that renders an increment count button. Use the `MainLayout` component's `TopbarSection` section static `object` as the SectionId (`MainLayout.TopbarSection`).

In `Counter.razor`:

razor

```razor
<SectionContent SectionId="MainLayout.TopbarSection">
    <button class="btn btn-primary" @onclick="IncrementCount">Click
me</button>
</SectionContent>
```

When the `Counter` component is accessed, the `MainLayout` component renders the increment count button where the SectionOutlet component is placed.

> **Note**
>
> SectionOutlet and SectionContent components can only set either SectionId or SectionName, not both.

Section interaction with other Blazor features

A section interacts with other Blazor features in the following ways:

- Cascading values flow into section content from where the content is defined by the SectionContent component.
- Unhandled exceptions are handled by error boundaries defined around a SectionContent component.
- A Razor component configured for streaming rendering also configures section content provided by a SectionContent component to use streaming rendering.

Control `<head>` content in ASP.NET Core Blazor apps

Article • 10/18/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

Razor components can modify the HTML `<head>` element content of a page, including setting the page's title (`<title>` element) and modifying metadata (`<meta>` elements).

Control `<head>` content in a Razor component

Specify the page's title with the PageTitle component, which enables rendering an HTML `<title>` element to a HeadOutlet component.

Specify `<head>` element content with the HeadContent component, which provides content to a HeadOutlet component.

The following example sets the page's title and description using Razor.

`ControlHeadContent.razor`:

razor

```
@page "/control-head-content"

<PageTitle>@title</PageTitle>

<h1>Control <head> Content Example</h1>

<p>
    Title: @title
</p>

<p>
    Description: @description
</p>
```

```razor
<HeadContent>
    <meta name="description" content="@description">
</HeadContent>

@code {
    private string description = "This description is set by the
component.";
    private string title = "Control <head> Content";
}
```

Set a page title for components via a layout

Set the page title in a layout component:

razor

```razor
@inherits LayoutComponentBase

<PageTitle>Page Title</PageTitle>

<div class="page">
    ...
</div>
```

`HeadOutlet` component

The HeadOutlet component renders content provided by PageTitle and HeadContent components.

In a Blazor Web App created from the project template, the HeadOutlet component in `App.razor` renders `<head>` content:

razor

```razor
<head>
    ...
    <HeadOutlet />
</head>
```

In an app created from the Blazor WebAssembly project template, the HeadOutlet component is added to the RootComponents collection of the WebAssemblyHostBuilder in the client-side `Program` file:

C#

```
builder.RootComponents.Add<HeadOutlet>("head::after");
```

When the ::after pseudo-selector is specified, the contents of the root component are appended to the existing head contents instead of replacing the content. This allows the app to retain static head content in `wwwroot/index.html` without having to repeat the content in the app's Razor components.

Set a default page title in a Blazor Web App

Set the page title in the `App` component (`App.razor`):

razor

```
<head>
    ...
    <HeadOutlet />
    <PageTitle>Page Title</PageTitle>
</head>
```

Not found page title in a Blazor WebAssembly app

In Blazor apps created from the Blazor WebAssembly Standalone App project template, the `NotFound` component template in the `App` component (`App.razor`) sets the page title to `Not found`.

`App.razor`:

razor

```
<NotFound>
    <PageTitle>Not found</PageTitle>
    ...
</NotFound>
```

ASP.NET Core Blazor cascading values and parameters

Article • 10/18/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article explains how to flow data from an ancestor Razor component to descendent components.

Cascading values and parameters provide a convenient way to flow data down a component hierarchy from an ancestor component to any number of descendent components. Unlike Component parameters, cascading values and parameters don't require an attribute assignment for each descendent component where the data is consumed. Cascading values and parameters also allow components to coordinate with each other across a component hierarchy.

> **Note**
>
> The code examples in this article adopt nullable reference types (NRTs) and .NET compiler null-state static analysis, which are supported in ASP.NET Core in .NET 6 or later. When targeting ASP.NET Core 5.0 or earlier, remove the null type designation (`?`) from the `CascadingType?`, `@ActiveTab?`, `RenderFragment?`, `ITab?`, `TabSet?`, and `string?` types in the article's examples.

Root-level cascading values

Root-level cascading values can be registered for the entire component hierarchy. Named cascading values and subscriptions for update notifications are supported.

The following class is used in this section's examples.

`Dalek.cs`:

C#

```
// "Dalek" ©Terry Nation https://www.imdb.com/name/nm0622334/
// "Doctor Who" ©BBC https://www.bbc.co.uk/programmes/b006q2x0

namespace BlazorSample;

public class Dalek
{
    public int Units { get; set; }
}
```

The following registrations are made in the app's `Program` file with AddCascadingValue:

- `Dalek` with a property value for `Units` is registered as a fixed cascading value.
- A second `Dalek` registration with a different property value for `Units` is named "`AlphaGroup`".

C#

```
builder.Services.AddCascadingValue(sp => new Dalek { Units = 123 });
builder.Services.AddCascadingValue("AlphaGroup", sp => new Dalek { Units =
456 });
```

The following `Daleks` component displays the cascaded values.

`Daleks.razor`:

razor

```
@page "/daleks"

<PageTitle>Daleks</PageTitle>

<h1>Root-level Cascading Value Example</h1>

<ul>
    <li>Dalek Units: @Dalek?.Units</li>
    <li>Alpha Group Dalek Units: @AlphaGroupDalek?.Units</li>
</ul>

<p>
    Dalek© <a href="https://www.imdb.com/name/nm0622334/">Terry Nation</a>
<br>
    Doctor Who© <a href="https://www.bbc.co.uk/programmes/b006q2x0">BBC</a>
</p>

@code {
    [CascadingParameter]
    public Dalek? Dalek { get; set; }
```

```
    [CascadingParameter(Name = "AlphaGroup")]
    public Dalek? AlphaGroupDalek { get; set; }
}
```

In the following example, `Dalek` is registered as a cascading value using CascadingValueSource<T>, where `<T>` is the type. The `isFixed` flag indicates whether the value is fixed. If false, all recipients are subscribed for update notifications, which are issued by calling NotifyChangedAsync. Subscriptions create overhead and reduce performance, so set `isFixed` to `true` if the value doesn't change.

C#

```
builder.Services.AddCascadingValue(sp =>
{
    var dalek = new Dalek { Units = 789 };
    var source = new CascadingValueSource<Dalek>(dalek, isFixed: false);

    return source;
});
```

> ⚠ **Warning**
>
> Registering a component type as a root-level cascading value doesn't register additional services for the type or permit service activation in the component.
>
> Treat required services separately from cascading values, registering them separately from the cascaded type.
>
> Avoid using AddCascadingValue to register a component type as a cascading value. Instead, wrap the `<Router>...</Router>` in the `Routes` component (`Components/Routes.razor`) with the component and adopt global interactive server-side rendering (interactive SSR). For an example, see the CascadingValue component section.

`CascadingValue` component

An ancestor component provides a cascading value using the Blazor framework's CascadingValue component, which wraps a subtree of a component hierarchy and supplies a single value to all of the components within its subtree.

The following example demonstrates the flow of theme information down the component hierarchy to provide a CSS style class to buttons in child components.

The following `ThemeInfo` C# class specifies the theme information.

> **Note**
>
> For the examples in this section, the app's namespace is `BlazorSample`. When experimenting with the code in your own sample app, change the app's namespace to your sample app's namespace.

`ThemeInfo.cs`:

```
C#

namespace BlazorSample;

public class ThemeInfo
{
    public string? ButtonClass { get; set; }
}
```

The following layout component specifies theme information (`ThemeInfo`) as a cascading value for all components that make up the layout body of the Body property. `ButtonClass` is assigned a value of btn-success, which is a Bootstrap button style. Any descendent component in the component hierarchy can use the `ButtonClass` property through the `ThemeInfo` cascading value.

`MainLayout.razor`:

```
razor

@inherits LayoutComponentBase

<div class="page">
    <div class="sidebar">
        <NavMenu />
    </div>

    <main>
        <div class="top-row px-4">
            <a href="https://learn.microsoft.com/aspnet/core/"
target="_blank">About</a>
        </div>

        <CascadingValue Value="theme">
            <article class="content px-4">
                @Body
            </article>
        </CascadingValue>
```

```
    </main>
</div>

<div id="blazor-error-ui" data-nosnippet>
    An unhandled error has occurred.
    <a href="." class="reload">Reload</a>
    <span class="dismiss">✕</span>
</div>

@code {
    private ThemeInfo theme = new() { ButtonClass = "btn-success" };
}
```

Blazor Web Apps provide alternative approaches for cascading values that apply more broadly to the app than furnishing them via a single layout file:

- Wrap the markup of the `Routes` component in a CascadingValue component to specify the data as a cascading value for all of the app's components.

  The following example cascades `ThemeInfo` data from the `Routes` component.

  `Routes.razor`:

  razor

  ```
  <CascadingValue Value="theme">
      <Router ...>
          ...
      </Router>
  </CascadingValue>

  @code {
      private ThemeInfo theme = new() { ButtonClass = "btn-success" };
  }
  ```

  > **Note**
  >
  > Wrapping the `Routes` component instance in the `App` component (`Components/App.razor`) with a CascadingValue component isn't supported.

- Specify a *root-level cascading value* as a service by calling the AddCascadingValue extension method on the service collection builder.

  The following example cascades `ThemeInfo` data from the `Program` file.

  `Program.cs`

C#

```
builder.Services.AddCascadingValue(sp =>
    new ThemeInfo() { ButtonClass = "btn-primary" });
```

For more information, see the following sections of this article:

- Root-level cascading values
- Cascading values/parameters and render mode boundaries

`[CascadingParameter]` attribute

To make use of cascading values, descendent components declare cascading parameters using the [CascadingParameter] attribute. Cascading values are bound to cascading parameters **by type**. Cascading multiple values of the same type is covered in the Cascade multiple values section later in this article.

The following component binds the `ThemeInfo` cascading value to a cascading parameter, optionally using the same name of `ThemeInfo`. The parameter is used to set the CSS class for the **`Increment Counter (Themed)`** button.

`ThemedCounter.razor`:

razor

```
@page "/themed-counter"

<PageTitle>Themed Counter</PageTitle>

<h1>Themed Counter Example</h1>

<p>Current count: @currentCount</p>

<p>
    <button @onclick="IncrementCount">
        Increment Counter (Unthemed)
    </button>
</p>

<p>
    <button
        class="btn @(ThemeInfo is not null ? ThemeInfo.ButtonClass :
string.Empty)"
        @onclick="IncrementCount">
        Increment Counter (Themed)
    </button>
</p>
```

```
@code {
    private int currentCount = 0;

    [CascadingParameter]
    protected ThemeInfo? ThemeInfo { get; set; }

    private void IncrementCount() => currentCount++;
}
```

Similar to a regular component parameter, components accepting a cascading parameter are rerendered when the cascading value is changed. For instance, configuring a different theme instance causes the `ThemedCounter` component from the CascadingValue component section to rerender.

`MainLayout.razor`:

razor

```
<main>
    <div class="top-row px-4">
        <a href="https://docs.microsoft.com/aspnet/"
target="_blank">About</a>
    </div>

    <CascadingValue Value="theme">
        <article class="content px-4">
            @Body
        </article>
    </CascadingValue>
    <button @onclick="ChangeToDarkTheme">Dark mode</button>
</main>

@code {
    private ThemeInfo theme = new() { ButtonClass = "btn-success" };

    private void ChangeToDarkTheme()
    {
        theme = new() { ButtonClass = "btn-secondary" };
    }
}
```

CascadingValue<TValue>.IsFixed can be used to indicate that a cascading parameter doesn't change after initialization.

Cascading values/parameters and render mode boundaries

Cascading parameters don't pass data across render mode boundaries:

- Interactive sessions run in a different context than the pages that use static server-side rendering (static SSR). There's no requirement that the server producing the page is even the same machine that hosts some later Interactive Server session, including for WebAssembly components where the server is a different machine to the client. The benefit of static server-side rendering (static SSR) is to gain the full performance of pure stateless HTML rendering.
- State crossing the boundary between static and interactive rendering must be serializable. Components are arbitrary objects that reference a vast chain of other objects, including the renderer, the DI container, and every DI service instance. You must explicitly cause state to be serialized from static SSR to make it available in subsequent interactively-rendered components. Two approaches are adopted:
  - Via the Blazor framework, parameters passed across a static SSR to interactive rendering boundary are serialized automatically if they're JSON-serializable, or an error is thrown.
  - State stored in PersistentComponentState is serialized and recovered automatically if it's JSON-serializable, or an error is thrown.

Cascading parameters aren't JSON-serializable because the typical usage patterns for cascading parameters are somewhat like DI services. There are often platform-specific variants of cascading parameters, so it would be unhelpful to developers if the framework stopped developers from having server-interactive-specific versions or WebAssembly-specific versions. Also, many cascading parameter values in general aren't serializable, so it would be impractical to update existing apps if you had to stop using all nonserializable cascading parameter values.

Recommendations:

- If you need to make state available to all interactive components as a cascading parameter, we recommend using root-level cascading values. A factory pattern is available, and the app can emit updated values after app startup. Root-level cascading values are available to all components, including interactive components, since they're processed as DI services.
- For component library authors, you can create an extension method for library consumers similar to the following:

```
C#

builder.Services.AddLibraryCascadingParameters();
```

Instruct developers to call your extension method. This is a sound alternative to instructing them to add a `<RootComponent>` component in their `MainLayout` component.

Cascade multiple values

To cascade multiple values of the same type within the same subtree, provide a unique Name string to each CascadingValue component and their corresponding [CascadingParameter] attributes.

In the following example, two CascadingValue components cascade different instances of `CascadingType`:

razor

```
<CascadingValue Value="parentCascadeParameter1" Name="CascadeParam1">
    <CascadingValue Value="ParentCascadeParameter2" Name="CascadeParam2">
        ...
    </CascadingValue>
</CascadingValue>

@code {
    private CascadingType? parentCascadeParameter1;

    [Parameter]
    public CascadingType? ParentCascadeParameter2 { get; set; }
}
```

In a descendant component, the cascaded parameters receive their cascaded values from the ancestor component by Name:

razor

```
@code {
    [CascadingParameter(Name = "CascadeParam1")]
    protected CascadingType? ChildCascadeParameter1 { get; set; }

    [CascadingParameter(Name = "CascadeParam2")]
    protected CascadingType? ChildCascadeParameter2 { get; set; }
}
```

Pass data across a component hierarchy

Cascading parameters also enable components to pass data across a component hierarchy. Consider the following UI tab set example, where a tab set component

maintains a series of individual tabs.

> **Note**
>
> For the examples in this section, the app's namespace is `BlazorSample`. When experimenting with the code in your own sample app, change the namespace to your sample app's namespace.

Create an `ITab` interface that tabs implement in a folder named `UIInterfaces`.

`UIInterfaces/ITab.cs`:

C#

```
using Microsoft.AspNetCore.Components;

namespace BlazorSample.UIInterfaces;

public interface ITab
{
    RenderFragment ChildContent { get; }
}
```

> **Note**
>
> For more information on RenderFragment, see ASP.NET Core Razor components.

The following `TabSet` component maintains a set of tabs. The tab set's `Tab` components, which are created later in this section, supply the list items (`<li>...</li>`) for the list (`<ul>...</ul>`).

Child `Tab` components aren't explicitly passed as parameters to the `TabSet`. Instead, the child `Tab` components are part of the child content of the `TabSet`. However, the `TabSet` still needs a reference each `Tab` component so that it can render the headers and the active tab. To enable this coordination without requiring additional code, the `TabSet` component *can provide itself as a cascading value* that is then picked up by the descendent `Tab` components.

`TabSet.razor`:

razor

```razor
@using BlazorSample.UIInterfaces

<!-- Display the tab headers -->

<CascadingValue Value="this">
    <ul class="nav nav-tabs">
        @ChildContent
    </ul>
</CascadingValue>

<!-- Display body for only the active tab -->

<div class="nav-tabs-body p-4">
    @ActiveTab?.ChildContent
</div>

@code {
    [Parameter]
    public RenderFragment? ChildContent { get; set; }

    public ITab? ActiveTab { get; private set; }

    public void AddTab(ITab tab)
    {
        if (ActiveTab is null)
        {
            SetActiveTab(tab);
        }
    }

    public void SetActiveTab(ITab tab)
    {
        if (ActiveTab != tab)
        {
            ActiveTab = tab;
            StateHasChanged();
        }
    }
}
```

Descendent `Tab` components capture the containing `TabSet` as a cascading parameter. The `Tab` components add themselves to the `TabSet` and coordinate to set the active tab.

`Tab.razor`:

razor

```razor
@using BlazorSample.UIInterfaces
@implements ITab
```

```
<li>
    <a @onclick="ActivateTab" class="nav-link @TitleCssClass" role="button">
        @Title
    </a>
</li>

@code {
    [CascadingParameter]
    public TabSet? ContainerTabSet { get; set; }

    [Parameter]
    public string? Title { get; set; }

    [Parameter]
    public RenderFragment? ChildContent { get; set; }

    private string? TitleCssClass =>
        ContainerTabSet?.ActiveTab == this ? "active" : null;

    protected override void OnInitialized()
    {
        ContainerTabSet?.AddTab(this);
    }

    private void ActivateTab()
    {
        ContainerTabSet?.SetActiveTab(this);
    }
}
```

The following `ExampleTabSet` component uses the `TabSet` component, which contains three `Tab` components.

`ExampleTabSet.razor`:

razor

```
@page "/example-tab-set"

<TabSet>
    <Tab Title="First tab">
        <h4>Greetings from the first tab!</h4>

        <label>
            <input type="checkbox" @bind="showThirdTab" />
            Toggle third tab
        </label>
    </Tab>

    <Tab Title="Second tab">
        <h4>Hello from the second tab!</h4>
    </Tab>
```

```
    @if (showThirdTab)
    {
        <Tab Title="Third tab">
            <h4>Welcome to the disappearing third tab!</h4>
            <p>Toggle this tab from the first tab.</p>
        </Tab>
    }
</TabSet>

@code {
    private bool showThirdTab;
}
```

ASP.NET Core Blazor event handling

Article • 10/18/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article explains Blazor's event handling features, including event argument types, event callbacks, and managing default browser events.

Delegate event handlers

Specify delegate event handlers in Razor component markup with `@on{DOM EVENT}="{DELEGATE}"` Razor syntax:

- The `{DOM EVENT}` placeholder is a DOM event (for example, `click`).
- The `{DELEGATE}` placeholder is the C# delegate event handler.

For event handling:

- Delegate event handlers in Blazor Web Apps are only called in components that adopt an interactive render mode. The examples throughout this article assume that the app adopts an interactive render mode globally in the app's root component, typically the `App` component. For more information, see ASP.NET Core Blazor render modes.
- Asynchronous delegate event handlers that return a Task are supported.
- Delegate event handlers automatically trigger a UI render, so there's no need to manually call StateHasChanged.
- Exceptions are logged.

The following code:

- Calls the `UpdateHeading` method when the button is selected in the UI.
- Calls the `CheckChanged` method when the checkbox is changed in the UI.

`EventHandler1.razor`:

razor

```razor
@page "/event-handler-1"

<PageTitle>Event Handler 1</PageTitle>

<h1>Event Handler Example 1</h1>

<h2>@headingValue</h2>

<p>
    <button @onclick="UpdateHeading">
        Update heading
    </button>
</p>

<p>
    <label>
        <input type="checkbox" @onchange="CheckChanged" />
        @checkedMessage
    </label>
</p>

@code {
    private string headingValue = "Initial heading";
    private string checkedMessage = "Not changed yet";

    private void UpdateHeading() => headingValue = $"New heading
({DateTime.Now})";

    private void CheckChanged() => checkedMessage = $"Last change
{DateTime.Now}";
}
```

In the following example, `UpdateHeading`:

- Is called asynchronously when the button is selected.
- Waits two seconds before updating the heading.

`EventHandler2.razor`:

razor

```razor
@page "/event-handler-2"

<PageTitle>Event Handler 2</PageTitle>

<h1>Event Handler Example 2</h1>

<h2>@headingValue</h2>

<p>
```

```
    <button @onclick="UpdateHeading">
        Update heading
    </button>
</p>

@code {
    private string headingValue = "Initial heading";

    private async Task UpdateHeading()
    {
        await Task.Delay(2000);

        headingValue = $"New heading ({DateTime.Now})";
    }
}
```

Built-in event arguments

For events that support an event argument type, specifying an event parameter in the event method definition is only necessary if the event type is used in the method. In the following example, MouseEventArgs is used in the `ReportPointerLocation` method to set message text that reports the mouse coordinates when the user selects a button in the UI.

`EventHandler3.razor`:

razor

```
@page "/event-handler-3"

<PageTitle>Event Handler 3</PageTitle>

<h1>Event Handler Example 3</h1>

@for (var i = 0; i < 4; i++)
{
    <p>
        <button @onclick="ReportPointerLocation">
            Where's my mouse pointer for this button?
        </button>
    </p>
}

<p>@mousePointerMessage</p>

@code {
    private string? mousePointerMessage;

    private void ReportPointerLocation(MouseEventArgs e) =>
```

```
        mousePointerMessage = $"Mouse coordinates: {e.ScreenX}:{e.ScreenY}";
}
```

Supported EventArgs are shown in the following table.

Expand table

Event	Class	DOM notes
Clipboard	ClipboardEventArgs	
Drag	DragEventArgs	DataTransfer and DataTransferItem hold dragged item data. Implement drag and drop in Blazor apps using JS interop with HTML Drag and Drop API.
Error	ErrorEventArgs	
Event	EventArgs	EventHandlers holds attributes to configure the mappings between event names and event argument types.
Focus	FocusEventArgs	Doesn't include support for `relatedTarget`.
Input	ChangeEventArgs	
Keyboard	KeyboardEventArgs	
Mouse	MouseEventArgs	
Mouse pointer	PointerEventArgs	
Mouse wheel	WheelEventArgs	
Progress	ProgressEventArgs	
Touch	TouchEventArgs	TouchPoint represents a single contact point on a touch-sensitive device.

For more information, see the following resources:

- EventArgs classes in the ASP.NET Core reference source (dotnet/aspnetcore main branch)

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release

of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

- EventHandlers holds attributes to configure the mappings between event names and event argument types.

Custom event arguments

Blazor supports custom event arguments, which enable you to pass arbitrary data to .NET event handlers with custom events.

General configuration

Custom events with custom event arguments are generally enabled with the following steps.

In JavaScript, define a function for building the custom event argument object from the source event:

JavaScript

```
function eventArgsCreator(event) {
  return {
    customProperty1: 'any value for property 1',
    customProperty2: event.srcElement.id
  };
}
```

The `event` parameter is a DOM Event (MDN documentation).

Register the custom event with the preceding handler in a JavaScript initializer. Provide the appropriate browser event name to `browserEventName`, which for the example shown in this section is `click` for a button selection in the UI.

`wwwroot/{PACKAGE ID/ASSEMBLY NAME}.lib.module.js` (the `{PACKAGE ID/ASSEMBLY NAME}` placeholder is the package ID or assembly name of the app):

For a Blazor Web App:

JavaScript

```
export function afterWebStarted(blazor) {
  blazor.registerCustomEventType('customevent', {
```

```
    browserEventName: 'click',
    createEventArgs: eventArgsCreator
  });
}
```

For a Blazor Server or Blazor WebAssembly app:

JavaScript

```
export function afterStarted(blazor) {
  blazor.registerCustomEventType('customevent', {
    browserEventName: 'click',
    createEventArgs: eventArgsCreator
  });
}
```

The call to `registerCustomEventType` is performed in a script only once per event.

For the call to `registerCustomEventType`, use the `blazor` parameter (lowercase `b`) provided by the Blazor start event. Although the registration is valid when using the `Blazor` object (uppercase `B`), the preferred approach is to use the parameter.

The custom event name, `customevent` in the preceding example, must not match a reserved Blazor event name. The reserved names can be found in the Blazor framework reference source (see the calls to the registerBuiltInEventType function).

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Define a class for the event arguments:

C#

```
namespace BlazorSample.CustomEvents;

public class CustomEventArgs : EventArgs
{
    public string? CustomProperty1 {get; set;}
    public string? CustomProperty2 {get; set;}
}
```

Wire up the custom event with the event arguments by adding an [EventHandler] attribute annotation for the custom event:

- In order for the compiler to find the `[EventHandler]` class, it must be placed into a C# class file (`.cs`), making it a normal top-level class.
- Mark the class `public`.
- The class doesn't require members.
- The class *must* be called "`EventHandlers`" in order to be found by the Razor compiler.
- Place the class under a namespace specific to your app.
- Import the namespace into the Razor component (`.razor`) where the event is used.

C#

```
using Microsoft.AspNetCore.Components;

namespace BlazorSample.CustomEvents;

[EventHandler("oncustomevent", typeof(CustomEventArgs),
    enableStopPropagation: true, enablePreventDefault: true)]
public static class EventHandlers
{
}
```

Register the event handler on one or more HTML elements. Access the data that was passed in from JavaScript in the delegate handler method:

razor

```
@using BlazorSample.CustomEvents

<button id="buttonId" @oncustomevent="HandleCustomEvent">Handle</button>

@if (!string.IsNullOrEmpty(propVal1) && !string.IsNullOrEmpty(propVal2))
{
    <ul>
        <li>propVal1: @propVal1</li>
        <li>propVal2: @propVal2</li>
    </ul>
}

@code
{
    private string? propVal1;
    private string? propVal2;

    private void HandleCustomEvent(CustomEventArgs eventArgs)
```

```
    {
        propVal1 = eventArgs.CustomProperty1;
        propVal2 = eventArgs.CustomProperty2;
    }
}
```

If the `@oncustomevent` attribute isn't recognized by IntelliSense, make sure that the component or the `_Imports.razor` file contains an `@using` statement for the namespace containing the `EventHandler` class.

Whenever the custom event is fired on the DOM, the event handler is called with the data passed from the JavaScript.

If you're attempting to fire a custom event, bubbles must be enabled by setting its value to `true`. Otherwise, the event doesn't reach the Blazor handler for processing into the C# custom [EventHandler] attribute class. For more information, see MDN Web Docs: Event bubbling.

Custom clipboard paste event example

The following example receives a custom clipboard paste event that includes the time of the paste and the user's pasted text.

Declare a custom name (`oncustompaste`) for the event and a .NET class (`CustomPasteEventArgs`) to hold the event arguments for this event:

`CustomEvents.cs`:

C#

```
using Microsoft.AspNetCore.Components;

namespace BlazorSample.CustomEvents;

[EventHandler("oncustompaste", typeof(CustomPasteEventArgs),
    enableStopPropagation: true, enablePreventDefault: true)]
public static class EventHandlers
{
}

public class CustomPasteEventArgs : EventArgs
{
    public DateTime EventTimestamp { get; set; }
    public string? PastedData { get; set; }
}
```

Add JavaScript code to supply data for the EventArgs subclass with the preceding handler in a JavaScript initializer. The following example only handles pasting text, but you could use arbitrary JavaScript APIs to deal with users pasting other types of data, such as images.

`wwwroot/{PACKAGE ID/ASSEMBLY NAME}.lib.module.js`:

For a Blazor Web App:

JavaScript

```
export function afterWebStarted(blazor) {
  blazor.registerCustomEventType('custompaste', {
    browserEventName: 'paste',
    createEventArgs: event => {
      return {
        eventTimestamp: new Date(),
        pastedData: event.clipboardData.getData('text')
      };
    }
  });
}
```

For a Blazor Server or Blazor WebAssembly app:

JavaScript

```
export function afterStarted(blazor) {
  blazor.registerCustomEventType('custompaste', {
    browserEventName: 'paste',
    createEventArgs: event => {
      return {
        eventTimestamp: new Date(),
        pastedData: event.clipboardData.getData('text')
      };
    }
  });
}
```

In the preceding example, the `{PACKAGE ID/ASSEMBLY NAME}` placeholder of the file name represents the package ID or assembly name of the app.

> **Note**

For the call to `registerCustomEventType`, use the `blazor` parameter (lowercase `b`) provided by the Blazor start event. Although the registration is valid when using the `Blazor` object (uppercase `B`), the preferred approach is to use the parameter.

The preceding code tells the browser that when a native paste event occurs:

- Raise a `custompaste` event.
- Supply the event arguments data using the custom logic stated:
  - For the `eventTimestamp`, create a new date.
  - For the `pastedData`, get the clipboard data as text. For more information, see MDN Web Docs: ClipboardEvent.clipboardData.

Event name conventions differ between .NET and JavaScript:

- In .NET, event names are prefixed with "`on`".
- In JavaScript, event names don't have a prefix.

In a Razor component, attach the custom handler to an element.

`CustomPasteArguments.razor`:

razor

```
@page "/custom-paste-arguments"
@using BlazorSample.CustomEvents

<label>
    Try pasting into the following text box:
    <input @oncustompaste="HandleCustomPaste" />
</label>

<p>
    @message
</p>

@code {
    private string? message;

    private void HandleCustomPaste(CustomPasteEventArgs eventArgs)
    {
        message = $"At {eventArgs.EventTimestamp.ToShortTimeString()}, " +
            $"you pasted: {eventArgs.PastedData}";
    }
}
```

Lambda expressions

Lambda expressions are supported as the delegate event handler.

`EventHandler4.razor`:

razor

```
@page "/event-handler-4"

<PageTitle>Event Handler 4</PageTitle>

<h1>Event Handler Example 4</h1>

<h2>@heading</h2>

<p>
    <button @onclick="@(e => heading = "New heading!!!")">
        Update heading
    </button>
</p>

@code {
    private string heading = "Initial heading";
}
```

It's often convenient to close over additional values using C# method parameters, such as when iterating over a set of elements. The following example creates three buttons, each of which calls `UpdateHeading` and passes the following data:

- An event argument (MouseEventArgs) in `e`.
- The button number in `buttonNumber`.

`EventHandler5.razor`:

razor

```
@page "/event-handler-5"

<PageTitle>Event Handler 5</PageTitle>

<h1>Event Handler Example 5</h1>

<h2>@heading</h2>

@for (var i = 1; i < 4; i++)
{
    var buttonNumber = i;

    <p>
        <button @onclick="@(e => UpdateHeading(e, buttonNumber))">
            Button #@i
```

```
        </button>
    </p>
}

@code {
    private string heading = "Select a button to learn its position";

    private void UpdateHeading(MouseEventArgs e, int buttonNumber) =>
        heading = $"Selected #{buttonNumber} at {e.ClientX}:{e.ClientY}";
}
```

Creating a large number of event delegates in a loop may cause poor rendering performance. For more information, see ASP.NET Core Blazor performance best practices.

Avoid using a loop variable directly in a lambda expression, such as `i` in the preceding `for` loop example. Otherwise, the same variable is used by all lambda expressions, which results in use of the same value in all lambdas. Capture the variable's value in a local variable. In the preceding example:

- The loop variable `i` is assigned to `buttonNumber`.
- `buttonNumber` is used in the lambda expression.

Alternatively, use a `foreach` loop with Enumerable.Range, which doesn't suffer from the preceding problem:

razor

```
@foreach (var buttonNumber in Enumerable.Range(1, 3))
{
    <p>
        <button @onclick="@(e => UpdateHeading(e, buttonNumber))">
            Button #@buttonNumber
        </button>
    </p>
}
```

EventCallback

A common scenario with nested components is executing a method in a parent component when a child component event occurs. An `onclick` event occurring in the child component is a common use case. To expose events across components, use an EventCallback. A parent component can assign a callback method to a child component's EventCallback.

The following `Child` component demonstrates how a button's `onclick` handler is set up to receive an EventCallback delegate from the sample's `ParentComponent`. The EventCallback is typed with MouseEventArgs, which is appropriate for an `onclick` event from a peripheral device.

`Child.razor`:

razor

```razor
<p>
    <button @onclick="OnClickCallback">
        Trigger a Parent component method
    </button>
</p>

@code {
    [Parameter]
    public string? Title { get; set; }

    [Parameter]
    public RenderFragment? ChildContent { get; set; }

    [Parameter]
    public EventCallback<MouseEventArgs> OnClickCallback { get; set; }
}
```

The parent component sets the child's EventCallback<TValue> (`OnClickCallback`) to its `ShowMessage` method.

`ParentChild.razor`:

razor

```razor
@page "/parent-child"

<PageTitle>Parent Child</PageTitle>

<h1>Parent Child Example</h1>

<Child Title="Panel Title from Parent" OnClickCallback="ShowMessage">
    Content of the child component is supplied by the parent component.
</Child>

<p>@message</p>

@code {
    private string? message;

    private void ShowMessage(MouseEventArgs e) =>
        message = $"Blaze a new trail with Blazor! ({e.ScreenX}:
```

```
{e.ScreenY})";
}
```

When the button is selected in the `ChildComponent`:

- The `Parent` component's `ShowMessage` method is called. `message` is updated and displayed in the `Parent` component.
- A call to StateHasChanged isn't required in the callback's method (`ShowMessage`). StateHasChanged is called automatically to rerender the `Parent` component, just as child events trigger component rerendering in event handlers that execute within the child. For more information, see ASP.NET Core Razor component rendering.

Use EventCallback and EventCallback<TValue> for event handling and binding component parameters.

Prefer the strongly typed EventCallback<TValue> over EventCallback. EventCallback<TValue> provides enhanced error feedback when an inappropriate type is used, guiding users of the component towards correct implementation. Similar to other UI event handlers, specifying the event parameter is optional. Use EventCallback when there's no value passed to the callback.

EventCallback and EventCallback<TValue> permit asynchronous delegates. EventCallback is weakly typed and allows passing any type argument in `InvokeAsync(Object)`. EventCallback<TValue> is strongly typed and requires passing a `T` argument in `InvokeAsync(T)` that's assignable to `TValue`.

Invoke an EventCallback or EventCallback<TValue> with InvokeAsync and await the Task:

C#

```
await OnClickCallback.InvokeAsync({ARGUMENT});
```

In the preceding example, the `{ARGUMENT}` placeholder is an optional argument.

The following parent-child example demonstrates the technique.

`Child2.razor`:

razor

```
<h3>Child2 Component</h3>

<button @onclick="TriggerEvent">Click Me</button>
```

```
@code {
    [Parameter]
    public EventCallback<string> OnClickCallback { get; set; }

    private async Task TriggerEvent()
    {
        await OnClickCallback.InvokeAsync("Blaze It!");
    }
}
```

`ParentChild2.razor`:

razor

```
@page "/parent-child-2"

<PageTitle>Parent Child 2</PageTitle>

<h1>Parent Child 2 Example</h1>

<div>
    <Child2 OnClickCallback="(value) => { message1 = value; }" />
    @message1
</div>

<div>
    <Child2 OnClickCallback=
        "async (value) => { await Task.Delay(2000); message2 = value; }" />
    @message2
</div>

@code {
    private string message1 = string.Empty;
    private string message2 = string.Empty;
}
```

The second occurrence of the `Child2` component demonstrates an asynchronous callback, and the new `message2` value is assigned and rendered with a delay of two seconds.

Prevent default actions

Use the @on{DOM EVENT}:preventDefault directive attribute to prevent the default action for an event, where the `{DOM EVENT}` placeholder is a DOM event.

When a key is selected on an input device and the element focus is on a text box, a browser normally displays the key's character in the text box. In the following example, the default behavior is prevented by specifying the `@onkeydown:preventDefault` directive

attribute. When the focus is on the `<input>` element, the counter increments with the key sequence `Shift`+`+`. The `+` character isn't assigned to the `<input>` element's value. For more information on `keydown`, see MDN Web Docs: Document: keydown event.

`EventHandler6.razor`:

razor

```razor
@page "/event-handler-6"

<PageTitle>Event Handler 6</PageTitle>

<h1>Event Handler Example 6</h1>

<p>For this example, give the <code><input></code> focus.</p>

<p>
    <label>
        Count of '+' key presses:
        <input value="@count" @onkeydown="KeyHandler"
@onkeydown:preventDefault />
    </label>
</p>

@code {
    private int count = 0;

    private void KeyHandler(KeyboardEventArgs e)
    {
        if (e.Key == "+")
        {
            count++;
        }
    }
}
```

Specifying the `@on{DOM EVENT}:preventDefault` attribute without a value is equivalent to `@on{DOM EVENT}:preventDefault="true"`.

An expression is also a permitted value of the attribute. In the following example, `shouldPreventDefault` is a `bool` field set to either `true` or `false`:

razor

```razor
<input @onkeydown:preventDefault="shouldPreventDefault" />

...

@code {
```

```
    private bool shouldPreventDefault = true;
}
```

Stop event propagation

Use the @on{DOM EVENT}:stopPropagation directive attribute to stop event propagation within the Blazor scope. `{DOM EVENT}` is a placeholder for a DOM event.

The `stopPropagation` directive attribute's effect is limited to the Blazor scope and doesn't extend to the HTML DOM. Events must propagate to the HTML DOM root before Blazor can act upon them. For a mechanism to prevent HTML DOM event propagation, consider the following approach:

- Obtain the event's path by calling Event.composedPath().
- Filter events based on the composed event targets (EventTarget).

In the following example, selecting the checkbox prevents click events from the second child `<div>` from propagating to the parent `<div>`. Since propagated click events normally fire the `OnSelectParentDiv` method, selecting the second child `<div>` results in the parent `<div>` message appearing unless the checkbox is selected.

`EventHandler7.razor`:

razor

```
@page "/event-handler-7"

<PageTitle>Event Handler 7</PageTitle>

<h1>Event Handler Example 7</h1>

<div>
    <b>stopPropagation</b>: @stopPropagation
</div>

<div>
    <button @onclick="StopPropagation">
        Stop Propagation (stopPropagation = true)
    </button>
    <button @onclick="EnablePropagation">
        Enable Propagation (stopPropagation = false)
    </button>
</div>

<div class="m-1 p-1 border border-primary" @onclick="OnSelectParentDiv">
    <h3>Parent div</h3>
```

```
    <div class="m-1 p-1 border" @onclick="OnSelectChildDiv">
        Child div that never stops propagation to the parent div when
        selected.
    </div>

    <div class="m-1 p-1 border" @onclick="OnSelectChildDiv"
            @onclick:stopPropagation="stopPropagation">
        Child div that stops propagation when selected if
        <b>stopPropagation</b> is <b>true</b>.
    </div>
</div>

<p>
    @message
</p>

@code {
    private bool stopPropagation = false;
    private string? message;

    private void StopPropagation() => stopPropagation = true;

    private void EnablePropagation() => stopPropagation = false;

    private void OnSelectParentDiv() =>
        message = $"The parent div was selected. {DateTime.Now}";

    private void OnSelectChildDiv() =>
        message = $"The child div was selected. {DateTime.Now}";
}
```

Focus an element

Call FocusAsync on an element reference to focus an element in code. In the following example, select the button to focus the `<input>` element.

`EventHandler8.razor`:

razor

```
@page "/event-handler-8"

<PageTitle>Event Handler 8</PageTitle>

<h1>Event Handler Example 8</h1>

<p>Select the button to give the <code><input></code> focus.</p>

<p>
    <label>
        Input:
```

```
        <input @ref="exampleInput" />
    </label>

</p>

<button @onclick="ChangeFocus">
    Focus the Input Element
</button>

@code {
    private ElementReference exampleInput;

    private async Task ChangeFocus()
    {
        await exampleInput.FocusAsync();
    }
}
```

ASP.NET Core Blazor data binding

Article • 10/18/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article explains data binding features for Razor components and DOM elements in Blazor apps.

Binding features

Razor components provide data binding features with the @bind Razor directive attribute with a field, property, or Razor expression value.

The following example binds:

- An `<input>` element value to the C# `inputValue` field.
- A second `<input>` element value to the C# `InputValue` property.

When an `<input>` element loses focus, its bound field or property is updated.

`Bind.razor`:

razor

```razor
@page "/bind"

<PageTitle>Bind</PageTitle>

<h1>Bind Example</h1>

<p>
    <label>
        inputValue:
        <input @bind="inputValue" />
    </label>
</p>

<p>
    <label>
```

```
        InputValue:
        <input @bind="InputValue" />
    </label>
</p>

<ul>
    <li><code>inputValue</code>: @inputValue</li>
    <li><code>InputValue</code>: @InputValue</li>
</ul>

@code {
    private string? inputValue;

    private string? InputValue { get; set; }
}
```

The text box is updated in the UI only when the component is rendered, not in response to changing the field's or property's value. Since components render themselves after event handler code executes, field and property updates are usually reflected in the UI immediately after an event handler is triggered.

As a demonstration of how data binding composes in HTML, the following example binds the `InputValue` property to the second `<input>` element's `value` and `onchange` attributes (change). *The second `<input>` element in the following example is a concept demonstration and isn't meant to suggest how you should bind data in Razor components.*

`BindTheory.razor`:

razor

```
@page "/bind-theory"

<PageTitle>Bind Theory</PageTitle>

<h1>Bind Theory Example</h1>

<p>
    <label>
        Normal Blazor binding:
        <input @bind="InputValue" />
    </label>
</p>

<p>
    <label>
        Demonstration of equivalent HTML binding:
        <input value="@InputValue" @onchange="@((ChangeEventArgs __e) =>
            InputValue = __e?.Value?.ToString())" />
    </label>
</p>
```

```
<p>
    <code>InputValue</code>: @InputValue
</p>

@code {
    private string? InputValue { get; set; }
}
```

When the `BindTheory` component is rendered, the `value` of the HTML demonstration `<input>` element comes from the `InputValue` property. When the user enters a value in the text box and changes element focus, the `onchange` event is fired and the `InputValue` property is set to the changed value. In reality, code execution is more complex because @bind handles cases where type conversions are performed. In general, @bind associates the current value of an expression with the `value` attribute of the `<input>` and handles changes using the registered handler.

Bind a property or field on other DOM events by including an `@bind:event="{EVENT}"` attribute with a DOM event for the `{EVENT}` placeholder. The following example binds the `InputValue` property to the `<input>` element's value when the element's `oninput` event (input) is triggered. Unlike the `onchange` event (change), which fires when the element loses focus, `oninput` (input) fires when the value of the text box changes.

`Page/BindEvent.razor`:

razor

```
@page "/bind-event"

<PageTitle>Bind Event</PageTitle>

<h1>Bind Event Example</h1>

<p>
    <label>
        InputValue:
        <input @bind="InputValue" @bind:event="oninput" />
    </label>

</p>

<p>
    <code>InputValue</code>: @InputValue
</p>

@code {
```

```
    private string? InputValue { get; set; }
}
```

To execute asynchronous logic after binding, use `@bind:after="{EVENT}"` with a DOM event for the `{EVENT}` placeholder. An assigned C# method isn't executed until the bound value is assigned synchronously.

Using an event callback parameter (EventCallback/EventCallback<T>) with `@bind:after` isn't supported. Instead, pass a method that returns an Action or Task to `@bind:after`.

In the following example:

- Each `<input>` element's `value` is bound to the `searchText` field synchronously.
- The `PerformSearch` method executes asynchronously:
  - When the first box loses focus (`onchange` event) after the value is changed.
  - After each keystroke (`oninput` event) in the second box.
- `PerformSearch` calls a service with an asynchronous method (`FetchAsync`) to return search results.

razor

```
@inject ISearchService SearchService

<input @bind="searchText" @bind:after="PerformSearch" />
<input @bind="searchText" @bind:event="oninput" @bind:after="PerformSearch"
/>

@code {
    private string? searchText;
    private string[]? searchResult;

    private async Task PerformSearch() =>
        searchResult = await SearchService.FetchAsync(searchText);
}
```

Additional examples

`BindAfter.razor`:

razor

```
@page "/bind-after"
@using Microsoft.AspNetCore.Components.Forms

<h1>Bind After Examples</h1>

<h2>Elements</h2>
```

```
<input type="text" @bind="text" @bind:after="() => { }" />

<input type="text" @bind="text" @bind:after="After" />

<input type="text" @bind="text" @bind:after="AfterAsync" />

<h2>Components</h2>

<InputText @bind-Value="text" @bind-Value:after="() => { }" />

<InputText @bind-Value="text" @bind-Value:after="After" />

<InputText @bind-Value="text" @bind-Value:after="AfterAsync" />

@code {
    private string text = "";

    private void After() {}
    private Task AfterAsync() { return Task.CompletedTask; }
}
```

For more information on the `InputText` component, see ASP.NET Core Blazor input components.

Components support two-way data binding by defining a pair of parameters:

- `@bind:get`: Specifies the value to bind.
- `@bind:set`: Specifies a callback for when the value changes.

The `@bind:get` and `@bind:set` modifiers are always used together.

Examples

`BindGetSet.razor`:

razor

```
@page "/bind-get-set"
@using Microsoft.AspNetCore.Components.Forms

<h1>Bind Get Set Examples</h1>

<h2>Elements</h2>

<input type="text" @bind:get="text" @bind:set="(value) => { text = value; }"
/>
<input type="text" @bind:get="text" @bind:set="Set" />
<input type="text" @bind:get="text" @bind:set="SetAsync" />

<h2>Components</h2>
```

```razor
<InputText @bind-Value:get="text" @bind-Value:set="(value) => { text =
value; }" />
<InputText @bind-Value:get="text" @bind-Value:set="Set" />
<InputText @bind-Value:get="text" @bind-Value:set="SetAsync" />

@code {
    private string text = "";

    private void Set(string value)
    {
        text = value;
    }

    private Task SetAsync(string value)
    {
        text = value;
        return Task.CompletedTask;
    }
}
```

For more information on the `InputText` component, see ASP.NET Core Blazor input components.

For another example use of `@bind:get` and `@bind:set`, see the Bind across more than two components section later in this article.

Razor attribute binding is case-sensitive:

- `@bind`, `@bind:event`, and `@bind:after` are valid.
- `@Bind`/`@bind:Event`/`@bind:aftEr` (capital letters) or `@BIND`/`@BIND:EVENT`/`@BIND:AFTER` (all capital letters) **are invalid**.

Use `@bind:get`/`@bind:set` modifiers and avoid event handlers for two-way data binding

Two-way data binding isn't possible to implement with an event handler. Use `@bind:get`/`@bind:set` modifiers for two-way data binding.

❌ Consider the following ***dysfunctional approach*** for two-way data binding using an event handler:

razor

```razor
<p>
    <input value="@inputValue" @oninput="OnInput" />
</p>
```

```
<p>
    <code>inputValue</code>: @inputValue
</p>

@code {
    private string? inputValue;

    private void OnInput(ChangeEventArgs args)
    {
        var newValue = args.Value?.ToString() ?? string.Empty;

        inputValue = newValue.Length > 4 ? "Long!" : newValue;
    }
}
```

The `OnInput` event handler updates the value of `inputValue` to `Long!` after a fourth character is provided. However, the user can continue adding characters to the element value in the UI. The value of `inputValue` isn't bound back to the element's value with each keystroke. The preceding example is only capable of one-way data binding.

The reason for this behavior is that Blazor isn't aware that your code intends to modify the value of `inputValue` in the event handler. Blazor doesn't try to force DOM element values and .NET variable values to match unless they're bound with `@bind` syntax. In earlier versions of Blazor, two-way data binding is implemented by binding the element to a property and controlling the property's value with its setter. In ASP.NET Core in .NET 7 or later, `@bind:get`/`@bind:set` modifier syntax is used to implement two-way data binding, as the next example demonstrates.

✔ Consider the following ***correct approach*** using `@bind:get`/`@bind:set` for two-way data binding:

razor

```
<p>
    <input @bind:event="oninput" @bind:get="inputValue" @bind:set="OnInput"
/>
</p>

<p>
    <code>inputValue</code>: @inputValue
</p>

@code {
    private string? inputValue;

    private void OnInput(string value)
    {
        var newValue = value ?? string.Empty;
```

```
        inputValue = newValue.Length > 4 ? "Long!" : newValue;
    }
}
```

Using `@bind:get`/`@bind:set` modifiers both controls the underlying value of `inputValue` via `@bind:set` and binds the value of `inputValue` to the element's value via `@bind:get`. The preceding example demonstrates the correct approach for implementing two-way data binding.

Binding to a property with C# `get` and `set` accessors

C# get and set accessors can be used to create custom binding format behavior, as the following `DecimalBinding` component demonstrates. The component binds a positive or negative decimal with up to three decimal places to an `<input>` element by way of a `string` property (`DecimalValue`).

`DecimalBinding.razor`:

razor

```
@page "/decimal-binding"
@using System.Globalization

<PageTitle>Decimal Binding</PageTitle>

<h1>Decimal Binding Example</h1>

<p>
    <label>
        Decimal value (±0.000 format):
        <input @bind="DecimalValue" />
    </label>
</p>

<p>
    <code>decimalValue</code>: @decimalValue
</p>

@code {
    private decimal decimalValue = 1.1M;
    private NumberStyles style =
        NumberStyles.AllowDecimalPoint | NumberStyles.AllowLeadingSign;
    private CultureInfo culture = CultureInfo.CreateSpecificCulture("en-
US");
```

```
    private string DecimalValue
    {
        get => decimalValue.ToString("0.000", culture);
        set
        {
            if (Decimal.TryParse(value, style, culture, out var number))
            {
                decimalValue = Math.Round(number, 3);
            }
        }
    }
}
```

> **Note**
>
> Two-way binding to a property with `get`/`set` accessors requires discarding the Task returned by EventCallback.InvokeAsync. For two-way data binding, we recommend using `@bind:get`/`@bind:set` modifiers. For more information, see the `@bind:get`/`@bind:set` guidance in the earlier in this article.

Multiple option selection with `<select>` elements

Binding supports multiple option selection with `<select>` elements. The @onchange event provides an array of the selected elements via event arguments (ChangeEventArgs). The value must be bound to an array type.

`BindMultipleInput.razor`:

razor

```
@page "/bind-multiple-input"

<h1>Bind Multiple <code>input</code>Example</h1>

<p>
    <label>
        Select one or more cars:
        <select @onchange="SelectedCarsChanged" multiple>
            <option value="audi">Audi</option>
            <option value="jeep">Jeep</option>
            <option value="opel">Opel</option>
            <option value="saab">Saab</option>
            <option value="volvo">Volvo</option>
        </select>
    </label>
```

```
</p>

<p>
    Selected Cars: @string.Join(", ", SelectedCars)
</p>

<p>
    <label>
        Select one or more cities:
        <select @bind="SelectedCities" multiple>
            <option value="bal">Baltimore</option>
            <option value="la">Los Angeles</option>
            <option value="pdx">Portland</option>
            <option value="sf">San Francisco</option>
            <option value="sea">Seattle</option>
        </select>
    </label>
</p>

<span>
    Selected Cities: @string.Join(", ", SelectedCities)
</span>

@code {
    public string[] SelectedCars { get; set; } = new string[] { };
    public string[] SelectedCities { get; set; } = new[] { "bal", "sea" };

    private void SelectedCarsChanged(ChangeEventArgs e)
    {
        if (e.Value is not null)
        {
            SelectedCars = (string[])e.Value;
        }
    }
}
```

For information on how empty strings and `null` values are handled in data binding, see the Binding <select> element options to C# object null values section.

Binding `<select>` element options to C# object `null` values

There's no sensible way to represent a `<select>` element option value as a C# object `null` value, because:

- HTML attributes can't have `null` values. The closest equivalent to `null` in HTML is absence of the HTML `value` attribute from the `<option>` element.

- When selecting an `<option>` with no `value` attribute, the browser treats the value as the *text content* of that `<option>`'s element.

The Blazor framework doesn't attempt to suppress the default behavior because it would involve:

- Creating a chain of special-case workarounds in the framework.
- Breaking changes to current framework behavior.

The most plausible `null` equivalent in HTML is an *empty string* `value`. The Blazor framework handles `null` to empty string conversions for two-way binding to a `<select>`'s value.

Unparsable values

When a user provides an unparsable value to a data-bound element, the unparsable value is automatically reverted to its previous value when the bind event is triggered.

Consider the following component, where an `<input>` element is bound to an `int` type with an initial value of `123`.

`UnparsableValues.razor`:

razor

```razor
@page "/unparsable-values"

<PageTitle>Unparsable Values</PageTitle>

<h1>Unparsable Values Example</h1>

<p>
    <label>
        inputValue:
        <input @bind="inputValue" />
    </label>

</p>

<p>
    <code>inputValue</code>: @inputValue
</p>

@code {
    private int inputValue = 123;
}
```

Binding applies to the element's `onchange` event. If the user updates the value of the text box's entry to `123.45` and changes the focus, the element's value is reverted to `123` when `onchange` fires. When the value `123.45` is rejected in favor of the original value of `123`, the user understands that their value wasn't accepted.

For the `oninput` event (`@bind:event="oninput"`), a value reversion occurs after any keystroke that introduces an unparsable value. When targeting the `oninput` event with an `int`-bound type, a user is prevented from typing a dot (`.`) character. A dot (`.`) character is immediately removed, so the user receives immediate feedback that only whole numbers are permitted. There are scenarios where reverting the value on the `oninput` event isn't ideal, such as when the user should be allowed to clear an unparsable `<input>` value. Alternatives include:

- Don't use the `oninput` event. Use the default `onchange` event, where an invalid value isn't reverted until the element loses focus.
- Bind to a nullable type, such as `int?` or `string` and either use `@bind:get`/`@bind:set` modifiers (described earlier in this article) or bind to a property with custom get and set accessor logic to handle invalid entries.
- Use an input component, such as InputNumber<TValue> or InputDate<TValue>, with form validation. Input components together with form validation components provide built-in support to manage invalid inputs:
  - Permit the user to provide invalid input and receive validation errors on the associated EditContext.
  - Display validation errors in the UI without interfering with the user entering additional webform data.

Format strings

Data binding works with a single DateTime format string using `@bind:format="{FORMAT STRING}"`, where the `{FORMAT STRING}` placeholder is the format string. Other format expressions, such as currency or number formats, aren't available at this time but might be added in a future release.

`DateBinding.razor`:

razor

```
@page "/date-binding"

<PageTitle>Date Binding</PageTitle>

<h1>Date Binding Example</h1>
```

```razor
<p>
    <label>
        <code>yyyy-MM-dd</code> format:
        <input @bind="startDate" @bind:format="yyyy-MM-dd" />
    </label>
</p>

<p>
    <code>startDate</code>: @startDate
</p>

@code {
    private DateTime startDate = new(2020, 1, 1);
}
```

In the preceding code, the `<input>` element's field type (`type` attribute) defaults to `text`.

Nullable System.DateTime and System.DateTimeOffset are supported:

C#

```
private DateTime? date;
private DateTimeOffset? dateOffset;
```

Specifying a format for the `date` field type isn't recommended because Blazor has built-in support to format dates. In spite of the recommendation, only use the `yyyy-MM-dd` date format for binding to function correctly if a format is supplied with the `date` field type:

razor

```
<input type="date" @bind="startDate" @bind:format="yyyy-MM-dd">
```

Binding with component parameters

A common scenario is binding a property of a child component to a property in its parent component. This scenario is called a *chained bind* because multiple levels of binding occur simultaneously.

You can't implement chained binds with @bind syntax in a child component. An event handler and value must be specified separately to support updating the property in the parent from the child component. The parent component still leverages @bind syntax to set up data binding with the child component.

The following `ChildBind` component has a `Year` component parameter and an EventCallback<TValue>. By convention, the EventCallback<TValue> for the parameter must be named as the component parameter name with a "`Changed`" suffix. The naming syntax is `{PARAMETER NAME}Changed`, where the `{PARAMETER NAME}` placeholder is the parameter name. In the following example, the EventCallback<TValue> is named `YearChanged`.

EventCallback.InvokeAsync invokes the delegate associated with the binding with the provided argument and dispatches an event notification for the changed property.

`ChildBind.razor`:

razor

```
<div class="card bg-light mt-3" style="width:18rem ">
    <div class="card-body">
        <h3 class="card-title">ChildBind Component</h3>
        <p class="card-text">
            Child <code>Year</code>: @Year
        </p>
        <button @onclick="UpdateYearFromChild">Update Year from
Child</button>
    </div>
</div>

@code {
    [Parameter]
    public int Year { get; set; }

    [Parameter]
    public EventCallback<int> YearChanged { get; set; }

    private async Task UpdateYearFromChild() =>
        await YearChanged.InvokeAsync(Random.Shared.Next(1950, 2021));
}
```

For more information on events and EventCallback<TValue>, see the *EventCallback* section of the ASP.NET Core Blazor event handling article.

In the following `Parent1` component, the `year` field is bound to the `Year` parameter of the child component. The `Year` parameter is bindable because it has a companion `YearChanged` event that matches the type of the `Year` parameter.

`Parent1.razor`:

razor

```razor
@page "/parent-1"

<PageTitle>Parent 1</PageTitle>

<h1>Parent Example 1</h1>

<p>Parent <code>year</code>: @year</p>

<button @onclick="UpdateYear">Update Parent <code>year</code></button>

<ChildBind @bind-Year="year" />

@code {
    private int year = 1979;

    private void UpdateYear() => year = Random.Shared.Next(1950, 2021);
}
```

Component parameter binding can also trigger `@bind:after` events. In the following example, the `YearUpdated` method executes asynchronously after binding the `Year` component parameter.

razor

```razor
<ChildBind @bind-Year="year" @bind-Year:after="YearUpdated" />

@code {
    ...

    private async Task YearUpdated()
    {
        ... = await ...;
    }
}
```

By convention, a property can be bound to a corresponding event handler by including an `@bind-{PROPERTY}:event` attribute assigned to the handler, where the `{PROPERTY}` placeholder is the property. `<ChildBind @bind-Year="year" />` is equivalent to writing:

razor

```razor
<ChildBind @bind-Year="year" @bind-Year:event="YearChanged" />
```

In a more sophisticated and real-world example, the following `PasswordEntry` component:

- Sets an `<input>` element's value to a `password` field.

- Exposes changes of a `Password` property to a parent component with an EventCallback that passes in the current value of the child's `password` field as its argument.
- Uses the `onclick` event to trigger the `ToggleShowPassword` method. For more information, see ASP.NET Core Blazor event handling.

> ⚠ **Warning**
>
> Don't store app secrets, connection strings, credentials, passwords, personal identification numbers (PINs), private C#/.NET code, or private keys/tokens in client-side code, which is ***always insecure***. In test/staging and production environments, server-side Blazor code and web APIs should use secure authentication flows that avoid maintaining credentials within project code or configuration files. Outside of local development testing, we recommend avoiding the use of environment variables to store sensitive data, as environment variables aren't the most secure approach. For local development testing, the Secret Manager tool is recommended for securing sensitive data. For more information, see Securely maintain sensitive data and credentials.

`PasswordEntry.razor`:

razor

```razor
<div class="card bg-light mt-3" style="width:22rem ">
    <div class="card-body">
        <h3 class="card-title">Password Component</h3>
        <p class="card-text">
            <label>
                Password:
                <input @oninput="OnPasswordChanged"
                       required
                       type="@(showPassword ? "text" : "password")"
                       value="@password" />
            </label>
        </p>
        <button class="btn btn-primary" @onclick="ToggleShowPassword">
            Show password
        </button>
    </div>
</div>

@code {
    private bool showPassword;
    private string? password;

    [Parameter]
    public string? Password { get; set; }
```

```
    [Parameter]
    public EventCallback<string> PasswordChanged { get; set; }

    private async Task OnPasswordChanged(ChangeEventArgs e)
    {
        password = e?.Value?.ToString();

        await PasswordChanged.InvokeAsync(password);
    }

    private void ToggleShowPassword() => showPassword = !showPassword;
}
```

The `PasswordEntry` component is used in another component, such as the following `PasswordBinding` component example.

`PasswordBinding.razor`:

razor

```
@page "/password-binding"

<PageTitle>Password Binding</PageTitle>

<h1>Password Binding Example</h1>

<PasswordEntry @bind-Password="password" />

<p>
    <code>password</code>: @password
</p>

@code {
    private string password = "Not set";
}
```

When the `PasswordBinding` component is initially rendered, the `password` value of `Not set` is displayed in the UI. After initial rendering, the value of `password` reflects changes made to the `Password` component parameter value in the `PasswordEntry` component.

> **Note**
>
> The preceding example binds the password one-way from the child `PasswordEntry` component to the parent `PasswordBinding` component. Two-way binding isn't a requirement in this scenario if the goal is for the app to have a shared password entry component for reuse around the app that merely passes the password to the

parent. For an approach that permits two-way binding without writing directly to the child component's parameter, see the `NestedChild` component example in the Bind across more than two components section of this article.

Perform checks or trap errors in the handler. The following revised `PasswordEntry` component provides immediate feedback to the user if a space is used in the password's value.

`PasswordEntry.razor`:

razor

```razor
<div class="card bg-light mt-3" style="width:22rem ">
    <div class="card-body">
        <h3 class="card-title">Password Component</h3>
        <p class="card-text">
            <label>
                Password:
                <input @oninput="OnPasswordChanged"
                       required
                       type="@(showPassword ? "text" : "password")"
                       value="@password" />
            </label>
            <span class="text-danger">@validationMessage</span>
        </p>
        <button class="btn btn-primary" @onclick="ToggleShowPassword">
            Show password
        </button>
    </div>
</div>

@code {
    private bool showPassword;
    private string? password;
    private string? validationMessage;

    [Parameter]
    public string? Password { get; set; }

    [Parameter]
    public EventCallback<string> PasswordChanged { get; set; }

    private Task OnPasswordChanged(ChangeEventArgs e)
    {
        password = e?.Value?.ToString();

        if (password != null && password.Contains(' '))
        {
            validationMessage = "Spaces not allowed!";

            return Task.CompletedTask;
```

```
        }
        else
        {
            validationMessage = string.Empty;

            return PasswordChanged.InvokeAsync(password);
        }
    }

    private void ToggleShowPassword() => showPassword = !showPassword;
}
```

Bind across more than two components

You can bind parameters through any number of nested components, but you must respect the one-way flow of data:

- Change notifications *flow up the hierarchy*.
- New parameter values *flow down the hierarchy*.

A common and recommended approach is to only store the underlying data in the parent component to avoid any confusion about what state must be updated, as shown in the following example.

`Parent2.razor`:

razor

```
@page "/parent-2"

<PageTitle>Parent 2</PageTitle>

<h1>Parent Example 2</h1>

<p>Parent Message: <b>@parentMessage</b></p>

<p>
    <button @onclick="ChangeValue">Change from Parent</button>
</p>

<NestedChild @bind-ChildMessage="parentMessage" />

@code {
    private string parentMessage = "Initial value set in Parent";

    private void ChangeValue() => parentMessage = $"Set in Parent
{DateTime.Now}";
}
```

In the following `NestedChild` component, the `NestedGrandchild` component:

- Assigns the value of `ChildMessage` to `GrandchildMessage` with `@bind:get` syntax.
- Updates `GrandchildMessage` when `ChildMessageChanged` executes with `@bind:set` syntax.

`NestedChild.razor`:

razor

```
<div class="border rounded m-1 p-1">
    <h2>Child Component</h2>

    <p>Child Message: <b>@ChildMessage</b></p>

    <p>
        <button @onclick="ChangeValue">Change from Child</button>
    </p>

    <NestedGrandchild @bind-GrandchildMessage:get="ChildMessage"
        @bind-GrandchildMessage:set="ChildMessageChanged" />
</div>

@code {
    [Parameter]
    public string? ChildMessage { get; set; }

    [Parameter]
    public EventCallback<string?> ChildMessageChanged { get; set; }

    private async Task ChangeValue() =>
        await ChildMessageChanged.InvokeAsync($"Set in Child
{DateTime.Now}");
}
```

`NestedGrandchild.razor`:

razor

```
<div class="border rounded m-1 p-1">
    <h3>Grandchild Component</h3>

    <p>Grandchild Message: <b>@GrandchildMessage</b></p>

    <p>
        <button @onclick="ChangeValue">Change from Grandchild</button>
    </p>
</div>

@code {
    [Parameter]
```

```
    public string? GrandchildMessage { get; set; }

    [Parameter]
    public EventCallback<string> GrandchildMessageChanged { get; set; }

    private async Task ChangeValue() =>
        await GrandchildMessageChanged.InvokeAsync(
            $"Set in Grandchild {DateTime.Now}");
}
```

For an alternative approach suited to sharing data in memory and across components that aren't necessarily nested, see ASP.NET Core Blazor state management.

Bound field or property expression tree

To facilitate deeper interactions with a binding, Blazor allows you to capture of the expression tree of a bound field or property. This is achieved by defining a property with the field or property name suffixed with `Expression`. For any given field or property named `{FIELD OR PROPERTY NAME}`, the corresponding expression tree property is named `{FIELD OR PROPERTY NAME}Expression`.

The following `ChildParameterExpression` component identifies the `Year` expression's model and field name. A FieldIdentifier, which is used to obtain the model and field name, uniquely identifies a single field that can be edited. This may correspond to a property on a model object or can be any other named value. Use of a parameter's expression is useful when creating custom validation components, which isn't covered by the Microsoft Blazor documentation but is addressed by numerous third-party resources.

`ChildParameterExpression.razor`:

razor

```
@using System.Linq.Expressions

<ul>
    <li>Year model: @yearField.Model</li>
    <li>Year field name: @yearField.FieldName</li>
</ul>

@code {
    private FieldIdentifier yearField;

    [Parameter]
    public int Year { get; set; }

    [Parameter]
```

```
    public EventCallback<int> YearChanged { get; set; }

    [Parameter]
    public Expression<Func<int>> YearExpression { get; set; } = default!;

    protected override void OnInitialized() =>
        yearField = FieldIdentifier.Create(YearExpression);
}
```

`Parent3.razor`:

razor

```
@page "/parent-3"

<PageTitle>Parent 3</PageTitle>

<h1>Parent Example 3</h1>

<p>Parent <code>year</code>: @year</p>

<ChildParameterExpression @bind-Year="year" />

@code {
    private int year = 1979;
}
```

ASP.NET Core Razor component lifecycle

Article • 10/18/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

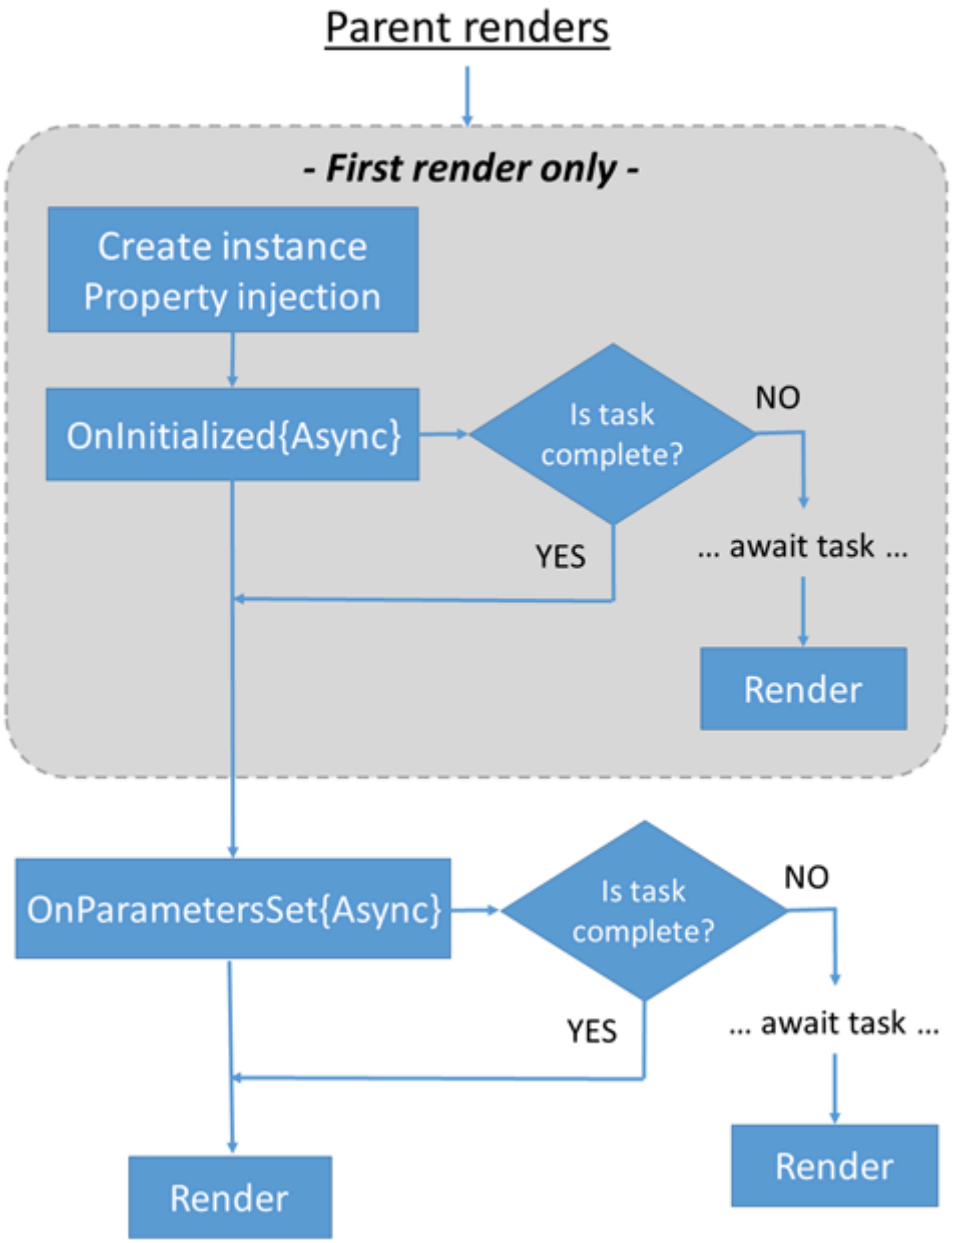
This article explains the ASP.NET Core Razor component lifecycle and how to use lifecycle events.

Lifecycle events

The Razor component processes Razor component lifecycle events in a set of synchronous and asynchronous lifecycle methods. The lifecycle methods can be overridden to perform additional operations in components during component initialization and rendering.

This article simplifies component lifecycle event processing in order to clarify complex framework logic and doesn't cover every change that was made over the years. You may need to access the ComponentBase reference source to integrate custom event processing with Blazor's lifecycle event processing. Code comments in the reference source include additional remarks on lifecycle event processing that don't appear in this article or in the API documentation.

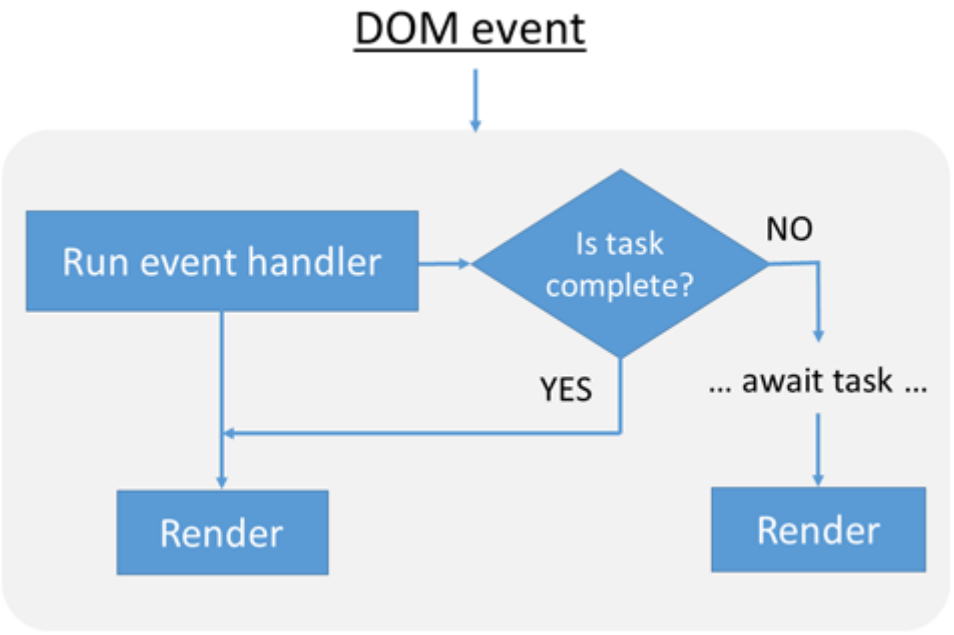
> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).



The following simplified diagrams illustrate Razor component lifecycle event processing. The C# methods associated with the lifecycle events are defined with examples in the following sections of this article.

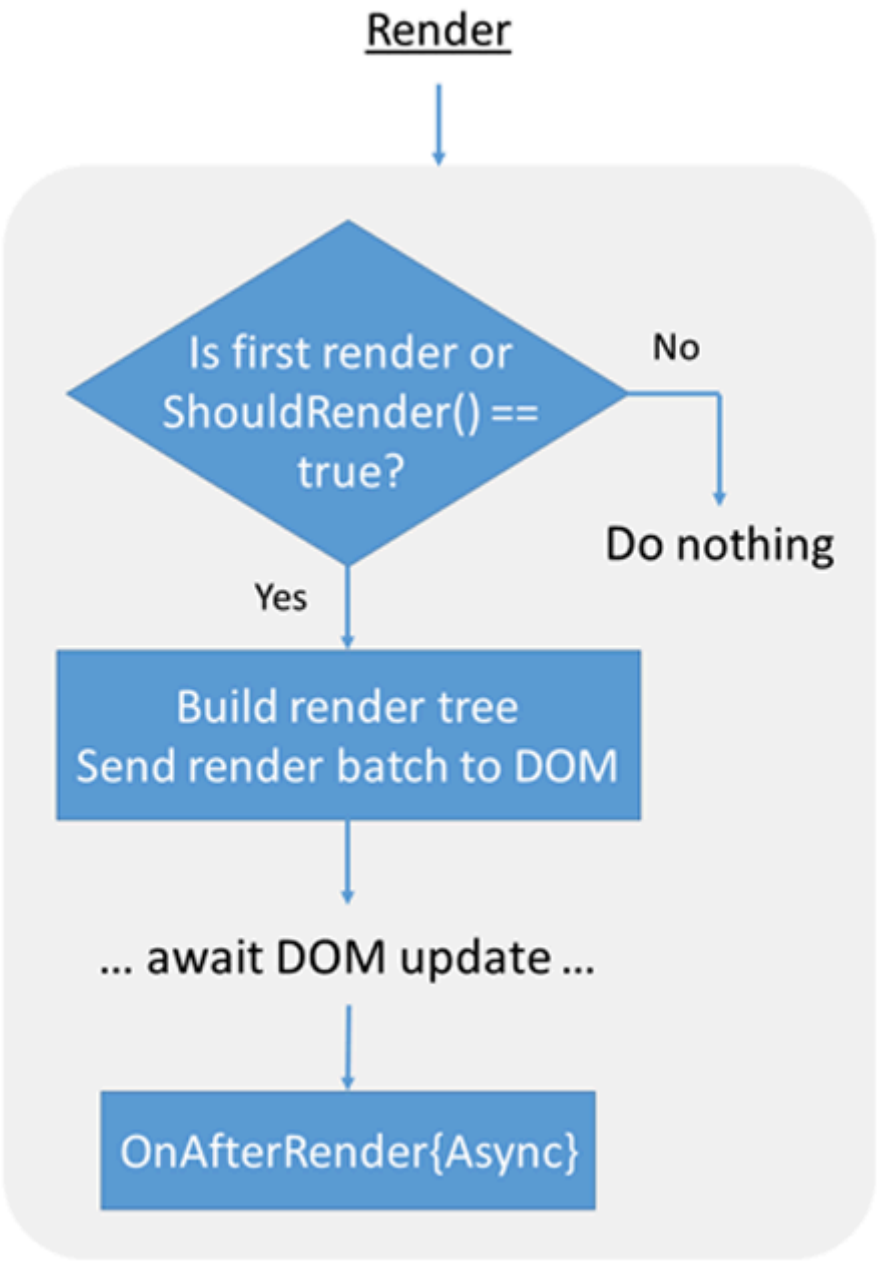
Component lifecycle events:

1. If the component is rendering for the first time on a request:
    - Create the component's instance.
    - Perform property injection.
    - Call OnInitialized{Async}. If an incomplete Task is returned, the Task is awaited and then the component is rerendered. The synchronous method is called prior to the asynchronous method.
2. Call OnParametersSet{Async}. If an incomplete Task is returned, the Task is awaited and then the component is rerendered. The synchronous method is called prior to the asynchronous method.
3. Render for all synchronous work and complete Tasks.



> ⓘ **Note**
>
> Asynchronous actions performed in lifecycle events might not complete before a component is rendered. For more information, see the **Handle incomplete async actions at render** section later in this article.

A parent component renders before its children components because rendering is what determines which children are present. If synchronous parent component initialization is used, the parent initialization is guaranteed to complete first. If asynchronous parent component initialization is used, the completion order of parent and child component initialization can't be determined because it depends on the initialization code running.



DOM event processing:

1. The event handler is run.
2. If an incomplete Task is returned, the Task is awaited and then the component is rerendered.
3. Render for all synchronous work and complete Tasks.

The `Render` lifecycle:

1. Avoid further rendering operations on the component when both of the following conditions are met:
    - It is not the first render.
    - ShouldRender returns `false`.
2. Build the render tree diff (difference) and render the component.
3. Await the DOM to update.
4. Call OnAfterRender{Async}. The synchronous method is called prior to the asynchronous method.

Developer calls to StateHasChanged result in a rerender. For more information, see ASP.NET Core Razor component rendering.

When parameters are set (`SetParametersAsync`)

SetParametersAsync sets parameters supplied by the component's parent in the render tree or from route parameters.

The method's ParameterView parameter contains the set of component parameter values for the component each time SetParametersAsync is called. By overriding the SetParametersAsync method, developer code can interact directly with ParameterView's parameters.

The default implementation of SetParametersAsync sets the value of each property with the [Parameter] or [CascadingParameter] attribute that has a corresponding value in the

ParameterView. Parameters that don't have a corresponding value in ParameterView are left unchanged.

Generally, your code should call the base class method (`await base.SetParametersAsync(parameters);`) when overriding SetParametersAsync. In advanced scenarios, developer code can interpret the incoming parameters' values in any way required by not invoking the base class method. For example, there's no requirement to assign the incoming parameters to the properties of the class. However, you must refer to the ComponentBase reference source when structuring your code without calling the base class method because it calls other lifecycle methods and triggers rendering in a complex fashion.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

If you want to rely on the initialization and rendering logic of ComponentBase.SetParametersAsync but not process incoming parameters, you have the option of passing an empty ParameterView to the base class method:

```
C#

await base.SetParametersAsync(ParameterView.Empty);
```

If event handlers are provided in developer code, unhook them on disposal. For more information, see the Component disposal with IDisposable and IAsyncDisposable section.

In the following example, ParameterView.TryGetValue assigns the `Param` parameter's value to `value` if parsing a route parameter for `Param` is successful. When `value` isn't `null`, the value is displayed by the component.

Although route parameter matching is case insensitive, TryGetValue only matches case-sensitive parameter names in the route template. The following example requires the use of `/{Param?}` in the route template in order to get the value with TryGetValue, not `/{param?}`. If `/{param?}` is used in this scenario, TryGetValue returns `false` and `message` isn't set to either `message` string.

`SetParamsAsync.razor`:

```razor
@page "/set-params-async/{Param?}"

<PageTitle>Set Parameters Async</PageTitle>

<h1>Set Parameters Async Example</h1>

<p>@message</p>

@code {
    private string message = "Not set";

    [Parameter]
    public string? Param { get; set; }

    public override async Task SetParametersAsync(ParameterView parameters)
    {
        if (parameters.TryGetValue<string>(nameof(Param), out var value))
        {
            if (value is null)
            {
                message = "The value of 'Param' is null.";
            }
            else
            {
                message = $"The value of 'Param' is {value}.";
            }
        }

        await base.SetParametersAsync(parameters);
    }
}
```

Component initialization (`OnInitialized{Async}`)

OnInitialized and OnInitializedAsync are used exclusively to initialize a component for the entire lifetime of the component instance. Parameter values and parameter value changes shouldn't affect the initialization performed in these methods. For example, loading static options into a dropdown list that doesn't change for the lifetime of the component and that isn't dependent on parameter values is performed in one of these lifecycle methods. If parameter values or changes in parameter values affect component state, use OnParametersSet{Async} instead.

These methods are invoked when the component is initialized after having received its initial parameters in SetParametersAsync. The synchronous method is called prior to the asynchronous method.

If synchronous parent component initialization is used, the parent initialization is guaranteed to complete before child component initialization. If asynchronous parent component initialization is used, the completion order of parent and child component initialization can't be determined because it depends on the initialization code running.

For a synchronous operation, override OnInitialized:

`OnInit.razor`:

razor

```razor
@page "/on-init"

<PageTitle>On Initialized</PageTitle>

<h1>On Initialized Example</h1>

<p>@message</p>

@code {
    private string? message;

    protected override void OnInitialized() =>
        message = $"Initialized at {DateTime.Now}";
}
```

To perform an asynchronous operation, override OnInitializedAsync and use the await operator:

C#

```
protected override async Task OnInitializedAsync()
{
    await ...
}
```

If a custom base class is used with custom initialization logic, call OnInitializedAsync on the base class:

C#

```
protected override async Task OnInitializedAsync()
{
    await ...
```

```
    await base.OnInitializedAsync();
}
```

It isn't necessary to call ComponentBase.OnInitializedAsync unless a custom base class is used with custom logic. For more information, see the Base class lifecycle methods section.

Blazor apps that prerender their content on the server call OnInitializedAsync *twice*:

- Once when the component is initially rendered statically as part of the page.
- A second time when the browser renders the component.

To prevent developer code in OnInitializedAsync from running twice when prerendering, see the Stateful reconnection after prerendering section. The content in the section focuses on Blazor Web Apps and stateful SignalR *reconnection*. To preserve state during the execution of initialization code while prerendering, see Prerender ASP.NET Core Razor components.

While a Blazor app is prerendering, certain actions, such as calling into JavaScript (JS interop), aren't possible. Components may need to render differently when prerendered. For more information, see the Prerendering with JavaScript interop section.

If event handlers are provided in developer code, unhook them on disposal. For more information, see the Component disposal with IDisposable IAsyncDisposable section.

Use *streaming rendering* with static server-side rendering (static SSR) or prerendering to improve the user experience for components that perform long-running asynchronous tasks in OnInitializedAsync to fully render. For more information, see ASP.NET Core Razor component rendering.

After parameters are set (`OnParametersSet{Async}`)

OnParametersSet or OnParametersSetAsync are called:

- After the component is initialized in OnInitialized or OnInitializedAsync.
- When the parent component rerenders and supplies:
  - Known or primitive immutable types when at least one parameter has changed.
  - Complex-typed parameters. The framework can't know whether the values of a complex-typed parameter have mutated internally, so the framework always

treats the parameter set as changed when one or more complex-typed parameters are present.

For more information on rendering conventions, see ASP.NET Core Razor component rendering.

The synchronous method is called prior to the asynchronous method.

The methods can be invoked even if the parameter values haven't changed. This behavior underscores the need for developers to implement additional logic within the methods to check whether parameter values have indeed changed before re-initializing data or state dependent on those parameters.

For the following example component, navigate to the component's page at a URL:

- With a start date that's received by `StartDate`: `/on-parameters-set/2021-03-19`
- Without a start date, where `StartDate` is assigned a value of the current local time: `/on-parameters-set`

> **Note**
>
> In a component route, it isn't possible to both constrain a DateTime parameter with the route constraint datetime and make the parameter optional. Therefore, the following `OnParamsSet` component uses two @page directives to handle routing with and without a supplied date segment in the URL.

`OnParamsSet.razor`:

razor

```razor
@page "/on-params-set"
@page "/on-params-set/{StartDate:datetime}"

<PageTitle>On Parameters Set</PageTitle>

<h1>On Parameters Set Example</h1>

<p>
    Pass a datetime in the URI of the browser's address bar.
    For example, add <code>/1-1-2024</code> to the address.
</p>

<p>@message</p>

@code {
    private string? message;
```

```
    [Parameter]
    public DateTime StartDate { get; set; }

    protected override void OnParametersSet()
    {
        if (StartDate == default)
        {
            StartDate = DateTime.Now;

            message = $"No start date in URL. Default value applied " +
                $"(StartDate: {StartDate}).";
        }
        else
        {
            message = $"The start date in the URL was used " +
                $"(StartDate: {StartDate}).";
        }
    }
}
```

Asynchronous work when applying parameters and property values must occur during the OnParametersSetAsync lifecycle event:

C#

```
protected override async Task OnParametersSetAsync()
{
    await ...
}
```

If a custom base class is used with custom initialization logic, call OnParametersSetAsync on the base class:

C#

```
protected override async Task OnParametersSetAsync()
{
    await ...

    await base.OnParametersSetAsync();
}
```

It isn't necessary to call ComponentBase.OnParametersSetAsync unless a custom base class is used with custom logic. For more information, see the Base class lifecycle methods section.

If event handlers are provided in developer code, unhook them on disposal. For more information, see the Component disposal with IDisposable IAsyncDisposable section.

For more information on route parameters and constraints, see ASP.NET Core Blazor routing and navigation.

For an example of implementing `SetParametersAsync` manually to improve performance in some scenarios, see ASP.NET Core Blazor performance best practices.

After component render (`OnAfterRender{Async}`)

OnAfterRender and OnAfterRenderAsync are invoked after a component has rendered interactively and the UI has finished updating (for example, after elements are added to the browser DOM). Element and component references are populated at this point. Use this stage to perform additional initialization steps with the rendered content, such as JS interop calls that interact with the rendered DOM elements. The synchronous method is called prior to the asynchronous method.

These methods aren't invoked during prerendering or static server-side rendering (static SSR) on the server because those processes aren't attached to a live browser DOM and are already complete before the DOM is updated.

For OnAfterRenderAsync, the component doesn't automatically rerender after the completion of any returned `Task` to avoid an infinite render loop.

The `firstRender` parameter for OnAfterRender and OnAfterRenderAsync:

- Is set to `true` the first time that the component instance is rendered.
- Can be used to ensure that initialization work is only performed once.

`AfterRender.razor`:

razor

```
@page "/after-render"
@inject ILogger<AfterRender> Logger

<PageTitle>After Render</PageTitle>

<h1>After Render Example</h1>

<p>
    <button @onclick="HandleClick">Log information (and trigger a render)
</button>
</p>

<p>Study logged messages in the console.</p>
```

```
@code {
    protected override void OnAfterRender(bool firstRender) =>
        Logger.LogInformation("firstRender = {FirstRender}", firstRender);

    private void HandleClick() => Logger.LogInformation("HandleClick
called");
}
```

The `AfterRender.razor` sample produces following output to console when the page is loaded and the button is selected:

> OnAfterRender: firstRender = True
> HandleClick called
> OnAfterRender: firstRender = False

Asynchronous work immediately after rendering must occur during the OnAfterRenderAsync lifecycle event:

C#

```
protected override async Task OnAfterRenderAsync(bool firstRender)
{
    ...
}
```

If a custom base class is used with custom initialization logic, call OnAfterRenderAsync on the base class:

C#

```
protected override async Task OnAfterRenderAsync(bool firstRender)
{
    ...

    await base.OnAfterRenderAsync(firstRender);
}
```

It isn't necessary to call ComponentBase.OnAfterRenderAsync unless a custom base class is used with custom logic. For more information, see the Base class lifecycle methods section.

Even if you return a Task from OnAfterRenderAsync, the framework doesn't schedule a further render cycle for your component once that task completes. This is to avoid an infinite render loop. This is different from the other lifecycle methods, which schedule a further render cycle once a returned Task completes.

OnAfterRender and OnAfterRenderAsync *aren't called during the prerendering process on the server*. The methods are called when the component is rendered interactively after prerendering. When the app prerenders:

1. The component executes on the server to produce some static HTML markup in the HTTP response. During this phase, OnAfterRender and OnAfterRenderAsync aren't called.
2. When the Blazor script (`blazor.{server|webassembly|web}.js`) starts in the browser, the component is restarted in an interactive rendering mode. After a component is restarted, OnAfterRender and OnAfterRenderAsync **are** called because the app isn't in the prerendering phase any longer.

If event handlers are provided in developer code, unhook them on disposal. For more information, see the Component disposal with IDisposable IAsyncDisposable section.

Base class lifecycle methods

When overriding Blazor's lifecycle methods, it isn't necessary to call base class lifecycle methods for ComponentBase. However, a component should call an overridden base class lifecycle method in the following situations:

- When overriding ComponentBase.SetParametersAsync, `await base.SetParametersAsync(parameters);` is usually invoked because the base class method calls other lifecycle methods and triggers rendering in a complex fashion. For more information, see the When parameters are set (SetParametersAsync) section.
- If the base class method contains logic that must be executed. Library consumers usually call base class lifecycle methods when inheriting a base class because library base classes often have custom lifecycle logic to execute. If the app uses a base class from a library, consult the library's documentation for guidance.

In the following example, `base.OnInitialized();` is called to ensure that the base class's `OnInitialized` method is executed. Without the call, `BlazorRocksBase2.OnInitialized` doesn't execute.

`BlazorRocks2.razor`:

razor

```razor
@page "/blazor-rocks-2"
@inherits BlazorRocksBase2
@inject ILogger<BlazorRocks2> Logger
```

```
<PageTitle>Blazor Rocks!</PageTitle>

<h1>Blazor Rocks! Example 2</h1>

<p>
    @BlazorRocksText
</p>

@code {
    protected override void OnInitialized()
    {
        Logger.LogInformation("Initialization code of BlazorRocks2
executed!");

        base.OnInitialized();
    }
}
```

`BlazorRocksBase2.cs`:

C#

```
using Microsoft.AspNetCore.Components;

namespace BlazorSample;

public class BlazorRocksBase2 : ComponentBase
{
    [Inject]
    private ILogger<BlazorRocksBase2> Logger { get; set; } = default!;

    public string BlazorRocksText { get; set; } = "Blazor rocks the
browser!";

    protected override void OnInitialized() =>
        Logger.LogInformation("Initialization code of BlazorRocksBase2
executed!");
}
```

State changes (`StateHasChanged`)

StateHasChanged notifies the component that its state has changed. When applicable, calling StateHasChanged enqueues a rerender that occurs when the app's main thread is free.

StateHasChanged is called automatically for EventCallback methods. For more information on event callbacks, see ASP.NET Core Blazor event handling.

For more information on component rendering and when to call StateHasChanged, including when to invoke it with ComponentBase.InvokeAsync, see ASP.NET Core Razor component rendering.

Handle incomplete async actions at render

Asynchronous actions performed in lifecycle events might not have completed before the component is rendered. Objects might be `null` or incompletely populated with data while the lifecycle method is executing. Provide rendering logic to confirm that objects are initialized. Render placeholder UI elements (for example, a loading message) while objects are `null`.

In the following component, OnInitializedAsync is overridden to asynchronously provide movie rating data (`movies`). When `movies` is `null`, a loading message is displayed to the user. After the `Task` returned by OnInitializedAsync completes, the component is rerendered with the updated state.

razor

```
<h1>Sci-Fi Movie Ratings</h1>

@if (movies == null)
{
    <p><em>Loading...</em></p>
}
else
{
    <ul>
        @foreach (var movie in movies)
        {
            <li>@movie.Title &mdash; @movie.Rating</li>
        }
    </ul>
}

@code {
    private Movies[]? movies;

    protected override async Task OnInitializedAsync()
    {
        movies = await GetMovieRatings(DateTime.Now);
    }
}
```

Handle errors

For information on handling errors during lifecycle method execution, see Handle errors in ASP.NET Core Blazor apps.

Stateful reconnection after prerendering

When prerendering on the server, a component is initially rendered statically as part of the page. Once the browser establishes a SignalR connection back to the server, the component is rendered *again* and interactive. If the OnInitialized{Async} lifecycle method for initializing the component is present, the method is executed *twice*:

- When the component is prerendered statically.
- After the server connection has been established.

This can result in a noticeable change in the data displayed in the UI when the component is finally rendered. To avoid this behavior, pass in an identifier to cache the state during prerendering and to retrieve the state after prerendering.

The following code demonstrates a `WeatherForecastService` that avoids the change in data display due to prerendering. The awaited Delay (`await Task.Delay(...)`) simulates a short delay before returning data from the `GetForecastAsync` method.

Add IMemoryCache services with AddMemoryCache on the service collection in the app's `Program` file:

C#

```
builder.Services.AddMemoryCache();
```

`WeatherForecastService.cs`:

C#

```
using Microsoft.Extensions.Caching.Memory;

namespace BlazorSample;

public class WeatherForecastService(IMemoryCache memoryCache)
{
    private static readonly string[] summaries =
    [
        "Freezing", "Bracing", "Chilly", "Cool", "Mild",
        "Warm", "Balmy", "Hot", "Sweltering", "Scorching"
    ];

    public IMemoryCache MemoryCache { get; } = memoryCache;
```

```
    public Task<WeatherForecast[]?> GetForecastAsync(DateOnly startDate)
    {
        return MemoryCache.GetOrCreateAsync(startDate, async e =>
        {
            e.SetOptions(new MemoryCacheEntryOptions
            {
                AbsoluteExpirationRelativeToNow =
                    TimeSpan.FromSeconds(30)
            });

            await Task.Delay(TimeSpan.FromSeconds(10));

            return Enumerable.Range(1, 5).Select(index => new
WeatherForecast
            {
                Date = startDate.AddDays(index),
                TemperatureC = Random.Shared.Next(-20, 55),
                Summary = summaries[Random.Shared.Next(summaries.Length)]
            }).ToArray();
        });
    }
}
```

For more information on the RenderMode, see ASP.NET Core Blazor SignalR guidance.

The content in this section focuses on Blazor Web Apps and stateful SignalR *reconnection*. To preserve state during the execution of initialization code while prerendering, see Prerender ASP.NET Core Razor components.

Prerendering with JavaScript interop

This section applies to server-side apps that prerender Razor components. Prerendering is covered in Prerender ASP.NET Core Razor components.

> **Note**
>
> Internal navigation for interactive routing in Blazor Web Apps doesn't involve requesting new page content from the server. Therefore, prerendering doesn't occur for internal page requests. If the app adopts interactive routing, perform a full page reload for component examples that demonstrate prerendering behavior. For more information, see Prerender ASP.NET Core Razor components.

During prerendering, calling into JavaScript (JS) isn't possible. The following example demonstrates how to use JS interop as part of a component's initialization logic in a way that's compatible with prerendering.

The following `scrollElementIntoView` function:

- Scrolls to the passed element with scrollIntoView.
- Returns the element's `top` property value from the getBoundingClientRect method.

JavaScript

```
window.scrollElementIntoView = (element) => {
  element.scrollIntoView();
  return element.getBoundingClientRect().top;
}
```

Where IJSRuntime.InvokeAsync calls the JS function in component code, the ElementReference is only used in OnAfterRenderAsync and not in any earlier lifecycle method because there's no HTML DOM element until after the component is rendered.

StateHasChanged (reference source) is called to enqueue rerendering of the component with the new state obtained from the JS interop call (for more information, see ASP.NET Core Razor component rendering). An infinite loop isn't created because StateHasChanged is only called when `scrollPosition` is `null`.

`PrerenderedInterop.razor`:

razor

```
@page "/prerendered-interop"
@using Microsoft.AspNetCore.Components
@using Microsoft.JSInterop
@inject IJSRuntime JS

<PageTitle>Prerendered Interop</PageTitle>

<h1>Prerendered Interop Example</h1>

<div @ref="divElement" style="margin-top:2000px">
    Set value via JS interop call: <strong>@scrollPosition</strong>
</div>

@code {
    private ElementReference divElement;
    private double? scrollPosition;

    protected override async Task OnAfterRenderAsync(bool firstRender)
    {
        if (firstRender && scrollPosition is null)
        {
            scrollPosition = await JS.InvokeAsync<double>(
                "scrollElementIntoView", divElement);
```

```
            StateHasChanged();
        }
    }
}
```

The preceding example pollutes the client with a global function. For a better approach in production apps, see JavaScript isolation in JavaScript modules.

Component disposal with `IDisposable` and `IAsyncDisposable`

If a component implements IDisposable or IAsyncDisposable, the framework calls for resource disposal when the component is removed from the UI. Don't rely on the exact timing of when these methods are executed. For example, IAsyncDisposable can be triggered before or after an asynchronous Task awaited in OnInitalizedAsync is called or completes. Also, object disposal code shouldn't assume that objects created during initialization or other lifecycle methods exist.

Components shouldn't need to implement IDisposable and IAsyncDisposable simultaneously. If both are implemented, the framework only executes the asynchronous overload.

Developer code must ensure that IAsyncDisposable implementations don't take a long time to complete.

Disposal of JavaScript interop object references

Examples throughout the JavaScript (JS) interop articles demonstrate typical object disposal patterns:

- When calling JS from .NET, as described in Call JavaScript functions from .NET methods in ASP.NET Core Blazor, dispose any created IJSObjectReference/IJSInProcessObjectReference/JSObjectReference either from .NET or from JS to avoid leaking JS memory.
- When calling .NET from JS, as described in Call .NET methods from JavaScript functions in ASP.NET Core Blazor, dispose of a created DotNetObjectReference either from .NET or from JS to avoid leaking .NET memory.

JS interop object references are implemented as a map keyed by an identifier on the side of the JS interop call that creates the reference. When object disposal is initiated

from either the .NET or JS side, Blazor removes the entry from the map, and the object can be garbage collected as long as no other strong reference to the object is present.

At a minimum, always dispose objects created on the .NET side to avoid leaking .NET managed memory.

DOM cleanup tasks during component disposal

For more information, see ASP.NET Core Blazor JavaScript interoperability (JS interop).

For guidance on JSDisconnectedException when a circuit is disconnected, see ASP.NET Core Blazor JavaScript interoperability (JS interop). For general JavaScript interop error handling guidance, see the *JavaScript interop* section in Handle errors in ASP.NET Core Blazor apps.

Synchronous `IDisposable`

For synchronous disposal tasks, use IDisposable.Dispose.

The following component:

- Implements IDisposable with the @implements Razor directive.
- Disposes of `obj`, which is a type that implements IDisposable.
- A null check is performed because `obj` is created in a lifecycle method (not shown).

razor

```
@implements IDisposable

...

@code {
    ...

    public void Dispose()
    {
        obj?.Dispose();
    }
}
```

If a single object requires disposal, a lambda can be used to dispose of the object when Dispose is called. The following example appears in the ASP.NET Core Razor component rendering article and demonstrates the use of a lambda expression for the disposal of a Timer.

`TimerDisposal1.razor`:

razor

```razor
@page "/timer-disposal-1"
@using System.Timers
@implements IDisposable

<PageTitle>Timer Disposal 1</PageTitle>

<h1>Timer Disposal Example 1</h1>

<p>Current count: @currentCount</p>

@code {
    private int currentCount = 0;
    private Timer timer = new(1000);

    protected override void OnInitialized()
    {
        timer.Elapsed += (sender, eventArgs) => OnTimerCallback();
        timer.Start();
    }

    private void OnTimerCallback()
    {
        _ = InvokeAsync(() =>
        {
            currentCount++;
            StateHasChanged();
        });
    }

    public void Dispose() => timer.Dispose();
}
```

> **Note**
>
> In the preceding example, the call to StateHasChanged is wrapped by a call to ComponentBase.InvokeAsync because the callback is invoked outside of Blazor's synchronization context. For more information, see ASP.NET Core Razor component rendering.

If the object is created in a lifecycle method, such as OnInitialized{Async}, check for `null` before calling `Dispose`.

`TimerDisposal2.razor`:

razor

```razor
@page "/timer-disposal-2"
@using System.Timers
@implements IDisposable

<PageTitle>Timer Disposal 2</PageTitle>

<h1>Timer Disposal Example 2</h1>

<p>Current count: @currentCount</p>

@code {
    private int currentCount = 0;
    private Timer? timer;

    protected override void OnInitialized()
    {
        timer = new Timer(1000);
        timer.Elapsed += (sender, eventArgs) => OnTimerCallback();
        timer.Start();
    }

    private void OnTimerCallback()
    {
        _ = InvokeAsync(() =>
        {
            currentCount++;
            StateHasChanged();
        });
    }

    public void Dispose() => timer?.Dispose();
}
```

For more information, see:

- Cleaning up unmanaged resources (.NET documentation)
- Null-conditional operators ?. and ?[]

Asynchronous `IAsyncDisposable`

For asynchronous disposal tasks, use IAsyncDisposable.DisposeAsync.

The following component:

- Implements IAsyncDisposable with the @implements Razor directive.
- Disposes of `obj`, which is an unmanaged type that implements IAsyncDisposable.
- A null check is performed because `obj` is created in a lifecycle method (not shown).

razor

```razor
@implements IAsyncDisposable

...

@code {
    ...

    public async ValueTask DisposeAsync()
    {
        if (obj is not null)
        {
            await obj.DisposeAsync();
        }
    }
}
```

For more information, see:

- Cleaning up unmanaged resources (.NET documentation)
- Null-conditional operators ?. and ?[]

Assignment of `null` to disposed objects

Usually, there's no need to assign `null` to disposed objects after calling Dispose/DisposeAsync. Rare cases for assigning `null` include the following:

- If the object's type is poorly implemented and doesn't tolerate repeat calls to Dispose/DisposeAsync, assign `null` after disposal to gracefully skip further calls to Dispose/DisposeAsync.
- If a long-lived process continues to hold a reference to a disposed object, assigning `null` allows the garbage collector to free the object in spite of the long-lived process holding a reference to it.

These are unusual scenarios. For objects that are implemented correctly and behave normally, there's no point in assigning `null` to disposed objects. In the rare cases where an object must be assigned `null`, we recommend documenting the reason and seeking a solution that prevents the need to assign `null`.

`StateHasChanged`

> ⓘ Note

Calling StateHasChanged in `Dispose` and `DisposeAsync` isn't supported. StateHasChanged might be invoked as part of tearing down the renderer, so requesting UI updates at that point isn't supported.

Event handlers

Always unsubscribe event handlers from .NET events. The following Blazor form examples show how to unsubscribe an event handler in the `Dispose` method:

- Private field and lambda approach

razor

```
@implements IDisposable

<EditForm ... EditContext="editContext" ...>
    ...
    <button type="submit" disabled="@formInvalid">Submit</button>
</EditForm>

@code {
    ...

    private EventHandler<FieldChangedEventArgs>? fieldChanged;

    protected override void OnInitialized()
    {
        editContext = new(model);

        fieldChanged = (_, __) =>
        {
            ...
        };

        editContext.OnFieldChanged += fieldChanged;
    }

    public void Dispose()
    {
        editContext.OnFieldChanged -= fieldChanged;
    }
}
```

- Private method approach

razor

```
@implements IDisposable
```

```
<EditForm ... EditContext="editContext" ...>
    ...
    <button type="submit" disabled="@formInvalid">Submit</button>
</EditForm>

@code {
    ...

    protected override void OnInitialized()
    {
        editContext = new(model);
        editContext.OnFieldChanged += HandleFieldChanged;
    }

    private void HandleFieldChanged(object sender,
FieldChangedEventArgs e)
    {
        ...
    }

    public void Dispose()
    {
        editContext.OnFieldChanged -= HandleFieldChanged;
    }
}
```

For more information, see the Component disposal with IDisposable and IAsyncDisposable section.

For more information on the EditForm component and forms, see ASP.NET Core Blazor forms overview and the other forms articles in the *Forms* node.

Anonymous functions, methods, and expressions

When anonymous functions, methods, or expressions, are used, it isn't necessary to implement IDisposable and unsubscribe delegates. However, failing to unsubscribe a delegate is a problem **when the object exposing the event outlives the lifetime of the component registering the delegate**. When this occurs, a memory leak results because the registered delegate keeps the original object alive. Therefore, only use the following approaches when you know that the event delegate disposes quickly. When in doubt about the lifetime of objects that require disposal, subscribe a delegate method and properly dispose the delegate as the earlier examples show.

- Anonymous lambda method approach (explicit disposal not required):

```
C#
```

```
private void HandleFieldChanged(object sender, FieldChangedEventArgs e)
{
    formInvalid = !editContext.Validate();
    StateHasChanged();
}

protected override void OnInitialized()
{
    editContext = new(starship);
    editContext.OnFieldChanged += (s, e) =>
HandleFieldChanged((editContext)s, e);
}
```

- Anonymous lambda expression approach (explicit disposal not required):

```
C#

private ValidationMessageStore? messageStore;

[CascadingParameter]
private EditContext? CurrentEditContext { get; set; }

protected override void OnInitialized()
{
    ...

    messageStore = new(CurrentEditContext);

    CurrentEditContext.OnValidationRequested += (s, e) =>
messageStore.Clear();
    CurrentEditContext.OnFieldChanged += (s, e) =>
        messageStore.Clear(e.FieldIdentifier);
}
```

  The full example of the preceding code with anonymous lambda expressions appears in the ASP.NET Core Blazor forms validation article.

For more information, see Cleaning up unmanaged resources and the topics that follow it on implementing the `Dispose` and `DisposeAsync` methods.

Cancelable background work

Components often perform long-running background work, such as making network calls (HttpClient) and interacting with databases. It's desirable to stop the background work to conserve system resources in several situations. For example, background asynchronous operations don't automatically stop when a user navigates away from a component.

Other reasons why background work items might require cancellation include:

- An executing background task was started with faulty input data or processing parameters.
- The current set of executing background work items must be replaced with a new set of work items.
- The priority of currently executing tasks must be changed.
- The app must be shut down for server redeployment.
- Server resources become limited, necessitating the rescheduling of background work items.

To implement a cancelable background work pattern in a component:

- Use a CancellationTokenSource and CancellationToken.
- On disposal of the component and at any point cancellation is desired by manually canceling the token, call CancellationTokenSource.Cancel to signal that the background work should be cancelled.
- After the asynchronous call returns, call ThrowIfCancellationRequested on the token.

In the following example:

- `await Task.Delay(5000, cts.Token);` represents long-running asynchronous background work.
- `BackgroundResourceMethod` represents a long-running background method that shouldn't start if the `Resource` is disposed before the method is called.

`BackgroundWork.razor`:

razor

```razor
@page "/background-work"
@implements IDisposable
@inject ILogger<BackgroundWork> Logger

<PageTitle>Background Work</PageTitle>

<h1>Background Work Example</h1>

<p>
    <button @onclick="LongRunningWork">Trigger long running work</button>
    <button @onclick="Dispose">Trigger Disposal</button>
</p>
<p>Study logged messages in the console.</p>
<p>
    If you trigger disposal within 10 seconds of page load, the
    <code>BackgroundResourceMethod</code> isn't executed.
```

```
</p>
<p>
    If disposal occurs after <code>BackgroundResourceMethod</code> is called
but
    before action is taken on the resource, an
<code>ObjectDisposedException</code>
    is thrown by <code>BackgroundResourceMethod</code>, and the resource
isn't
    processed.
</p>

@code {
    private Resource resource = new();
    private CancellationTokenSource cts = new();
    private IList<string> messages = [];

    protected async Task LongRunningWork()
    {
        Logger.LogInformation("Long running work started");

        await Task.Delay(10000, cts.Token);

        cts.Token.ThrowIfCancellationRequested();
        resource.BackgroundResourceMethod(Logger);
    }

    public void Dispose()
    {
        Logger.LogInformation("Executing Dispose");

        if (!cts.IsCancellationRequested)
        {
            cts.Cancel();
        }

        cts?.Dispose();
        resource?.Dispose();
    }

    private class Resource : IDisposable
    {
        private bool disposed;

        public void BackgroundResourceMethod(ILogger<BackgroundWork> logger)
        {
            logger.LogInformation("BackgroundResourceMethod: Start method");

            if (disposed)
            {
                logger.LogInformation("BackgroundResourceMethod: Disposed");
                throw new ObjectDisposedException(nameof(Resource));
            }

            // Take action on the Resource
```

```
            logger.LogInformation("BackgroundResourceMethod: Action on
Resource");
        }

        public void Dispose() => disposed = true;
    }
}
```

Blazor Server reconnection events

The component lifecycle events covered in this article operate separately from server-side reconnection event handlers. When the SignalR connection to the client is lost, only UI updates are interrupted. UI updates are resumed when the connection is re-established. For more information on circuit handler events and configuration, see ASP.NET Core Blazor SignalR guidance.

ASP.NET Core Razor component virtualization

Article • 10/18/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article explains how to use component virtualization in ASP.NET Core Blazor apps.

Virtualization

Improve the perceived performance of component rendering using the Blazor framework's built-in virtualization support with the Virtualize<TItem> component. Virtualization is a technique for limiting UI rendering to just the parts that are currently visible. For example, virtualization is helpful when the app must render a long list of items and only a subset of items is required to be visible at any given time.

Use the Virtualize<TItem> component when:

- Rendering a set of data items in a loop.
- Most of the items aren't visible due to scrolling.
- The rendered items are the same size.

When the user scrolls to an arbitrary point in the Virtualize<TItem> component's list of items, the component calculates the visible items to show. Unseen items aren't rendered.

Without virtualization, a typical list might use a C# foreach loop to render each item in a list. In the following example:

- `allFlights` is a collection of airplane flights.
- The `FlightSummary` component displays details about each flight.
- The @key directive attribute preserves the relationship of each `FlightSummary` component to its rendered flight by the flight's `FlightId`.

razor

```razor
<div style="height:500px;overflow-y:scroll">
    @foreach (var flight in allFlights)
    {
        <FlightSummary @key="flight.FlightId" Details="@flight.Summary" />
    }
</div>
```

If the collection contains thousands of flights, rendering the flights takes a long time and users experience a noticeable UI lag. Most of the flights fall outside of the height of the `<div>` element, so most of them aren't seen.

Instead of rendering the entire list of flights at once, replace the foreach loop in the preceding example with the Virtualize<TItem> component:

- Specify `allFlights` as a fixed item source to Virtualize<TItem>.Items. Only the currently visible flights are rendered by the Virtualize<TItem> component.

  If a non-generic collection supplies the items, for example a collection of DataRow, follow the guidance in the Item provider delegate section to supply the items.

- Specify a context for each flight with the `Context` parameter. In the following example, `flight` is used as the context, which provides access to each flight's members.

razor

```razor
<div style="height:500px;overflow-y:scroll">
    <Virtualize Items="allFlights" Context="flight">
        <FlightSummary @key="flight.FlightId" Details="@flight.Summary" />
    </Virtualize>
</div>
```

If a context isn't specified with the `Context` parameter, use the value of `context` in the item content template to access each flight's members:

razor

```razor
<div style="height:500px;overflow-y:scroll">
    <Virtualize Items="allFlights">
        <FlightSummary @key="context.FlightId" Details="@context.Summary" />
    </Virtualize>
</div>
```

The Virtualize<TItem> component:

- Calculates the number of items to render based on the height of the container and the size of the rendered items.
- Recalculates and rerenders the items as the user scrolls.
- Only fetches the slice of records from an external API that correspond to the currently visible region, including overscan, when `ItemsProvider` is used instead of `Items` (see the Item provider delegate section).

The item content for the Virtualize<TItem> component can include:

- Plain HTML and Razor code, as the preceding example shows.
- One or more Razor components.
- A mix of HTML/Razor and Razor components.

Item provider delegate

If you don't want to load all of the items into memory or the collection isn't a generic ICollection<T>, you can specify an items provider delegate method to the component's Virtualize<TItem>.ItemsProvider parameter that asynchronously retrieves the requested items on demand. In the following example, the `LoadEmployees` method provides the items to the Virtualize<TItem> component:

razor

```
<Virtualize Context="employee" ItemsProvider="LoadEmployees">
    <p>
        @employee.FirstName @employee.LastName has the
        job title of @employee.JobTitle.
    </p>
</Virtualize>
```

The items provider receives an ItemsProviderRequest, which specifies the required number of items starting at a specific start index. The items provider then retrieves the requested items from a database or other service and returns them as an ItemsProviderResult<TItem> along with a count of the total items. The items provider can choose to retrieve the items with each request or cache them so that they're readily available.

A Virtualize<TItem> component can only accept **one item source** from its parameters, so don't attempt to simultaneously use an items provider and assign a collection to `Items`. If both are assigned, an InvalidOperationException is thrown when the component's parameters are set at runtime.

The following example loads employees from an `EmployeeService` (not shown):

C#

```
private async ValueTask<ItemsProviderResult<Employee>> LoadEmployees(
    ItemsProviderRequest request)
{
    var numEmployees = Math.Min(request.Count, totalEmployees -
request.StartIndex);
    var employees = await
EmployeesService.GetEmployeesAsync(request.StartIndex,
        numEmployees, request.CancellationToken);

    return new ItemsProviderResult<Employee>(employees, totalEmployees);
}
```

In the following example, a collection of DataRow is a non-generic collection, so an items provider delegate is used for virtualization:

razor

```
<Virtualize Context="row" ItemsProvider="GetRows">
    ...
</Virtualize>

@code{
    ...

    private ValueTask<ItemsProviderResult<DataRow>>
GetRows(ItemsProviderRequest request) =>
        new(new ItemsProviderResult<DataRow>(
            dataTable.Rows.OfType<DataRow>
().Skip(request.StartIndex).Take(request.Count),
            dataTable.Rows.Count));
}
```

Virtualize<TItem>.RefreshDataAsync instructs the component to rerequest data from its ItemsProvider. This is useful when external data changes. There's usually no need to call RefreshDataAsync when using Items.

RefreshDataAsync updates a Virtualize<TItem> component's data without causing a rerender. If RefreshDataAsync is invoked from a Blazor event handler or component lifecycle method, triggering a render isn't required because a render is automatically triggered at the end of the event handler or lifecycle method. If RefreshDataAsync is triggered separately from a background task or event, such as in the following `ForecastUpdated` delegate, call StateHasChanged to update the UI at the end of the background task or event:

C#

```
<Virtualize ... @ref="virtualizeComponent">
    ...
</Virtualize>

...

private Virtualize<FetchData>? virtualizeComponent;

protected override void OnInitialized()
{
    WeatherForecastSource.ForecastUpdated += async () =>
    {
        await InvokeAsync(async () =>
        {
            await virtualizeComponent?.RefreshDataAsync();
            StateHasChanged();
        });
    });
}
```

In the preceding example:

- RefreshDataAsync is called first to obtain new data for the Virtualize<TItem> component.
- `StateHasChanged` is called to rerender the component.

Placeholder

Because requesting items from a remote data source might take some time, you have the option to render a placeholder with item content:

- Use a Placeholder (`<Placeholder>...</Placeholder>`) to display content until the item data is available.
- Use Virtualize<TItem>.ItemContent to set the item template for the list.

razor

```
<Virtualize Context="employee" ItemsProvider="LoadEmployees">
    <ItemContent>
        <p>
            @employee.FirstName @employee.LastName has the
            job title of @employee.JobTitle.
        </p>
    </ItemContent>
    <Placeholder>
        <p>
            Loading&hellip;
        </p>
```

```
    </Placeholder>
</Virtualize>
```

Empty content

Use the EmptyContent parameter to supply content when the component has loaded and either Items is empty or ItemsProviderResult<TItem>.TotalItemCount is zero.

`EmptyContent.razor`:

razor

```razor
@page "/empty-content"

<PageTitle>Empty Content</PageTitle>

<h1>Empty Content Example</h1>

<Virtualize Items="stringList">
    <ItemContent>
        <p>
            @context
        </p>
    </ItemContent>
    <EmptyContent>
        <p>
            There are no strings to display.
        </p>
    </EmptyContent>
</Virtualize>

@code {
    private List<string>? stringList;

    protected override void OnInitialized() => stringList ??= new();
}
```

Change the `OnInitialized` method lambda to see the component display strings:

C#

```
protected override void OnInitialized() =>
    stringList ??= new() { "Here's a string!", "Here's another string!" };
```

Item size

The height of each item in pixels can be set with Virtualize<TItem>.ItemSize (default: 50). The following example changes the height of each item from the default of 50 pixels to 25 pixels:

```razor
<Virtualize Context="employee" Items="employees" ItemSize="25">
    ...
</Virtualize>
```

The Virtualize<TItem> component measures the rendering size (height) of individual items *after* the initial render occurs. Use ItemSize to provide an exact item size in advance to assist with accurate initial render performance and to ensure the correct scroll position for page reloads. If the default ItemSize causes some items to render outside of the currently visible view, a second rerender is triggered. To correctly maintain the browser's scroll position in a virtualized list, the initial render must be correct. If not, users might view the wrong items.

Overscan count

Virtualize<TItem>.OverscanCount determines how many additional items are rendered before and after the visible region. This setting helps to reduce the frequency of rendering during scrolling. However, higher values result in more elements rendered in the page (default: 3). The following example changes the overscan count from the default of three items to four items:

```razor
<Virtualize Context="employee" Items="employees" OverscanCount="4">
    ...
</Virtualize>
```

State changes

When making changes to items rendered by the Virtualize<TItem> component, call StateHasChanged to enqueue re-evaluation and rerendering of the component. For more information, see ASP.NET Core Razor component rendering.

Keyboard scroll support

To allow users to scroll virtualized content using their keyboard, ensure that the virtualized elements or scroll container itself is focusable. If you fail to take this step, keyboard scrolling doesn't work in Chromium-based browsers.

For example, you can use a `tabindex` attribute on the scroll container:

razor

```
<div style="height:500px; overflow-y:scroll" tabindex="-1">
    <Virtualize Items="allFlights">
        <div class="flight-info">...</div>
    </Virtualize>
</div>
```

To learn more about the meaning of `tabindex` value `-1`, `0`, or other values, see tabindex (MDN documentation).

Advanced styles and scroll detection

The Virtualize<TItem> component is only designed to support specific element layout mechanisms. To understand which element layouts work correctly, the following explains how `Virtualize` detects which elements should be visible for display in the correct place.

If your source code looks like the following:

razor

```
<div style="height:500px; overflow-y:scroll" tabindex="-1">
    <Virtualize Items="allFlights" ItemSize="100">
        <div class="flight-info">Flight @context.Id</div>
    </Virtualize>
</div>
```

At runtime, the Virtualize<TItem> component renders a DOM structure similar to the following:

HTML

```
<div style="height:500px; overflow-y:scroll" tabindex="-1">
    <div style="height:1100px"></div>
    <div class="flight-info">Flight 12</div>
    <div class="flight-info">Flight 13</div>
    <div class="flight-info">Flight 14</div>
    <div class="flight-info">Flight 15</div>
    <div class="flight-info">Flight 16</div>
```

```
    <div style="height:3400px"></div>
</div>
```

The actual number of rows rendered and the size of the spacers vary according to your styling and `Items` collection size. However, notice that there are spacer `div` elements injected before and after your content. These serve two purposes:

- To provide an offset before and after your content, causing currently-visible items to appear at the correct location in the scroll range and the scroll range itself to represent the total size of all content.
- To detect when the user is scrolling beyond the current visible range, meaning that different content must be rendered.

> ⓘ **Note**
>
> To learn how to control the spacer HTML element tag, see the **Control the spacer element tag name** section later in this article.

The spacer elements internally use an Intersection Observer to receive notification when they're becoming visible. `Virtualize` depends on receiving these events.

`Virtualize` works under the following conditions:

- **All rendered content items, including placeholder content, are of identical height.** This makes it possible to calculate which content corresponds to a given scroll position without first fetching every data item and rendering the data into a DOM element.

- **Both the spacers and the content rows are rendered in a single vertical stack with every item filling the entire horizontal width.** In typical use cases, `Virtualize` works with `div` elements. If you're using CSS to create a more advanced layout, bear in mind the following requirements:
  - Scroll container styling requires a `display` with any of the following values:
    - `block` (the default for a `div`).
    - `table-row-group` (the default for a `tbody`).
    - `flex` with `flex-direction` set to `column`. Ensure that immediate children of the Virtualize<TItem> component don't shrink under flex rules. For example, add `.mycontainer > div { flex-shrink: 0 }`.
  - Content row styling requires a `display` with either of the following values:
    - `block` (the default for a `div`).
    - `table-row` (the default for a `tr`).

- Don't use CSS to interfere with the layout for the spacer elements. The spacer elements have a `display` value of `block`, except if the parent is a table row group, in which case they default to `table-row`. Don't try to influence spacer element width or height, including by causing them to have a border or `content` pseudo-elements.

Any approach that stops the spacers and content elements from rendering as a single vertical stack, or causes the content items to vary in height, prevents correct functioning of the Virtualize<TItem> component.

Root-level virtualization

The Virtualize<TItem> component supports using the document itself as the scroll root, as an alternative to having some other element with `overflow-y: scroll`. In the following example, the `<html>` or `<body>` elements are styled in a component with `overflow-y: scroll`:

razor

```
<HeadContent>
    <style>
        html, body { overflow-y: scroll }
    </style>
</HeadContent>
```

Control the spacer element tag name

If the Virtualize<TItem> component is placed inside an element that requires a specific child tag name, SpacerElement allows you to obtain or set the virtualization spacer tag name. The default value is `div`. For the following example, the Virtualize<TItem> component renders inside a table body element (tbody), so the appropriate child element for a table row (tr) is set as the spacer.

`VirtualizedTable.razor`:

razor

```
@page "/virtualized-table"

<PageTitle>Virtualized Table</PageTitle>

<HeadContent>
    <style>
```

```
        html, body {
            overflow-y: scroll
        }
    </style>
</HeadContent>

<h1>Virtualized Table Example</h1>

<table id="virtualized-table">
    <thead style="position: sticky; top: 0; background-color: silver">
        <tr>
            <th>Item</th>
            <th>Another column</th>
        </tr>
    </thead>
    <tbody>
        <Virtualize Items="fixedItems" ItemSize="30" SpacerElement="tr">
            <tr @key="context" style="height: 30px;" id="row-@context">
                <td>Item @context</td>
                <td>Another value</td>
            </tr>
        </Virtualize>
    </tbody>
</table>

@code {
    private List<int> fixedItems = Enumerable.Range(0, 1000).ToList();
}
```

In the preceding example, the document root is used as the scroll container, so the `html` and `body` elements are styled with `overflow-y: scroll`. For more information, see the following resources:

- Root-level virtualization section

ASP.NET Core Razor component rendering

Article • 10/18/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article explains Razor component rendering in ASP.NET Core Blazor apps, including when to call StateHasChanged to manually trigger a component to render.

Rendering conventions for `ComponentBase`

Components *must* render when they're first added to the component hierarchy by a parent component. This is the only time that a component must render. Components *may* render at other times according to their own logic and conventions.

Razor components inherit from the ComponentBase base class, which contains logic to trigger rerendering at the following times:

- After applying an updated set of parameters from a parent component.
- After applying an updated value for a cascading parameter.
- After notification of an event and invoking one of its own event handlers.
- After a call to its own StateHasChanged method (see ASP.NET Core Razor component lifecycle). For guidance on how to prevent overwriting child component parameters when StateHasChanged is called in a parent component, see Avoid overwriting parameters in ASP.NET Core Blazor.

Components inherited from ComponentBase skip rerenders due to parameter updates if either of the following are true:

- All of the parameters are from a set of known types† or any primitive type that hasn't changed since the previous set of parameters were set.

  †The Blazor framework uses a set of built-in rules and explicit parameter type checks for change detection. These rules and the types are subject to change at

any time. For more information, see the ChangeDetection API in the ASP.NET Core reference source.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

- The override of the component's ShouldRender method returns `false` (the default `ComponentBase` implementation always returns `true`).

Control the rendering flow

In most cases, ComponentBase conventions result in the correct subset of component rerenders after an event occurs. Developers aren't usually required to provide manual logic to tell the framework which components to rerender and when to rerender them. The overall effect of the framework's conventions is that the component receiving an event rerenders itself, which recursively triggers rerendering of descendant components whose parameter values may have changed.

For more information on the performance implications of the framework's conventions and how to optimize an app's component hierarchy for rendering, see ASP.NET Core Blazor performance best practices.

Streaming rendering

Use *streaming rendering* with static server-side rendering (static SSR) or prerendering to stream content updates on the response stream and improve the user experience for components that perform long-running asynchronous tasks to fully render.

For example, consider a component that makes a long-running database query or web API call to render data when the page loads. Normally, asynchronous tasks executed as part of rendering a server-side component must complete before the rendered response is sent, which can delay loading the page. Any significant delay in rendering the page harms the user experience. To improve the user experience, streaming rendering initially renders the entire page quickly with placeholder content while asynchronous operations execute. After the operations are complete, the updated

content is sent to the client on the same response connection and patched into the DOM.

Streaming rendering requires the server to avoid buffering the output. The response data must flow to the client as the data is generated. For hosts that enforce buffering, streaming rendering degrades gracefully, and the page loads without streaming rendering.

To stream content updates when using static server-side rendering (static SSR) or prerendering, apply the `[StreamRendering(true)]` attribute to the component. Streaming rendering must be explicitly enabled because streamed updates may cause content on the page to shift. Components without the attribute automatically adopt streaming rendering if the parent component uses the feature. Pass `false` to the attribute in a child component to disable the feature at that point and further down the component subtree. The attribute is functional when applied to components supplied by a Razor class library.

The following example is based on the `Weather` component in an app created from the Blazor Web App project template. The call to Task.Delay simulates retrieving weather data asynchronously. The component initially renders placeholder content ("`Loading...`") without waiting for the asynchronous delay to complete. When the asynchronous delay completes and the weather data content is generated, the content is streamed to the response and patched into the weather forecast table.

`Weather.razor`:

razor

```razor
@page "/weather"
@attribute [StreamRendering(true)]

...

@if (forecasts == null)
{
    <p><em>Loading...</em></p>
}
else
{
    <table class="table">
        ...
        <tbody>
            @foreach (var forecast in forecasts)
            {
                <tr>
                    <td>@forecast.Date.ToShortDateString()</td>
                    <td>@forecast.TemperatureC</td>
```

```
                    <td>@forecast.TemperatureF</td>
                    <td>@forecast.Summary</td>
                </tr>
            }
        </tbody>
    </table>
}

@code {
    ...

    private WeatherForecast[]? forecasts;

    protected override async Task OnInitializedAsync()
    {
        await Task.Delay(500);

        ...

        forecasts = ...
    }
}
```

Suppress UI refreshing (`ShouldRender`)

ShouldRender is called each time a component is rendered. Override ShouldRender to manage UI refreshing. If the implementation returns `true`, the UI is refreshed.

Even if ShouldRender is overridden, the component is always initially rendered.

`ControlRender.razor`:

razor

```
@page "/control-render"

<PageTitle>Control Render</PageTitle>

<h1>Control Render Example</h1>

<label>
    <input type="checkbox" @bind="shouldRender" />
    Should Render?
</label>

<p>Current count: @currentCount</p>

<p>
    <button @onclick="IncrementCount">Click me</button>
</p>
```

```
@code {
    private int currentCount = 0;
    private bool shouldRender = true;

    protected override bool ShouldRender() => shouldRender;

    private void IncrementCount() => currentCount++;
}
```

For more information on performance best practices pertaining to ShouldRender, see ASP.NET Core Blazor performance best practices.

`StateHasChanged`

Calling StateHasChanged enqueues a rerender to occur when the app's main thread is free.

Components are enqueued for rendering, and they aren't enqueued again if there's already a pending rerender. If a component calls StateHasChanged five times in a row in a loop, the component only renders once. This behavior is encoded in ComponentBase, which checks first if it has queued a rerender before enqueuing an additional one.

A component can render multiple times during the same cycle, which commonly occurs when a component has children that interact with each other:

- A parent component renders several children.
- Child components render and trigger an update on the parent.
- A parent component rerenders with new state.

This design allows for StateHasChanged to be called when necessary without the risk of introducing unnecessary rendering. You can always take control of this behavior in individual components by implementing IComponent directly and manually handling when the component renders.

Consider the following `IncrementCount` method that increments a count, calls StateHasChanged, and increments the count again:

C#

```
private void IncrementCount()
{
    currentCount++;
    StateHasChanged();
    currentCount++;
}
```

Stepping through the code in the debugger, you might think that the count updates in the UI for the first `currentCount++` execution immediately after StateHasChanged is called. However, the UI doesn't show an updated count at that point due to the synchronous processing taking place for this method's execution. There's no opportunity for the renderer to render the component until after the event handler is finished. The UI displays increases for both `currentCount++` executions *in a single render*.

If you await something between the `currentCount++` lines, the awaited call gives the renderer a chance to render. This has led to some developers calling Delay with a one millisecond delay in their components to allow a render to occur, but we don't recommend arbitrarily slowing down an app to enqueue a render.

The best approach is to await Task.Yield, which forces the component to process code asynchronously and render during the current batch with a second render in a separate batch after the yielded task runs the continuation.

Consider the following revised `IncrementCount` method, which updates the UI twice because the render enqueued by StateHasChanged is performed when the task is yielded with the call to Task.Yield:

C#

```
private async Task IncrementCount()
{
    currentCount++;
    StateHasChanged();
    await Task.Yield();
    currentCount++;
}
```

Be careful not to call StateHasChanged unnecessarily, which is a common mistake that imposes unnecessary rendering costs. Code shouldn't need to call StateHasChanged when:

- Routinely handling events, whether synchronously or asynchronously, since ComponentBase triggers a render for most routine event handlers.
- Implementing typical lifecycle logic, such as OnInitialized or OnParametersSetAsync, whether synchronously or asynchronously, since ComponentBase triggers a render for typical lifecycle events.

However, it might make sense to call StateHasChanged in the cases described in the following sections of this article:

- An asynchronous handler involves multiple asynchronous phases

- Receiving a call from something external to the Blazor rendering and event handling system
- To render component outside the subtree that is rerendered by a particular event

An asynchronous handler involves multiple asynchronous phases

Due to the way that tasks are defined in .NET, a receiver of a Task can only observe its final completion, not intermediate asynchronous states. Therefore, ComponentBase can only trigger rerendering when the Task is first returned and when the Task finally completes. The framework can't know to rerender a component at other intermediate points, such as when an IAsyncEnumerable<T> returns data in a series of intermediate Tasks. If you want to rerender at intermediate points, call StateHasChanged at those points.

Consider the following `CounterState1` component, which updates the count four times each time the `IncrementCount` method executes:

- Automatic renders occur after the first and last increments of `currentCount`.
- Manual renders are triggered by calls to StateHasChanged when the framework doesn't automatically trigger rerenders at intermediate processing points where `currentCount` is incremented.

`CounterState1.razor`:

razor

```
@page "/counter-state-1"

<PageTitle>Counter State 1</PageTitle>

<h1>Counter State Example 1</h1>

<p>
    Current count: @currentCount
</p>

<p>
    <button class="btn btn-primary" @onclick="IncrementCount">Click
me</button>
</p>

@code {
    private int currentCount = 0;

    private async Task IncrementCount()
    {
```

```
        currentCount++;
        // Renders here automatically

        await Task.Delay(1000);
        currentCount++;
        StateHasChanged();

        await Task.Delay(1000);
        currentCount++;
        StateHasChanged();

        await Task.Delay(1000);
        currentCount++;
        // Renders here automatically
    }
}
```

Receiving a call from something external to the Blazor rendering and event handling system

ComponentBase only knows about its own lifecycle methods and Blazor-triggered events. ComponentBase doesn't know about other events that may occur in code. For example, any C# events raised by a custom data store are unknown to Blazor. In order for such events to trigger rerendering to display updated values in the UI, call StateHasChanged.

Consider the following `CounterState2` component that uses System.Timers.Timer to update a count at a regular interval and calls StateHasChanged to update the UI:

- `OnTimerCallback` runs outside of any Blazor-managed rendering flow or event notification. Therefore, `OnTimerCallback` must call StateHasChanged because Blazor isn't aware of the changes to `currentCount` in the callback.
- The component implements IDisposable, where the Timer is disposed when the framework calls the `Dispose` method. For more information, see ASP.NET Core Razor component lifecycle.

Because the callback is invoked outside of Blazor's synchronization context, the component must wrap the logic of `OnTimerCallback` in ComponentBase.InvokeAsync to move it onto the renderer's synchronization context. This is equivalent to marshalling to the UI thread in other UI frameworks. StateHasChanged can only be called from the renderer's synchronization context and throws an exception otherwise:

> System.InvalidOperationException: 'The current thread is not associated with the Dispatcher. Use InvokeAsync() to switch execution to the Dispatcher when triggering rendering or component state.'

`CounterState2.razor`:

razor

```razor
@page "/counter-state-2"
@using System.Timers
@implements IDisposable

<PageTitle>Counter State 2</PageTitle>

<h1>Counter State Example 2</h1>

<p>
    This counter demonstrates <code>Timer</code> disposal.
</p>

<p>
    Current count: @currentCount
</p>

@code {
    private int currentCount = 0;
    private Timer timer = new(1000);

    protected override void OnInitialized()
    {
        timer.Elapsed += (sender, eventArgs) => OnTimerCallback();
        timer.Start();
    }

    private void OnTimerCallback()
    {
        _ = InvokeAsync(() =>
        {
            currentCount++;
            StateHasChanged();
        });
    }

    public void Dispose() => timer.Dispose();
}
```

To render a component outside the subtree that's rerendered by a particular event

The UI might involve:

1. Dispatching an event to one component.
2. Changing some state.

3. Rerendering a completely different component that isn't a descendant of the component receiving the event.

One way to deal with this scenario is to provide a *state management* class, often as a dependency injection (DI) service, injected into multiple components. When one component calls a method on the state manager, the state manager raises a C# event that's then received by an independent component.

For approaches to manage state, see the following resources:

- Bind across more than two components using data bindings.
- Pass data across a component hierarchy using cascading values and parameters.
- Server-side in-memory state container service (client-side equivalent) section of the *State management* article.

For the state manager approach, C# events are outside the Blazor rendering pipeline. Call StateHasChanged on other components you wish to rerender in response to the state manager's events.

The state manager approach is similar to the earlier case with System.Timers.Timer in the previous section. Since the execution call stack typically remains on the renderer's synchronization context, calling InvokeAsync isn't normally required. Calling InvokeAsync is only required if the logic escapes the synchronization context, such as calling ContinueWith on a Task or awaiting a Task with ConfigureAwait(false). For more information, see the Receiving a call from something external to the Blazor rendering and event handling system section.

WebAssembly loading progress indicator for Blazor Web Apps

A loading progress indicator isn't present in an app created from the Blazor Web App project template. A new loading progress indicator feature is planned for a future release of .NET. In the meantime, an app can adopt custom code to create a loading progress indicator. For more information, see ASP.NET Core Blazor startup.

ASP.NET Core Blazor templated components

By Robert Haken

This article explains how templated components can accept one or more UI templates as parameters, which can then be used as part of the component's rendering logic.

Templated components

Templated components are components that receive one or more UI templates as parameters, which can be utilized in the rendering logic of the component. By using templated components, you can create higher-level components that are more reusable. Examples include:

- A table component that allows a user to specify templates for the table's header, rows, and footer.
- A list component that allows a user to specify a template for rendering items in a list.
- A navigation bar component that allows a user to specify a template for start content and navigation links.

A templated component is defined by specifying one or more component parameters of type RenderFragment or RenderFragment<TValue>. A render fragment represents a segment of UI to render. RenderFragment<TValue> takes a type parameter that can be specified when the render fragment is invoked.

> **Note**
>
> For more information on RenderFragment, see ASP.NET Core Razor components.

Often, templated components are generically typed, as the following `TemplatedNavBar` component (`TemplatedNavBar.razor`) demonstrates. The generic type (`<T>`) in the following example is used to render IReadOnlyList<T> values, which in this case is a list of pets for a component that displays a navigation bar with links to a pet detail component.

`TemplatedNavBar.razor`:

```
@typeparam TItem

<nav class="navbar navbar-expand navbar-light bg-light">
    <div class="container justify-content-start">
        @StartContent
        <div class="navbar-nav">
            @foreach (var item in Items)
            {
                @ItemTemplate(item)
            }
        </div>
    </div>
</nav>

@code {
    [Parameter]
    public RenderFragment? StartContent { get; set; }

    [Parameter, EditorRequired]
    public RenderFragment<TItem> ItemTemplate { get; set; } = default!;

    [Parameter, EditorRequired]
    public IReadOnlyList<TItem> Items { get; set; } = default!;
}
```

When using a templated component, the template parameters can be specified using child elements that match the names of the parameters. In the following example, `<StartContent>...</StartContent>` and `<ItemTemplate>...</ItemTemplate>` supply RenderFragment<TValue> templates for `StartContent` and `ItemTemplate` of the `TemplatedNavBar` component.

Specify the `Context` attribute on the component element when you want to specify the content parameter name for implicit child content (without any wrapping child element). In the following example, the `Context` attribute appears on the `TemplatedNavBar` element and applies to all RenderFragment<TValue> template parameters.

`Pets1.razor`:

```
@page "/pets-1"

<PageTitle>Pets 1</PageTitle>

<h1>Pets Example 1</h1>

<TemplatedNavBar Items="pets" Context="pet">
    <StartContent>
        <a href="/" class="navbar-brand">PetsApp</a>
    </StartContent>
    <ItemTemplate>
        <NavLink href="@($"/pet-detail/{pet.PetId}?ReturnUrl=%2Fpets-1")"
class="nav-link">
            @pet.Name
        </NavLink>
    </ItemTemplate>
</TemplatedNavBar>

@code {
    private List<Pet> pets = new()
    {
        new Pet { PetId = 1, Name = "Mr. Bigglesworth" },
        new Pet { PetId = 2, Name = "Salem Saberhagen" },
        new Pet { PetId = 3, Name = "K-9" }
    };

    private class Pet
    {
        public int PetId { get; set; }
        public string? Name { get; set; }
    }
}
```

Alternatively, you can change the parameter name using the `Context` attribute on the RenderFragment<TValue> child element. In the following example, the `Context` is set on `ItemTemplate` rather than `TemplatedNavBar`.

`Pets2.razor`:

```
@page "/pets-2"

<PageTitle>Pets 2</PageTitle>

<h1>Pets Example 2</h1>

<TemplatedNavBar Items="pets">
    <StartContent>
        <a href="/" class="navbar-brand">PetsApp</a>
    </StartContent>
    <ItemTemplate Context="pet">
        <NavLink href="@($"/pet-detail/{pet.PetId}?ReturnUrl=%2Fpets-2")"
```

```
class="nav-link">
            @pet.Name
        </NavLink>
    </ItemTemplate>
</TemplatedNavBar>

@code {
    private List<Pet> pets = new()
    {
        new Pet { PetId = 1, Name = "Mr. Bigglesworth" },
        new Pet { PetId = 2, Name = "Salem Saberhagen" },
        new Pet { PetId = 3, Name = "K-9" }
    };

    private class Pet
    {
        public int PetId { get; set; }
        public string? Name { get; set; }
    }
}
```

Component arguments of type RenderFragment<TValue> have an implicit parameter named `context`, which can be used. In the following example, `Context` isn't set. `@context.{PROPERTY}` supplies pet values to the template, where `{PROPERTY}` is a `Pet` property:

`Pets3.razor`:

```
@page "/pets-3"

<PageTitle>Pets 3</PageTitle>

<h1>Pets Example 3</h1>

<TemplatedNavBar Items="pets">
    <StartContent>
        <a href="/" class="navbar-brand">PetsApp</a>
    </StartContent>
    <ItemTemplate>
        <NavLink href="@($"/pet-detail/{context.PetId}?ReturnUrl=%2Fpets-
3")" class="nav-link">
            @context.Name
        </NavLink>
    </ItemTemplate>
</TemplatedNavBar>

@code {
    private List<Pet> pets = new()
    {
        new Pet { PetId = 1, Name = "Mr. Bigglesworth" },
        new Pet { PetId = 2, Name = "Salem Saberhagen" },
```

```
        new Pet { PetId = 3, Name = "K-9" }
    };

    private class Pet
    {
        public int PetId { get; set; }
        public string? Name { get; set; }
    }
}
```

When using generic-typed components, the type parameter is inferred if possible. However, you can explicitly specify the type with an attribute that has a name matching the type parameter, which is `TItem` in the preceding example:

`Pets4.razor`:

```
@page "/pets-4"

<PageTitle>Pets 4</PageTitle>

<h1>Pets Example 4</h1>

<TemplatedNavBar Items="pets" Context="pet" TItem="Pet">
    <StartContent>
        <a href="/" class="navbar-brand">PetsApp</a>
    </StartContent>
    <ItemTemplate>
        <NavLink href="@($"/pet-detail/{pet.PetId}?ReturnUrl=%2Fpets-4")"
class="nav-link">
            @pet.Name
        </NavLink>
    </ItemTemplate>
</TemplatedNavBar>

@code {
    private List<Pet> pets = new()
    {
        new Pet { PetId = 2, Name = "Mr. Bigglesworth" },
        new Pet { PetId = 4, Name = "Salem Saberhagen" },
        new Pet { PetId = 7, Name = "K-9" }
    };

    private class Pet
    {
        public int PetId { get; set; }
        public string? Name { get; set; }
    }
}
```

The example provided in the `TemplatedNavBar` component (`TemplatedNavBar.razor`) assumes that the `Items` collection doesn't change after the initial render; or that if it does change, maintaining the state of components/elements used in `ItemTemplate` isn't necessary. For templated components where such usage can't be anticipated, see the Preserve relationships with @key section.

Preserve relationships with `@key`

Templated components are often used to render collections of items, such as tables or lists. In such general scenarios, we can't assume that the user will avoid stateful components/elements in the item template definition or that there won't be additional changes to the `Items` collection. For such templated components, it's necessary to preserve the relationships with the `@key` directive attribute.

> ⓘ Note
>
> For more information on the `@key` directive attribute, see Retain element, component, and model relationships in ASP.NET Core Blazor.

The following `TableTemplate` component (`TableTemplate.razor`) demonstrates a templated component that preserves relationships with `@key`.

`TableTemplate.razor`:

```
@typeparam TItem

<table class="table">
    <thead>
        <tr>@TableHeader</tr>
    </thead>
    <tbody>
        @foreach (var item in Items)
        {
            <tr @key="@item">@RowTemplate(item)</tr>
        }
    </tbody>
</table>

@code {
    [Parameter]
    public RenderFragment? TableHeader { get; set; }

    [Parameter, EditorRequired]
    public RenderFragment<TItem> RowTemplate { get; set; } = default!;
```

```
    [Parameter, EditorRequired]
    public IReadOnlyList<TItem> Items { get; set; } = default!;
}
```

Consider the following `Pets5` component (`Pets5.razor`), which demonstrates the importance of keying data to preserve model relationships. In the component, each iteration of adding a pet in OnAfterRenderAsync results in Blazor rerendering the `TableTemplate` component.

`Pets5.razor`:

```
@page "/pets-5"

<PageTitle>Pets 5</PageTitle>

<h1>Pets Example 5</h1>

<TableTemplate Items="pets" Context="pet">
    <TableHeader>
        <th>ID</th>
        <th>Name</th>
    </TableHeader>
    <RowTemplate>
        <td><input value="@pet.PetId" /></td>
        <td><input value="@pet.Name" /></td>
    </RowTemplate>
</TableTemplate>

@code {
    private List<Pet> pets = new()
    {
        new Pet { PetId = 1, Name = "Mr. Bigglesworth" },
        new Pet { PetId = 2, Name = "Salem Saberhagen" },
        new Pet { PetId = 3, Name = "K-9" }
    };

    protected override async Task OnAfterRenderAsync(bool firstRender)
    {
        // Insert new pet every 5 seconds
        if (pets.Count < 10)
        {
            await Task.Delay(5000);
            pets.Insert(0, new Pet() { PetId = pets.Count + 1, Name = "<new
pet>" });
            StateHasChanged();
        }
    }

    private class Pet
    {
```

```
        public int PetId { get; set; }
        public string? Name { get; set; }
    }
}
```

This demonstration allows you to:

- Select an `<input>` from among several rendered table rows.
- Study the behavior of the page's focus as the pets collection automatically grows.

Without using the `@key` directive attribute in the `TableTemplate` component, the page's focus remains on the same index position (row) of the table, causing the focus to shift each time a pet is added. To demonstrate this, remove the `@key` directive attribute and value, restart the app, and attempt to modify a field value as items are added.

ASP.NET Core Blazor CSS isolation

Article • 09/12/2024

> **Important**
>

>
> For the current release, see the .NET 8 version of this article.

By Dave Brock

This article explains how CSS isolation scopes CSS to Razor components, which can simplify CSS and avoid collisions with other components or libraries.

Isolate CSS styles to individual pages, views, and components to reduce or avoid:

- Dependencies on global styles that can be challenging to maintain.
- Style conflicts in nested content.

Enable CSS isolation

To define component-specific styles, create a `.razor.css` file matching the name of the `.razor` file for the component in the same folder. The `.razor.css` file is a *scoped CSS file*.

For an `Example` component in an `Example.razor` file, create a file alongside the component named `Example.razor.css`. The `Example.razor.css` file must reside in the same folder as the `Example` component (`Example.razor`). The "`Example`" base name of the file is **not** case-sensitive.

`Example.razor`:

```razor
@page "/example"

<h1>Scoped CSS Example</h1>
```

`Example.razor.css`:

```css
h1 {
    color: brown;
    font-family: Tahoma, Geneva, Verdana, sans-serif;
}
```

The styles defined in `Example.razor.css` are only applied to the rendered output of the `Example` component. CSS isolation is applied to HTML elements in the matching Razor file. Any `h1` CSS declarations defined elsewhere in the app don't conflict with the `Example` component's styles.

> ⓘ Note
>
> In order to guarantee style isolation when bundling occurs, importing CSS in Razor code blocks isn't supported.

CSS isolation bundling

CSS isolation occurs at build time. Blazor rewrites CSS selectors to match markup rendered by the component. The rewritten CSS styles are bundled and produced as a static asset. The stylesheet is referenced inside the `<head>` tag (location of <head> content). The following `<link>` element is added to an app created from the Blazor project templates:

Blazor Web Apps:

```HTML
<link href="@Assets["{ASSEMBLY NAME}.styles.css"]" rel="stylesheet">
```

Standalone Blazor WebAssembly apps:

```HTML
<link href="{ASSEMBLY NAME}.styles.css" rel="stylesheet">
```

The `{ASSEMBLY NAME}` placeholder is the project's assembly name.

Within the bundled file, each component is associated with a scope identifier. For each styled component, an HTML attribute is appended with the format `b-{STRING}`, where

the `{STRING}` placeholder is a ten-character string generated by the framework. The identifier is unique for each app. In the rendered `Counter` component, Blazor appends a scope identifier to the `h1` element:

HTML

```
<h1 b-3xxtam6d07>
```

The `{ASSEMBLY NAME}.styles.css` file uses the scope identifier to group a style declaration with its component. The following example provides the style for the preceding `<h1>` element:

css

```
/* /Components/Pages/Counter.razor.rz.scp.css */
h1[b-3xxtam6d07] {
    color: brown;
}
```

At build time, a project bundle is created with the convention `obj/{CONFIGURATION}/{TARGET FRAMEWORK}/scopedcss/projectbundle/{ASSEMBLY NAME}.bundle.scp.css`, where the placeholders are:

- `{CONFIGURATION}`: The app's build configuration (for example, `Debug`, `Release`).
- `{TARGET FRAMEWORK}`: The target framework (for example, `net6.0`).
- `{ASSEMBLY NAME}`: The app's assembly name (for example, `BlazorSample`).

Child component support

CSS isolation only applies to the component you associate with the format `{COMPONENT NAME}.razor.css`, where the `{COMPONENT NAME}` placeholder is usually the component name. To apply changes to a child component, use the `::deep` pseudo-element to any descendant elements in the parent component's `.razor.css` file. The `::deep` pseudo-element selects elements that are *descendants* of an element's generated scope identifier.

The following example shows a parent component called `Parent` with a child component called `Child`.

`Parent.razor`:

razor

```razor
@page "/parent"

<div>
    <h1>Parent component</h1>

    <Child />
</div>
```

`Child.razor`:

razor

```razor
<h1>Child Component</h1>
```

Update the `h1` declaration in `Parent.razor.css` with the `::deep` pseudo-element to signify the `h1` style declaration must apply to the parent component and its children.

`Parent.razor.css`:

css

```css
::deep h1 {
    color: red;
}
```

The `h1` style now applies to the `Parent` and `Child` components without the need to create a separate scoped CSS file for the child component.

The `::deep` pseudo-element only works with descendant elements. The following markup applies the `h1` styles to components as expected. The parent component's scope identifier is applied to the `div` element, so the browser knows to inherit styles from the parent component.

`Parent.razor`:

razor

```razor
<div>
    <h1>Parent</h1>

    <Child />
</div>
```

However, excluding the `div` element removes the descendant relationship. In the following example, the style is **not** applied to the child component.

`Parent.razor`:

```razor
<h1>Parent</h1>

<Child />
```

The `::deep` pseudo-element affects where the scope attribute is applied to the rule. When you define a CSS rule in a scoped CSS file, the scope is applied to the right most element. For example: `div > a` is transformed to `div > a[b-{STRING}]`, where the `{STRING}` placeholder is a ten-character string generated by the framework (for example, `b-3xxtam6d07`). If you instead want the rule to apply to a different selector, the `::deep` pseudo-element allows you do so. For example, `div ::deep > a` is transformed to `div[b-{STRING}] > a` (for example, `div[b-3xxtam6d07] > a`).

The ability to attach the `::deep` pseudo-element to any HTML element allows you to create scoped CSS styles that affect elements rendered by other components when you can determine the structure of the rendered HTML tags. For a component that renders an hyperlink tag (`<a>`) inside another component, ensure the component is wrapped in a `div` (or any other element) and use the rule `::deep > a` to create a style that's only applied to that component when the parent component renders.

> **ⓘ Important**
>
> Scoped CSS only applies to ***HTML elements*** and not to Razor components or Tag Helpers, including elements with a Tag Helper applied, such as `<input asp-for="..." />`.

CSS preprocessor support

CSS preprocessors are useful for improving CSS development by utilizing features such as variables, nesting, modules, mixins, and inheritance. While CSS isolation doesn't natively support CSS preprocessors such as Sass or Less, integrating CSS preprocessors is seamless as long as preprocessor compilation occurs before Blazor rewrites the CSS selectors during the build process. Using Visual Studio for example, configure existing

preprocessor compilation as a **Before Build** task in the Visual Studio Task Runner Explorer.

Many third-party NuGet packages, such as AspNetCore.SassCompiler, can compile SASS/SCSS files at the beginning of the build process before CSS isolation occurs.

CSS isolation configuration

CSS isolation is designed to work out-of-the-box but provides configuration for some advanced scenarios, such as when there are dependencies on existing tools or workflows.

Customize scope identifier format

Scope identifiers use the format `b-{STRING}`, where the `{STRING}` placeholder is a ten-character string generated by the framework. To customize the scope identifier format, update the project file to a desired pattern:

XML

```
<ItemGroup>
  <None Update="Components/Pages/Example.razor.css" CssScope="custom-scope-identifier" />
</ItemGroup>
```

In the preceding example, the CSS generated for `Example.razor.css` changes its scope identifier from `b-{STRING}` to `custom-scope-identifier`.

Use scope identifiers to achieve inheritance with scoped CSS files. In the following project file example, a `BaseComponent.razor.css` file contains common styles across components. A `DerivedComponent.razor.css` file inherits these styles.

XML

```
<ItemGroup>
  <None Update="Components/Pages/BaseComponent.razor.css" CssScope="custom-scope-identifier" />
  <None Update="Components/Pages/DerivedComponent.razor.css" CssScope="custom-scope-identifier" />
</ItemGroup>
```

Use the wildcard (`*`) operator to share scope identifiers across multiple files:

XML

```
<ItemGroup>
  <None Update="Components/Pages/*.razor.css" CssScope="custom-scope-
identifier" />
</ItemGroup>
```

Change base path for static web assets

The `scoped.styles.css` file is generated at the root of the app. In the project file, use the <StaticWebAssetBasePath> property to change the default path. The following example places the `scoped.styles.css` file, and the rest of the app's assets, at the `_content` path:

XML

```
<PropertyGroup>
  <StaticWebAssetBasePath>_content/$(PackageId)</StaticWebAssetBasePath>
</PropertyGroup>
```

Disable automatic bundling

To opt out of how Blazor publishes and loads scoped files at runtime, use the `DisableScopedCssBundling` property. When using this property, it means other tools or processes are responsible for taking the isolated CSS files from the `obj` directory and publishing and loading them at runtime:

XML

```
<PropertyGroup>
  <DisableScopedCssBundling>true</DisableScopedCssBundling>
</PropertyGroup>
```

Disable CSS isolation

Disable CSS isolation for a project by setting the `<ScopedCssEnabled>` property to `false` in the app's project file:

XML

```
<ScopedCssEnabled>false</ScopedCssEnabled>
```

Razor class library (RCL) support

Isolated styles for components in a NuGet package or Razor class library (RCL) are automatically bundled:

- The app uses CSS imports to reference the RCL's bundled styles. For a class library named `ClassLib` and a Blazor app with a `BlazorSample.styles.css` stylesheet, the RCL's stylesheet is imported at the top of the app's stylesheet:

  ```
  css
  ```

  ```
  @import '_content/ClassLib/ClassLib.bundle.scp.css';
  ```

- The RCL's bundled styles aren't published as a static web asset of the app that consumes the styles.

For more information on RCLs, see the following articles:

- Consume ASP.NET Core Razor components from a Razor class library (RCL)
- Reusable Razor UI in class libraries with ASP.NET Core

Dynamically-rendered ASP.NET Core Razor components

Article • 11/06/2024

>
> For the current release, see the .NET 8 version of this article.

By Dave Brock

Use the built-in DynamicComponent component to render components by type.

Dynamic components

A DynamicComponent is useful for rendering components without iterating through possible types or using conditional logic. For example, DynamicComponent can render a component based on a user selection from a dropdown list.

In the following example:

- `componentType` specifies the type.
- `parameters` specifies component parameters to pass to the `componentType` component.

razor

```
<DynamicComponent Type="componentType" Parameters="parameters" />

@code {
    private Type componentType = ...;
    private IDictionary<string, object> parameters = ...;
}
```

For more information on passing parameter values, see the Pass parameters section later in this article.

Example

In the following example, a Razor component renders a component based on the user's selection from a dropdown list of four possible values.

Expand table

User spaceflight carrier selection	Shared Razor component to render
Rocket Lab®	`RocketLab.razor`
SpaceX®	`SpaceX.razor`
ULA®	`UnitedLaunchAlliance.razor`
Virgin Galactic®	`VirginGalactic.razor`

`RocketLab.razor`:

razor

```razor
<h2>Rocket Lab®</h2>

<p>
    Rocket Lab is a registered trademark of
    <a href="https://www.rocketlabusa.com/">Rocket Lab USA Inc.</a>
</p>
```

`SpaceX.razor`:

razor

```razor
<h2>SpaceX®</h2>

<p>
    SpaceX is a registered trademark of
    <a href="https://www.spacex.com/">Space Exploration Technologies Corp.
</a>
</p>
```

`UnitedLaunchAlliance.razor`:

razor

```razor
<h2>United Launch Alliance®</h2>

<p>
    United Launch Alliance and ULA are registered trademarks of
```

```
    <a href="https://www.ulalaunch.com/">United Launch Alliance, LLC</a>.
</p>
```

`VirginGalactic.razor`:

razor

```
<h2>Virgin Galactic®</h2>

<p>
    Virgin Galactic is a registered trademark of
    <a href="https://www.virgingalactic.com/">Galactic Enterprises, LLC</a>.
</p>
```

`DynamicComponent1.razor`:

razor

```
@page "/dynamic-component-1"

<PageTitle>Dynamic Component 1</PageTitle>

<h1>Dynamic Component Example 1</h1>

<p>
    <label>
        Select your transport:
        <select @onchange="OnDropdownChange">
            <option value="">Select a value</option>
            @foreach (var entry in components.Keys)
            {
                <option value="@entry">@entry</option>
            }
        </select>
    </label>
</p>

@if (selectedType is not null)
{
    <div class="border border-primary my-1 p-1">
        <DynamicComponent Type="selectedType" />
    </div>
}

@code {
    private readonly Dictionary<string, Type> components = new()
    {
        ["Rocket Lab"] = typeof(RocketLab),
        ["SpaceX"] = typeof(SpaceX),
        ["ULA"] = typeof(UnitedLaunchAlliance),
        ["Virgin Galactic"] = typeof(VirginGalactic)
```

```
    };
    private Type? selectedType;

    private void OnDropdownChange(ChangeEventArgs e)
    {
        if ((e.Value is string dropdownValue) &&
            !String.IsNullOrWhiteSpace(dropdownValue))
        {
            selectedType = components[dropdownValue];
        }
        else
        {
            selectedType = null;
        }
    }
}
```

In the preceding example:

- An Dictionary<TKey,TValue> is used to manage components to be displayed.
- Names serve as the dictionary keys and are provided as selection options.
- Component types are stored as dictionary values using the typeof operator.

Pass parameters

If dynamically-rendered components have component parameters, pass them into the DynamicComponent as an `IDictionary<string, object>`. The `string` is the name of the parameter, and the `object` is the parameter's value.

The following example configures a component metadata object (`ComponentMetadata`) to supply parameter values to dynamically-rendered components based on the type name. The example is just one of several approaches that you can adopt. Parameter data can also be provided from a web API, a database, or a method. The only requirement is that the approach returns an `IDictionary<string, object>`.

`ComponentMetadata.cs`:

C#

```
namespace BlazorSample;

public class ComponentMetadata
{
    public required Type Type { get; init; }
    public required string Name { get; init; }
    public Dictionary<string, object> Parameters { get; } = [];
}
```

The following `RocketLabWithWindowSeat` component (`RocketLabWithWindowSeat.razor`) has been updated from the preceding example to include a component parameter named `WindowSeat` to specify if the passenger prefers a window seat on their flight:

`RocketLabWithWindowSeat.razor`:

```razor
<h2>Rocket Lab®</h2>

<p>
    User selected a window seat: @WindowSeat
</p>

<p>
    Rocket Lab is a trademark of
    <a href="https://www.rocketlabusa.com/">Rocket Lab USA Inc.</a>
</p>

@code {
    [Parameter]
    public bool WindowSeat { get; set; }
}
```

In the following example:

- Only the `RocketLabWithWindowSeat` component's parameter for a window seat (`WindowSeat`) receives the value of the **`Window Seat`** checkbox.
- Component names are used as dictionary keys using the nameof operator, which returns component names as constant strings.
- The dynamically-rendered components are shared components:
  - Shown in this article section: `RocketLabWithWindowSeat` (`RocketLabWithWindowSeat.razor`)
  - Components shown in the Example section earlier in this article:
    - `SpaceX` (`SpaceX.razor`)
    - `UnitedLaunchAlliance` (`UnitedLaunchAlliance.razor`)
    - `VirginGalactic` (`VirginGalactic.razor`)

`DynamicComponent2.razor`:

```razor
@page "/dynamic-component-2"

<PageTitle>Dynamic Component 2</PageTitle>

<h1>Dynamic Component Example 2</h1>
```

```
<p>
    <label>
        <input type="checkbox" @bind="windowSeat"
            @bind:after="HandleWindowSeatChanged" />
        Window Seat (Rocket Lab only)
    </label>
</p>

<p>
    <label>
        Select your transport:
        <select @onchange="OnDropdownChange">
            <option value="">Select a value</option>
            @foreach (var c in components)
            {
                <option value="@c.Key">@c.Value.Name</option>
            }
        </select>
    </label>
</p>

@if (selectedComponent is not null)
{
    <div class="border border-primary my-1 p-1">
        <DynamicComponent Type="selectedComponent.Type"
            Parameters="selectedComponent.Parameters" />
    </div>
}

@code {
    private Dictionary<string, ComponentMetadata> components =
        new()
        {
            [nameof(RocketLabWithWindowSeat)] = new ComponentMetadata()
            {
                Type = typeof(RocketLabWithWindowSeat),
                Name = "Rocket Lab with Window Seat",
                Parameters = { [nameof(RocketLabWithWindowSeat.WindowSeat)]
= false }
            },
            [nameof(VirginGalactic)] = new ComponentMetadata()
            {
                Type = typeof(VirginGalactic),
                Name = "Virgin Galactic"
            },
            [nameof(UnitedLaunchAlliance)] = new ComponentMetadata()
            {
                Type = typeof(UnitedLaunchAlliance),
                Name = "ULA"
            },
            [nameof(SpaceX)] = new ComponentMetadata()
            {
                Type = typeof(SpaceX),
                Name = "SpaceX"
```

```
            }
        };
    private ComponentMetadata? selectedComponent;
    private bool windowSeat;

    private void HandleWindowSeatChanged()
    {
        components[nameof(RocketLabWithWindowSeat)]
            .Parameters[nameof(RocketLabWithWindowSeat.WindowSeat)] =
windowSeat;
    }

    private void OnDropdownChange(ChangeEventArgs e)
    {
        if ((e.Value is string dropdownValue) &&
!String.IsNullOrWhiteSpace(dropdownValue))
        {
            selectedComponent = components[dropdownValue];
        }
        else
        {
            selectedComponent = null;
        }
    }
}
```

Event callbacks (`EventCallback`)

Event callbacks (EventCallback) can be passed to a DynamicComponent in its parameter dictionary.

`ComponentMetadata.cs`:

C#

```
namespace BlazorSample;

public class ComponentMetadata
{
    public required Type Type { get; init; }
    public required string Name { get; init; }
    public Dictionary<string, object> Parameters { get; } = [];
}
```

Implement an event callback parameter (EventCallback) within each dynamically-rendered component.

`RocketLab2.razor`:

razor

```razor
<h2>Rocket Lab®</h2>

<p>
    Rocket Lab is a registered trademark of
    <a href="https://www.rocketlabusa.com/">Rocket Lab USA Inc.</a>
</p>

<button @onclick="OnClickCallback">
    Trigger a Parent component method
</button>

@code {
    [Parameter]
    public EventCallback<MouseEventArgs> OnClickCallback { get; set; }
}
```

`SpaceX2.razor`:

razor

```razor
<h2>SpaceX®</h2>

<p>
    SpaceX is a registered trademark of
    <a href="https://www.spacex.com/">Space Exploration Technologies Corp.
</a>
</p>

<button @onclick="OnClickCallback">
    Trigger a Parent component method
</button>

@code {
    [Parameter]
    public EventCallback<MouseEventArgs> OnClickCallback { get; set; }
}
```

`UnitedLaunchAlliance2.razor`:

razor

```razor
<h2>United Launch Alliance®</h2>

<p>
    United Launch Alliance and ULA are registered trademarks of
    <a href="https://www.ulalaunch.com/">United Launch Alliance, LLC</a>.
</p>

<button @onclick="OnClickCallback">
```

```
    Trigger a Parent component method
</button>

@code {
    [Parameter]
    public EventCallback<MouseEventArgs> OnClickCallback { get; set; }
}
```

`VirginGalactic2.razor`:

razor

```
<h2>Virgin Galactic®</h2>

<p>
    Virgin Galactic is a registered trademark of
    <a href="https://www.virgingalactic.com/">Galactic Enterprises, LLC</a>.
</p>

<button @onclick="OnClickCallback">
    Trigger a Parent component method
</button>

@code {
    [Parameter]
    public EventCallback<MouseEventArgs> OnClickCallback { get; set; }
}
```

In the following parent component example, the `ShowDTMessage` method assigns a string with the current time to `message`, and the value of `message` is rendered.

The parent component passes the callback method, `ShowDTMessage` in the parameter dictionary:

- The `string` key is the callback method's name, `OnClickCallback`.
- The `object` value is created by EventCallbackFactory.Create for the parent callback method, `ShowDTMessage`. Note that the this keyword isn't supported in C# field initialization, so a C# property is used for the parameter dictionary.

`DynamicComponent3.razor`:

razor

```
@page "/dynamic-component-3"

<PageTitle>Dynamic Component 3</PageTitle>

<h1>Dynamic Component Example 3</h1>
```

```
<p>
    <label>
        Select your transport:
        <select @onchange="OnDropdownChange">
            <option value="">Select a value</option>
            @foreach (var c in Components)
            {
                <option value="@c.Key">@c.Value.Name</option>
            }
        </select>
    </label>
</p>

@if (selectedComponent is not null)
{
    <div class="border border-primary my-1 p-1">
        <DynamicComponent Type="selectedComponent.Type"
            Parameters="selectedComponent.Parameters" />
    </div>
}

<p>
    @message
</p>

@code {
    private ComponentMetadata? selectedComponent;
    private string? message;

    private Dictionary<string, ComponentMetadata> Components =>
        new()
        {
            [nameof(RocketLab2)] = new ComponentMetadata()
            {
                Type = typeof(RocketLab2),
                Name = "Rocket Lab",
                Parameters = { [nameof(RocketLab2.OnClickCallback)] =
                    EventCallback.Factory.Create<MouseEventArgs>(this,
ShowDTMessage) }
            },
            [nameof(VirginGalactic2)] = new ComponentMetadata()
            {
                Type = typeof(VirginGalactic2),
                Name = "Virgin Galactic",
                Parameters = { [nameof(VirginGalactic2.OnClickCallback)] =
                    EventCallback.Factory.Create<MouseEventArgs>(this,
ShowDTMessage) }
            },
            [nameof(UnitedLaunchAlliance2)] = new ComponentMetadata()
            {
                Type = typeof(UnitedLaunchAlliance2),
                Name = "ULA",
                Parameters = {
[nameof(UnitedLaunchAlliance2.OnClickCallback)] =
                    EventCallback.Factory.Create<MouseEventArgs>(this,
```

```
ShowDTMessage) }
            },
            [nameof(SpaceX2)] = new ComponentMetadata()
            {
                Type = typeof(SpaceX2),
                Name = "SpaceX",
                Parameters = { [nameof(SpaceX2.OnClickCallback)] =
                    EventCallback.Factory.Create<MouseEventArgs>(this,
ShowDTMessage) }
            }
        };

    private void OnDropdownChange(ChangeEventArgs e)
    {
        if ((e.Value is string dropdownValue) &&
!String.IsNullOrWhiteSpace(dropdownValue))
        {
            selectedComponent = Components[dropdownValue];
        }
        else
        {
            selectedComponent = null;
        }
    }

    private void ShowDTMessage(MouseEventArgs e) =>
        message = $"The current DT is: {DateTime.Now}.";
}
```

Avoid catch-all parameters

Avoid the use of catch-all parameters. If catch-all parameters are used, every explicit parameter on DynamicComponent effectively is a reserved word that you can't pass to a dynamic child. Any new parameters passed to DynamicComponent are a breaking change, as they start shadowing child component parameters that happen to have the same name. It's unlikely that the caller always knows a fixed set of parameter names to pass to all possible dynamic children.

Access the dynamically-created component instance

Use the Instance property to access the dynamically-created component instance.

Create an interface to describe the dynamically-created component instance with any methods and properties that you need to access from the parent component when the

component is dynamically loaded. The following example specifies a `Log` method for implementation in components.

`Interfaces/ILoggable.cs`:

C#

```
using Microsoft.AspNetCore.Components;

namespace BlazorSample.Interfaces;

public interface ILoggable : IComponent
{
    public void Log();
}
```

Each component definition implements the interface. The following example is a modified Rocket Lab® component from the Example section that logs a string via its `Log` method.

`RocketLab3.razor`:

razor

```
@using BlazorSample.Interfaces
@implements ILoggable
@inject ILogger<RocketLab3> Logger

<h2>Rocket Lab®</h2>

<p>
    Rocket Lab is a registered trademark of
    <a href="https://www.rocketlabusa.com/">Rocket Lab USA Inc.</a>
</p>

@code {
    public void Log() => Logger.LogInformation("Woot! I logged this call!");
}
```

The remaining three shared components (`VirginGalactic3`, `UnitedLaunchAlliance3`, `SpaceX3`) receive similar treatment:

- The following directives are added to the components, where the `{COMPONENT TYPE}` placeholder is the component type:

  razor

```
@using BlazorSample.Interfaces
@implements ILoggable
@inject ILogger<{COMPONENT TYPE}> Logger
```

- Each component implements a `Log` method. The log category written by the logger includes the fully-qualified name of the component type when LogInformation is called:

  razor

  ```
  @code {
      public void Log()
      {
          Logger.LogInformation("Woot! I logged this call!");
      }
  }
  ```

The parent component casts the dynamically-loaded component instance as an `ILoggable` to access members of the interface. In the following example, the loaded component's `Log` method is called when a button is selected in the UI:

razor

```
...
@using BlazorSample.Interfaces

...

<DynamicComponent Type="..." @ref="dc" />

...

<button @onclick="LogFromLoadedComponent">Log from loaded component</button>

@code {
    private DynamicComponent? dc;

    ...

    private void LogFromLoadedComponent() => (dc?.Instance as
ILoggable)?.Log();
}
```

For a working demonstration of the preceding example, see the DynamicComponent4 component in the Blazor sample app.

Trademarks

Rocket Lab is a registered trademark of Rocket Lab USA Inc. SpaceX is a registered trademark of Space Exploration Technologies Corp. United Launch Alliance and ULA are registered trademarks of United Launch Alliance, LLC. Virgin Galactic is a registered trademark of Galactic Enterprises, LLC.

ASP.NET Core Blazor `QuickGrid` component

Article • 11/04/2024

The QuickGrid component is a Razor component for quickly and efficiently displaying data in tabular form. `QuickGrid` provides a simple and convenient data grid component for common grid rendering scenarios and serves as a reference architecture and performance baseline for building data grid components. `QuickGrid` is highly optimized and uses advanced techniques to achieve optimal rendering performance.

Package

Add a package reference for the Microsoft.AspNetCore.Components.QuickGrid package.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

Sample app

For various `QuickGrid` demonstrations, see the **QuickGrid for Blazor** sample app. The demo site is hosted on GitHub Pages. The site loads fast thanks to static prerendering using the community-maintained BlazorWasmPrerendering.Build GitHub project.

`QuickGrid` implementation

To implement a `QuickGrid` component:

- Specify tags for the `QuickGrid` component in Razor markup (`<QuickGrid>...</QuickGrid>`).
- Name a queryable source of data for the grid. Use ***either*** of the following data sources:
  - Items: A nullable `IQueryable<TGridItem>`, where `TGridItem` is the type of data represented by each row in the grid.

    - ItemsProvider: A callback that supplies data for the grid.
- Class: An optional CSS class name. If provided, the class name is included in the `class` attribute of the rendered table.
- Theme: A theme name (default value: `default`). This affects which styling rules match the table.
- Virtualize: If true, the grid is rendered with virtualization. This is normally used in conjunction with scrolling and causes the grid to fetch and render only the data around the current scroll viewport. This can greatly improve the performance when scrolling through large data sets. If you use Virtualize, you should supply a value for ItemSize and must ensure that every row renders with a constant height. Generally, it's preferable not to use Virtualize if the amount of data rendered is small or if you're using pagination.
- ItemSize: Only applicable when using Virtualize. ItemSize defines an expected height in pixels for each row, allowing the virtualization mechanism to fetch the correct number of items to match the display size and to ensure accurate scrolling.
- ItemKey: Optionally defines a value for `@key` on each rendered row. Typically, this is used to specify a unique identifier, such as a primary key value, for each data item. This allows the grid to preserve the association between row elements and data items based on their unique identifiers, even when the `TGridItem` instances are replaced by new copies (for example, after a new query against the underlying data store). If not set, the `@key` is the `TGridItem` instance.
- `OverscanCount`: Defines how many additional items to render before and after the visible region to reduce rendering frequency during scrolling. While higher values can improve scroll smoothness by rendering more items off-screen, a higher value can also result in an increase in initial load times. Finding a balance based on your data set size and user experience requirements is recommended. The default value is 3. Only available when using Virtualize.
- Pagination: Optionally links this `TGridItem` instance with a PaginationState model, causing the grid to fetch and render only the current page of data. This is normally used in conjunction with a Paginator component or some other UI logic that displays and updates the supplied PaginationState instance.
- In the `QuickGrid` child content (RenderFragment), specify PropertyColumn<TGridItem,TProp>s, which represent `TGridItem` columns whose cells display values:
    - Property: Defines the value to be displayed in this column's cells.
    - Format: Optionally specifies a format string for the value. Using Format requires the `TProp` type to implement IFormattable.
    - Sortable: Indicates whether the data should be sortable by this column. The default value may vary according to the column type. For example, a TemplateColumn<TGridItem> is sorted if any SortBy parameter is specified.

- InitialSortDirection: Indicates the sort direction if IsDefaultSortColumn is `true`.
- IsDefaultSortColumn: Indicates whether this column should be sorted by default.
- PlaceholderTemplate: If specified, virtualized grids use this template to render cells whose data hasn't been loaded.
- HeaderTemplate: An optional template for this column's header cell. If not specified, the default header template includes the Title, along with any applicable sort indicators and options buttons.
- Title: Title text for the column. The title is rendered automatically if HeaderTemplate isn't used.

For example, add the following component to render a grid.

For Blazor Web Apps, the `QuickGrid` component must adopt an interactive render mode to enable interactive features, such as paging and sorting.

`PromotionGrid.razor`:

razor

```
@page "/promotion-grid"
@using Microsoft.AspNetCore.Components.QuickGrid

<PageTitle>Promotion Grid</PageTitle>

<h1>Promotion Grid Example</h1>

<QuickGrid Items="people">
    <PropertyColumn Property="@(p => p.PersonId)" Sortable="true" />
    <PropertyColumn Property="@(p => p.Name)" Sortable="true" />
    <PropertyColumn Property="@(p => p.PromotionDate)" Format="yyyy-MM-dd"
Sortable="true" />
</QuickGrid>

@code {
    private record Person(int PersonId, string Name, DateOnly
PromotionDate);

    private IQueryable<Person> people = new[]
    {
        new Person(10895, "Jean Martin", new DateOnly(1985, 3, 16)),
        new Person(10944, "António Langa", new DateOnly(1991, 12, 1)),
        new Person(11203, "Julie Smith", new DateOnly(1958, 10, 10)),
        new Person(11205, "Nur Sari", new DateOnly(1922, 4, 27)),
        new Person(11898, "Jose Hernandez", new DateOnly(2011, 5, 3)),
        new Person(12130, "Kenji Sato", new DateOnly(2004, 1, 9)),
    }.AsQueryable();
}
```

Access the component in a browser at the relative path `/promotion-grid`.

There aren't current plans to extend `QuickGrid` with features that full-blown commercial grids tend to offer, for example, hierarchical rows, drag-to-reorder columns, or Excel-like range selections. If you require advanced features that you don't wish to develop on your own, continue using third-party grids.

Sort by column

The `QuickGrid` component can sort items by columns. In Blazor Web Apps, sorting requires the component to adopt an interactive render mode.

Add `Sortable="true"` (Sortable) to the PropertyColumn<TGridItem,TProp> tag:

```razor
<PropertyColumn Property="..." Sortable="true" />
```

In the running app, sort the `QuickGrid` column by selecting the rendered column title.

Page items with a `Paginator` component

The `QuickGrid` component can page data from the data source. In Blazor Web Apps, paging requires the component to adopt an interactive render mode.

Add a PaginationState instance to the component's `@code` block. Set the ItemsPerPage to the number of items to display per page. In the following example, the instance is named `pagination`, and ten items per page is set:

```C#
PaginationState pagination = new PaginationState { ItemsPerPage = 10 };
```

Set the `QuickGrid` component's Pagination property to `pagination`:

```razor
<QuickGrid Items="..." Pagination="pagination">
```

To provide a UI for pagination, add a Paginator component above or below the `QuickGrid` component. Set the Paginator.State to `pagination`:

razor

```
<Paginator State="pagination" />
```

In the running app, page through the items using a rendered `Paginator` component.

Custom attributes and styles

QuickGrid also supports passing custom attributes and style classes (Class) to the rendered table element:

razor

```
<QuickGrid Items="..." custom-attribute="value" Class="custom-class">
```

Entity Framework Core (EF Core) data source

Use the factory pattern to resolve an EF Core database context that provides data to a `QuickGrid` component. For more information on why the factory pattern is recommended, see ASP.NET Core Blazor with Entity Framework Core (EF Core).

A database context factory (IDbContextFactory<TContext>) is injected into the component with the `@inject` directive. The factory approach requires disposal of the database context, so the component implements the IAsyncDisposable interface with the `@implements` directive. The item provider for the `QuickGrid` component is a `DbSet<T>` obtained from the created database context (CreateDbContext) of the injected database context factory.

QuickGrid recognizes EF-supplied IQueryable instances and knows how to resolve queries asynchronously for efficiency.

Add a package reference for the Microsoft.AspNetCore.Components.QuickGrid.EntityFrameworkAdapter NuGet package.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

Call AddQuickGridEntityFrameworkAdapter on the service collection in the `Program` file to register an EF-aware IAsyncQueryExecutor implementation:

C#

```
builder.Services.AddQuickGridEntityFrameworkAdapter();
```

The following example uses an `ExampleTable` DbSet<TEntity> (table) from a `AppDbContext` database context (`context`) as the data source for a `QuickGrid` component:

razor

```
@using Microsoft.AspNetCore.Components.QuickGrid
@using Microsoft.EntityFrameworkCore
@implements IAsyncDisposable
@inject IDbContextFactory<AppDbContext> DbFactory

...

<QuickGrid ... Items="context.ExampleTable" ...>
    ...
</QuickGrid>

@code {
    private AppDbContext context = default!;

    protected override void OnInitialized()
    {
        context = DbFactory.CreateDbContext();
    }

    public async ValueTask DisposeAsync() => await context.DisposeAsync();
}
```

In the code block (`@code`) of the preceding example:

- The `context` field holds the database context, typed as an `AppDbContext`.
- The `OnInitialized` lifecycle method assigns a new database context (CreateDbContext) to the `context` field from the injected factory (`DbFactory`).
- The asynchronous `DisposeAsync` method disposes of the database context when the component is disposed.

You may also use any EF-supported LINQ operator to filter the data before passing it to the Items parameter.

The following example filters movies by a movie title entered in a search box. The database context is `BlazorWebAppMoviesContext`, and the model is `Movie`. The movie's `Title` property is used for the filter operation.

razor

```
@using Microsoft.AspNetCore.Components.QuickGrid
@using Microsoft.EntityFrameworkCore
@implements IAsyncDisposable
@inject IDbContextFactory<BlazorWebAppMoviesContext> DbFactory

...

<p>
    <input type="search" @bind="titleFilter" @bind:event="oninput" />
</p>

<QuickGrid ... Items="FilteredMovies" ...>
    ...
</QuickGrid>

@code {
    private string titleFilter = string.Empty;
    private BlazorWebAppMoviesContext context = default!;

    protected override void OnInitialized()
    {
        context = DbFactory.CreateDbContext();
    }

    private IQueryable<Movie> FilteredMovies =>
        context.Movie.Where(m => m.Title!.Contains(titleFilter));

    public async ValueTask DisposeAsync() => await context.DisposeAsync();
}
```

Display name support

A column title can be assigned using ColumnBase<TGridItem>.Title in the PropertyColumn<TGridItem,TProp>'s tag. In the following movie example, the column is given the name "`Release Date`" for the column's movie release date data:

razor

```
<PropertyColumn Property="movie => movie.ReleaseDate" Title="Release Date"
/>
```

However, managing column titles (names) from bound model properties is usually a better choice for maintaining an app. A model can control the display name of a property with the [Display] attribute. In the following example, the model specifies a movie release date display name of "`Release Date`" for its `ReleaseDate` property:

C#

```
[Display(Name = "Release Date")]
public DateTime ReleaseDate { get; set; }
```

To enable the `QuickGrid` component to use the DisplayAttribute.Name, subclass PropertyColumn<TGridItem,TProp> either in the component or in a separate class:

C#

```
public class DisplayNameColumn<TGridItem, TProp> : PropertyColumn<TGridItem,
TProp>
{
    protected override void OnParametersSet()
    {
        if (Title is null && Property.Body is MemberExpression
memberExpression)
        {
            var memberInfo = memberExpression.Member;
            Title =
                memberInfo.GetCustomAttribute<DisplayNameAttribute>
().DisplayName ??
                memberInfo.GetCustomAttribute<DisplayAttribute>().Name ??
                memberInfo.Name;
        }

        base.OnParametersSet();
    }
}
```

Use the subclass in the `QuickGrid` component. In the following example, the preceding `DisplayNameColumn` is used. The name "`Release Date`" is provided by the [Display] attribute in the model, so there's no need to specify a Title:

razor

```
<DisplayNameColumn Property="movie => movie.ReleaseDate" />
```

The [DisplayName] attribute is also supported:

C#

```
[DisplayName("Release Date")]
public DateTime ReleaseDate { get; set; }
```

However, the `[Display]` attribute is recommended because it makes additional properties available. For example, the `[Display]` attribute offers the ability to assign a resource type for localization.

Remote data

In Blazor WebAssembly apps, fetching data from a JSON-based web API on a server is a common requirement. To fetch only the data that's required for the current page/viewport of data and apply sorting or filtering rules on the server, use the ItemsProvider parameter.

ItemsProvider can also be used in a server-side Blazor app if the app is required to query an external endpoint or in other cases where the requirements aren't covered by an IQueryable.

Supply a callback matching the GridItemsProvider<TGridItem> delegate type, where `TGridItem` is the type of data displayed in the grid. The callback is given a parameter of type GridItemsProviderRequest<TGridItem>, which specifies the start index, maximum row count, and sort order of data to return. In addition to returning the matching items, a total item count (`totalItemCount`) is also required for paging and virtualization to function correctly.

The following example obtains data from the public OpenFDA Food Enforcement database.

The GridItemsProvider<TGridItem> converts the GridItemsProviderRequest<TGridItem> into a query against the OpenFDA database. Query parameters are translated into the particular URL format supported by the external JSON API. It's only possible to perform sorting and filtering via sorting and filtering that's supported by the external API. The OpenFDA endpoint doesn't support sorting, so none of the columns are marked as sortable. However, it does support skipping records (`skip` parameter) and limiting the return of records (`limit` parameter), so the component can enable virtualization and scroll quickly through tens of thousands of records.

`FoodRecalls.razor`:

```
razor
```

```
@page "/food-recalls"
@inject HttpClient Http
@inject NavigationManager Navigation

<PageTitle>Food Recalls</PageTitle>

<h1>OpenFDA Food Recalls</h1>

<div class="grid" tabindex="-1">
    <QuickGrid ItemsProvider="@foodRecallProvider" Virtualize="true">
        <PropertyColumn Title="ID" Property="@(c => c.Event_Id)" />
        <PropertyColumn Property="@(c => c.State)" />
        <PropertyColumn Property="@(c => c.City)" />
        <PropertyColumn Title="Company" Property="@(c => c.Recalling_Firm)"
/>
        <PropertyColumn Property="@(c => c.Status)" />
    </QuickGrid>
</div>

<p>Total: <strong>@numResults results found</strong></p>

@code {
    private GridItemsProvider<FoodRecall>? foodRecallProvider;
    private int numResults;

    protected override async Task OnInitializedAsync()
    {
        foodRecallProvider = async req =>
        {
            var url = Navigation.GetUriWithQueryParameters(
                "https://api.fda.gov/food/enforcement.json",
                new Dictionary<string, object?>
            {
                { "skip", req.StartIndex },
                { "limit", req.Count },
            });

            var response = await
Http.GetFromJsonAsync<FoodRecallQueryResult>(
                url, req.CancellationToken);

            return GridItemsProviderResult.From(
                items: response!.Results,
                totalItemCount: response!.Meta.Results.Total);
        };

        numResults = (await Http.GetFromJsonAsync<FoodRecallQueryResult>(

"https://api.fda.gov/food/enforcement.json"))!.Meta.Results.Total;
    }
}
```

For more information on calling web APIs, see Call a web API from an ASP.NET Core Blazor app.

`QuickGrid` scaffolder

The `QuickGrid` scaffolder scaffolds Razor components with `QuickGrid` to display data from a database.

The scaffolder generates basic Create, Read, Update, and Delete (CRUD) pages based on an Entity Framework Core data model. You can scaffold individual pages or all of the CRUD pages. You select the model class and the `DbContext`, optionally creating a new `DbContext` if needed.

The scaffolded Razor components are added to the project's in a generated folder named after the model class. The generated `Index` component uses a `QuickGrid` component to display the data. Customize the generated components as needed and enable interactivity to take advantage of interactive features, such as paging, sorting and filtering.

The components produced by the scaffolder require server-side rendering (SSR), so they aren't supported when running on WebAssembly.

Visual Studio

Right-click on the `Components/Pages` folder and select **Add** > **New Scaffolded Item**.

With the **Add New Scaffold Item** dialog open to **Installed** > **Common** > **Blazor** > **Razor Component**, select **Razor Components using Entity Framework (CRUD)**. Select the **Add** button.

CRUD is an acronym for Create, Read, Update, and Delete. The scaffolder produces create, edit, delete, details, and index components for the app.

Complete the **Add Razor Components using Entity Framework (CRUD)** dialog:

- The **Template** dropdown list includes other templates for specifically creating create, edit, delete, details, and list components. This dropdown list comes in handy when you only need to create a specific type of component scaffolded to a model class. Leave the **Template** dropdown list set to **CRUD** to scaffold a full set of components.
- In the **Model class** dropdown list, select the model class. A folder is created for the generated components from the model name (if the model class is

named `Movie`, the folder is automatically named `MoviePages`).

- For **DbContext class**, select an existing database context or select the + (plus sign) button and **Add Data Context** modal dialog to add a new database context.
- After the model dialog closes, the **Database provider** dropdown list defaults to **SQL Server**. You can select the appropriate provider for the database that you're using. The options include SQL Server, SQLite, PostgreSQL, and Azure Cosmos DB.
- Select **Add**.

Integrate ASP.NET Core Razor components into ASP.NET Core apps

Article • 10/04/2024

This article explains Razor component integration scenarios for ASP.NET Core apps.

Razor component integration

Razor components can be integrated into Razor Pages, MVC, and other types of ASP.NET Core apps. Razor components can also be integrated into any web app, including apps not based on ASP.NET Core, as custom HTML elements.

Use the guidance in the following sections depending on the app's requirements:

- To integrate components that aren't directly routable from user requests, follow the guidance in the Use non-routable components in pages or views section. Follow this guidance when the app should only embed components into existing pages and views with the Component Tag Helper.
- To integrate components with full Blazor support, follow the guidance in the Add Blazor support to an ASP.NET Core app section.

Use non-routable components in pages or views

Use the following guidance to integrate Razor components into pages or views of an existing Razor Pages or MVC app with the Component Tag Helper.

> **Note**
>
> If your app requires directly-routable components (not embedded into pages or views), skip this section and use the guidance in the Add Blazor support to an ASP.NET Core app section.

When server prerendering is used and the page or view renders:

- The component is prerendered with the page or view.
- The initial component state used for prerendering is lost.
- New component state is created when the SignalR connection is established.

For more information on rendering modes, including non-interactive static component rendering, see Component Tag Helper in ASP.NET Core. To save the state of prerendered Razor components, see Persist Component State Tag Helper in ASP.NET Core.

Add a `Components` folder to the root folder of the project.

Add an imports file to the `Components` folder with the following content. Change the `{APP NAMESPACE}` placeholder to the namespace of the project.

`Components/_Imports.razor`:

razor

```razor
@using System.Net.Http
@using System.Net.Http.Json
@using Microsoft.AspNetCore.Components.Forms
@using Microsoft.AspNetCore.Components.Routing
@using Microsoft.AspNetCore.Components.Web
@using static Microsoft.AspNetCore.Components.Web.RenderMode
@using Microsoft.AspNetCore.Components.Web.Virtualization
@using Microsoft.JSInterop
@using {APP NAMESPACE}
@using {APP NAMESPACE}.Components
```

In the project's layout file (`Pages/Shared/_Layout.cshtml` in Razor Pages apps or `Views/Shared/_Layout.cshtml` in MVC apps):

- Add the following `<base>` tag and Component Tag Helper for a HeadOutlet component to the `<head>` markup:

  CSHTML

  ```cshtml
  <base href="~/" />
  <component
  type="typeof(Microsoft.AspNetCore.Components.Web.HeadOutlet)"
      render-mode="ServerPrerendered" />
  ```

  The `href` value (the *app base path*) in the preceding example assumes that the app resides at the root URL path (`/`). If the app is a sub-application, follow the guidance in the *App base path* section of the Host and deploy ASP.NET Core Blazor article.

  The HeadOutlet component is used to render head (`<head>`) content for page titles (PageTitle component) and other head elements (HeadContent component) set by

Razor components. For more information, see Control head content in ASP.NET Core Blazor apps.

- Add a `<script>` tag for the `blazor.web.js` script immediately before the `Scripts` render section (`@await RenderSectionAsync(...)`):

  ```
  HTML
  ```

  ```
  <script src="_framework/blazor.web.js"></script>
  ```

  The Blazor framework automatically adds the `blazor.web.js` script to the app.

> **Note**
>
> Typically, the layout loads via a `_ViewStart.cshtml` file.

Add an non-operational (no-op) `App` component to the project.

`Components/App.razor`:

```
razor
```

```
@* No-op App component *@
```

Where services are registered, add services for Razor components and services to support rendering Interactive Server components.

At the top of the `Program` file, add a `using` statement to the top of the file for the project's components:

```
C#
```

```
using {APP NAMESPACE}.Components;
```

In the preceding line, change the `{APP NAMESPACE}` placeholder to the app's namespace. For example:

```
C#
```

```
using BlazorSample.Components;
```

In the `Program` file before the line that builds the app (`builder.Build()`):

C#

```
builder.Services.AddRazorComponents()
    .AddInteractiveServerComponents();
```

For more information on adding support for Interactive Server and WebAssembly components, see ASP.NET Core Blazor render modes.

In the `Program` file immediately after the call to map Razor Pages (MapRazorPages) in a Razor Pages app or to map the default controller route (MapControllerRoute) in an MVC app, call MapRazorComponents to discover available components and specify the app's root component (the first component loaded). By default, the app's root component is the `App` component (`App.razor`). Chain a call to AddInteractiveServerRenderMode to configure interactive server-side rendering (interactive SSR) for the app:

C#

```
app.MapRazorComponents<App>()
    .AddInteractiveServerRenderMode();
```

> **Note**
>
> If the app hasn't already been updated to include Antiforgery Middleware, add the following line after UseAuthorization is called:
>
> C#
>
> ```
> app.UseAntiforgery();
> ```

Integrate components into any page or view. For example, add an `EmbeddedCounter` component to the project's `Components` folder.

`Components/EmbeddedCounter.razor`:

razor

```
<h1>Embedded Counter</h1>

<p>Current count: @currentCount</p>

<button class="btn btn-primary" @onclick="IncrementCount">Click me</button>

@code {
    private int currentCount = 0;
```

```
    private void IncrementCount()
    {
        currentCount++;
    }
}
```

Razor Pages:

In the project's `Index` page of a Razor Pages app, add the `EmbeddedCounter` component's namespace and embed the component into the page. When the `Index` page loads, the `EmbeddedCounter` component is prerendered in the page. In the following example, replace the `{APP NAMESPACE}` placeholder with the project's namespace.

`Pages/Index.cshtml`:

CSHTML

```
@page
@using {APP NAMESPACE}.Components
@model IndexModel
@{
    ViewData["Title"] = "Home page";
}

<component type="typeof(EmbeddedCounter)" render-mode="ServerPrerendered" />
```

MVC:

In the project's `Index` view of an MVC app, add the `EmbeddedCounter` component's namespace and embed the component into the view. When the `Index` view loads, the `EmbeddedCounter` component is prerendered in the page. In the following example, replace the `{APP NAMESPACE}` placeholder with the project's namespace.

`Views/Home/Index.cshtml`:

CSHTML

```
@using {APP NAMESPACE}.Components
@{
    ViewData["Title"] = "Home Page";
}

<component type="typeof(EmbeddedCounter)" render-mode="ServerPrerendered" />
```

Add Blazor support to an ASP.NET Core app

This section covers adding Blazor support to an ASP.NET Core app:

- Add static server-side rendering (static SSR)
- Enable interactive server-side rendering (interactive SSR)
- Enable interactive automatic (Auto) or client-side rendering (CSR)

> **Note**
>
> For the examples in this section, the example app's name and namespace is `BlazorSample`.

Add static server-side rendering (static SSR)

Add a `Components` folder to the app.

Add the following `_Imports` file for namespaces used by Razor components.

`Components/_Imports.razor`:

```razor
@using System.Net.Http
@using System.Net.Http.Json
@using Microsoft.AspNetCore.Components.Forms
@using Microsoft.AspNetCore.Components.Routing
@using Microsoft.AspNetCore.Components.Web
@using static Microsoft.AspNetCore.Components.Web.RenderMode
@using Microsoft.AspNetCore.Components.Web.Virtualization
@using Microsoft.JSInterop
@using {APP NAMESPACE}
@using {APP NAMESPACE}.Components
```

Change the namespace placeholder (`{APP NAMESPACE}`) to the namespace of the app. For example:

```razor
@using BlazorSample
@using BlazorSample.Components
```

Add the Blazor router (`<Router>`, Router) to the app in a `Routes` component, which is placed in the app's `Components` folder.

`Components/Routes.razor`:

```razor
<Router AppAssembly="typeof(Program).Assembly">
    <Found Context="routeData">
        <RouteView RouteData="routeData" />
        <FocusOnNavigate RouteData="routeData" Selector="h1" />
    </Found>
</Router>
```

Add an `App` component to the app, which serves as the root component, which is the first component the app loads.

`Components/App.razor`:

```razor
<!DOCTYPE html>
<html lang="en">

<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <base href="/" />
    <link rel="stylesheet" href="@Assets["{ASSEMBLY NAME}.styles.css"]" />
    <HeadOutlet />
</head>

<body>
    <Routes />
    <script src="_framework/blazor.web.js"></script>
</body>

</html>
```

The `{ASSEMBLY NAME}` placeholder is the app's assembly name. For example, a project with an assembly name of `ContosoApp` uses the `ContosoApp.styles.css` stylesheet file name.

Add a `Pages` folder to the `Components` folder to hold routable Razor components.

Add the following `Welcome` component to demonstrate static SSR.

`Components/Pages/Welcome.razor`:

```razor
```

```
@page "/welcome"

<PageTitle>Welcome!</PageTitle>

<h1>Welcome to Blazor!</h1>

<p>@message</p>

@code {
    private string message =
        "Hello from a Razor component and welcome to Blazor!";
}
```

In the ASP.NET Core project's `Program` file:

- Add a `using` statement to the top of the file for the project's components:

  C#

  ```
  using {APP NAMESPACE}.Components;
  ```

  In the preceding line, change the `{APP NAMESPACE}` placeholder to the app's namespace. For example:

  C#

  ```
  using BlazorSample.Components;
  ```

- Add Razor component services (AddRazorComponents), which also automatically adds antiforgery services (AddAntiforgery). Add the following line before the line that calls `builder.Build()`):

  C#

  ```
  builder.Services.AddRazorComponents();
  ```

- Add Antiforgery Middleware to the request processing pipeline with UseAntiforgery. UseAntiforgery is called after the call to UseRouting. If there are calls to UseRouting and UseEndpoints, the call to UseAntiforgery must go between them. A call to UseAntiforgery must be placed after calls to UseAuthentication and UseAuthorization.

  C#

```
app.UseAntiforgery();
```

- Add MapRazorComponents to the app's request processing pipeline with the `App` component (`App.razor`) specified as the default root component (the first component loaded). Place the following code before the line that calls `app.Run`:

  C#

  ```
  app.MapRazorComponents<App>();
  ```

When the app is run, the `Welcome` component is accessed at the `/welcome` endpoint.

Enable interactive server-side rendering (interactive SSR)

Follow the guidance in the Add static server-side rendering (static SSR) section.

In the app's `Program` file, add a call to AddInteractiveServerComponents where Razor component services are added with AddRazorComponents:

C#

```
builder.Services.AddRazorComponents()
    .AddInteractiveServerComponents();
```

Add a call to AddInteractiveServerRenderMode where Razor components are mapped with MapRazorComponents:

C#

```
app.MapRazorComponents<App>()
    .AddInteractiveServerRenderMode();
```

Add the following `Counter` component to the app that adopts interactive server-side rendering (interactive SSR).

`Components/Pages/Counter.razor`:

razor

```
@page "/counter"
@rendermode InteractiveServer

<PageTitle>Counter</PageTitle>
```

```
<h1>Counter</h1>

<p role="status">Current count: @currentCount</p>

<button class="btn btn-primary" @onclick="IncrementCount">Click me</button>

@code {
    private int currentCount = 0;

    private void IncrementCount()
    {
        currentCount++;
    }
}
```

When the app is run, the `Counter` component is accessed at `/counter`.

Enable interactive automatic (Auto) or client-side rendering (CSR)

Follow the guidance in the Add static server-side rendering (static SSR) section.

Components using the Interactive Auto render mode initially use interactive SSR. The .NET runtime and app bundle are downloaded to the client in the background and cached so that they can be used on future visits. Components using the Interactive WebAssembly render mode only render interactively on the client after the Blazor bundle is downloaded and the Blazor runtime activates. Keep in mind that when using the Interactive Auto or Interactive WebAssembly render modes, component code downloaded to the client isn't private. For more information, see ASP.NET Core Blazor render modes.

After deciding which render mode to adopt:

- If you plan to adopt the Interactive Auto render mode, follow the guidance in the Enable interactive server-side rendering (interactive SSR) section.
- If you plan to only adopt Interactive WebAssembly rendering, continue without adding interactive SSR.

Add a package reference for the Microsoft.AspNetCore.Components.WebAssembly.Server NuGet package to the app.

> **Note**

For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

Create a donor Blazor Web App to provide assets to the app. Follow the guidance in the Tooling for ASP.NET Core Blazor article, selecting support for the following template features when generating the Blazor Web App.

For the app's name, use the same name as the ASP.NET Core app, which results in matching app name markup in components and matching namespaces in code. Using the same name/namespace isn't strictly required, as namespaces can be adjusted after assets are moved from the donor app to the ASP.NET Core app. However, time is saved by matching the namespaces at the outset.

Visual Studio:

- For **Interactive render mode**, select **Auto (Server and WebAssembly)**.
- Set the **Interactivity location** to **Per page/component**.
- Deselect the checkbox for **Include sample pages**.

.NET CLI:

- Use the `-int Auto` option.
- Don't use the `-ai|--all-interactive` option.
- Pass the `-e|--empty` option.

From the donor Blazor Web App, copy the entire `.Client` project into the solution folder of the ASP.NET Core app.

> **ⓘ Important**
>
> **Don't copy the `.Client` folder into the ASP.NET Core project's folder.** The best approach for organizing .NET solutions is to place each project of the solution into its own folder inside of a top-level solution folder. If a solution folder above the ASP.NET Core project's folder doesn't exist, create one. Next, copy the `.Client` project's folder from the donor Blazor Web App into the solution folder. The final project folder structure should have the following layout:
>
> - `BlazorSampleSolution` (top-level solution folder)
>   - `BlazorSample` (original ASP.NET Core project)
>   - `BlazorSample.Client` (`.Client` project folder from the donor Blazor Web App)

> For the ASP.NET Core solution file, you can leave it in the ASP.NET Core project's folder. Alternatively, you can move the solution file or create a new one in the top-level solution folder as long as the project references correctly point to the project files (`.csproj`) of the two projects in the solution folder.

If you named the donor Blazor Web App when you created the donor project the same as the ASP.NET Core app, the namespaces used by the donated assets match those in the ASP.NET Core app. You shouldn't need to take further steps to match namespaces. If you used a different namespace when creating the donor Blazor Web App project, you must adjust the namespaces across the donated assets to match if you intend to use the rest of this guidance exactly as presented. If the namespaces don't match, ***either*** adjust the namespaces before proceeding ***or*** adjust the namespaces as you follow the remaining guidance in this section.

Delete the donor Blazor Web App, as it has no further use in this process.

Add the `.Client` project to the solution:

- Visual Studio: Right-click the solution in **Solution Explorer** and select **Add** > **Existing Project**. Navigate to the `.Client` folder and select the project file (`.csproj`).
- .NET CLI: Use the dotnet sln add command to add the `.Client` project to the solution.

Add a project reference from the ASP.NET Core project to the client project:

- Visual Studio: Right-click the ASP.NET Core project and select **Add** > **Project Reference**. Select the `.Client` project and select **OK**.
- .NET CLI: From the ASP.NET Core project's folder, use the following command:

  .NET CLI

  ```
  dotnet add reference ../BlazorSample.Client/BlazorSample.Client.csproj
  ```

  The preceding command assumes the following:
  - The project file name is `BlazorSample.Client.csproj`.
  - The `.Client` project is in a `BlazorSample.Client` folder inside the solution folder. The `.Client` folder is side-by-side with the ASP.NET Core project's folder.

For more information on the `dotnet add reference` command, see dotnet add reference (.NET documentation).

Make the following changes to the ASP.NET Core app's `Program` file:

- Add Interactive WebAssembly component services with AddInteractiveWebAssemblyComponents where Razor component services are added with AddRazorComponents.

  For interactive Auto rendering:

  ```
  C#

  builder.Services.AddRazorComponents()
      .AddInteractiveServerComponents()
      .AddInteractiveWebAssemblyComponents();
  ```

  For only Interactive WebAssembly rendering:

  ```
  C#

  builder.Services.AddRazorComponents()
      .AddInteractiveWebAssemblyComponents();
  ```

- Add the Interactive WebAssembly render mode (AddInteractiveWebAssemblyRenderMode) and additional assemblies for the `.Client` project where Razor components are mapped with MapRazorComponents.

  For interactive automatic (Auto) rendering:

  ```
  C#

  app.MapRazorComponents<App>()
      .AddInteractiveServerRenderMode()
      .AddInteractiveWebAssemblyRenderMode()

  .AddAdditionalAssemblies(typeof(BlazorSample.Client._Imports).Assembly)
  ;
  ```

  For only Interactive WebAssembly rendering:

  ```
  C#

  app.MapRazorComponents<App>()
      .AddInteractiveWebAssemblyRenderMode()
  ```

```
.AddAdditionalAssemblies(typeof(BlazorSample.Client._Imports).Assembly)
;
```

In the preceding examples, change `BlazorSample.Client` to match the `.Client` project's namespace.

Add a `Pages` folder to the `.Client` project.

If the ASP.NET Core project has an existing `Counter` component:

- Move the component to the `Pages` folder of the `.Client` project.
- Remove the `@rendermode` directive at the top of the component file.

If the ASP.NET Core app doesn't have a `Counter` component, add the following `Counter` component (`Pages/Counter.razor`) to the `.Client` project:

razor

```
@page "/counter"
@rendermode InteractiveAuto

<PageTitle>Counter</PageTitle>

<h1>Counter</h1>

<p role="status">Current count: @currentCount</p>

<button class="btn btn-primary" @onclick="IncrementCount">Click me</button>

@code {
    private int currentCount = 0;

    private void IncrementCount()
    {
        currentCount++;
    }
}
```

If the app is only adopting Interactive WebAssembly rendering, remove the `@rendermode` directive and value:

diff

```
- @rendermode InteractiveAuto
```

Run the solution from the ***ASP.NET Core app*** project:

- Visual Studio: Confirm that the ASP.NET Core project is selected in **Solution Explorer** when running the app.
- .NET CLI: Run the project from the ASP.NET Core project's folder.

To load the `Counter` component, navigate to `/counter`.

Implement Blazor's layout and styles

Optionally, assign a default layout component using the RouteView.DefaultLayout parameter of the `RouteView` component.

In `Routes.razor`, the following example uses a `MainLayout` component as the default layout:

```razor
<RouteView RouteData="routeData" DefaultLayout="typeof(MainLayout)" />
```

For more information, see ASP.NET Core Blazor layouts.

Blazor project template layout and stylesheets are available from the dotnet/aspnetcore GitHub repository:

- `MainLayout.razor`
- `MainLayout.razor.css`
- `NavMenu.razor`
- `NavMenu.razor.css`

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Depending on how you organize your layout files in the app, you might need to add an `@using` statement for the layout files' folder in the app's `_Imports.razor` file in order to surface them for use in the app's components.

There's no need to explicitly reference stylesheets when using CSS isolation. The Blazor framework automatically bundles individual component stylesheets. The app's bundled stylesheet is already referenced in the app's `App` component (`{ASSEMBLY NAME}.styles.css`, where the `{ASSEMBLY NAME}` placeholder is the app's assembly name).

Return a `RazorComponentResult` from an MVC controller action

An MVC controller action can return a component with RazorComponentResult<TComponent>.

`Components/Welcome.razor`:

razor

```razor
<PageTitle>Welcome!</PageTitle>

<h1>Welcome!</h1>

<p>@Message</p>

@code {
    [Parameter]
    public string? Message { get; set; }
}
```

In a controller:

C#

```
public IResult GetWelcomeComponent() =>
    new RazorComponentResult<Welcome>(new { Message = "Hello, world!" });
```

Only HTML markup for the rendered component is returned. Layouts and HTML page markup aren't automatically rendered with the component. To produce a complete HTML page, the app can maintain a Blazor layout that provides HTML markup for `<html>`, `<head>`, `<body>`, and other tags. The component includes the layout with the @layout Razor directive at the top of the component definition file, `Welcome.razor` for the example in this section. The following example assumes that the app has a layout named `RazorComponentResultLayout` (`Components/Layout/RazorComponentResultLayout.razor`):

razor

```
@using BlazorSample.Components.Layout
@layout RazorComponentResultLayout
```

You can avoid placing the `@using` statement for the `Layout` folder in individual components by moving it to the app's `_Imports.razor` file.

For more information, see ASP.NET Core Blazor layouts.

Component namespaces

When using a custom folder to hold the project's Razor components, add the namespace representing the folder to either the page/view or to the `_ViewImports.cshtml` file. In the following example:

- Components are stored in the `Components` folder of the project.
- The `{APP NAMESPACE}` placeholder is the project's namespace. `Components` represents the name of the folder.

CSHTML

```
@using {APP NAMESPACE}.Components
```

For example:

CSHTML

```
@using BlazorSample.Components
```

The `_ViewImports.cshtml` file is located in the `Pages` folder of a Razor Pages app or the `Views` folder of an MVC app.

For more information, see ASP.NET Core Razor components.

Prerender ASP.NET Core Razor components

Consume ASP.NET Core Razor components from a Razor class library (RCL)

Article • 09/12/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

Components can be shared in a Razor class library (RCL) across projects. Include components and static assets in an app from:

- Another project in the solution.
- A referenced .NET library.
- A NuGet package.

Just as components are regular .NET types, components provided by an RCL are normal .NET assemblies.

Create an RCL

Visual Studio

1. Create a new project.
2. In the **Create a new project** dialog, select **Razor Class Library** from the list of ASP.NET Core project templates. Select **Next**.
3. In the **Configure your new project** dialog, provide a project name in the **Project name** field. Examples in this topic use the project name `ComponentLibrary`. Select **Next**.
4. In the **Additional information** dialog, don't select **Support pages and views**. Select **Create**.
5. Add the RCL to a solution:
   a. Open the solution.
   b. Right-click the solution in **Solution Explorer**. Select **Add** > **Existing Project**.

c. Navigate to the RCL's project file.
d. Select the RCL's project file (`.csproj`).

6. Add a reference to the RCL from the app:
   a. Right-click the app project. Select **Add** > **Project Reference**.
   b. Select the RCL project. Select **OK**.

Consume a Razor component from an RCL

To consume components from an RCL in another project, use either of the following approaches:

- Use the full component type name, which includes the RCL's namespace.
- Individual components can be added by name without the RCL's namespace if Razor's @using directive declares the RCL's namespace. Use the following approaches:
  - Add the `@using` directive to individual components.
  - include the `@using` directive in the top-level `_Imports.razor` file to make the library's components available to an entire project. Add the directive to an `_Imports.razor` file at any level to apply the namespace to a single component or set of components within a folder. When an `_Imports.razor` file is used, individual components don't require an `@using` directive for the RCL's namespace.

In the following examples, `ComponentLibrary` is an RCL containing the `Component1` component. The `Component1` component is an example component automatically added to an RCL created from the RCL project template that isn't created to support pages and views.

`Component1.razor` in the `ComponentLibrary` RCL:

razor

```
<div class="my-component">
    This component is defined in the <strong>ComponentLibrary</strong>
package.
</div>
```

In the app that consumes the RCL, reference the `Component1` component using its namespace, as the following example shows.

`ConsumeComponent1.razor`:

razor

```razor
@page "/consume-component-1"

<h1>Consume component (full namespace example)</h1>

<ComponentLibrary.Component1 />
```

Alternatively, add a @using directive and use the component without its namespace. The following `@using` directive can also appear in any `_Imports.razor` file in or above the current folder.

`ConsumeComponent2.razor`:

razor

```razor
@page "/consume-component-2"
@using ComponentLibrary

<h1>Consume component (<code>@@using</code> example)</h1>

<Component1 />
```

For library components that use CSS isolation, the component styles are automatically made available to the consuming app. There's no need to manually link or import the library's individual component stylesheets or its bundled CSS file in the app that consumes the library. The app uses CSS imports to reference the RCL's bundled styles. The bundled styles aren't published as a static web asset of the app that consumes the library. For a class library named `ClassLib` and a Blazor app with a `BlazorSample.styles.css` stylesheet, the RCL's stylesheet is imported at the top of the app's stylesheet automatically at build time:

css

```css
@import '_content/ClassLib/ClassLib.bundle.scp.css';
```

For the preceding examples, `Component1`'s stylesheet (`Component1.razor.css`) is bundled automatically.

`Component1.razor.css` in the `ComponentLibrary` RCL:

css

```css
.my-component {
    border: 2px dashed red;
```

```
    padding: 1em;
    margin: 1em 0;
    background-image: url('background.png');
}
```

The background image is also included from the RCL project template and resides in the `wwwroot` folder of the RCL.

`wwwroot/background.png` in the `ComponentLibrary` RCL:

To provide additional library component styles from stylesheets in the library's `wwwroot` folder, add stylesheet `<link>` tags to the RCL's consumer, as the next example demonstrates.

> **ⓘ Important**
>
> Generally, library components use CSS isolation to bundle and provide component styles. Component styles that rely upon CSS isolation are automatically made available to the app that uses the RCL. There's no need to manually link or import the library's individual component stylesheets or its bundled CSS file in the app that consumes the library. The following example is for providing global stylesheets *outside of CSS isolation*, which usually isn't a requirement for typical apps that consume RCLs.

The following background image is used in the next example. If you implement the example shown in this section, right-click the image to save it locally.

`wwwroot/extra-background.png` in the `ComponentLibrary` RCL:

Add a new stylesheet to the RCL with an `extra-style` class.

`wwwroot/additionalStyles.css` in the `ComponentLibrary` RCL:

```
css

.extra-style {
    border: 2px dashed blue;
    padding: 1em;
    margin: 1em 0;
```

```
    background-image: url('extra-background.png');
}
```

Add a component to the RCL that uses the `extra-style` class.

`ExtraStyles.razor` in the `ComponentLibrary` RCL:

razor

```
<div class="extra-style">
    <p>
        This component is defined in the <strong>ComponentLibrary</strong>
package.
    </p>
</div>
```

Add a page to the app that uses the `ExtraStyles` component from the RCL.

`ConsumeComponent3.razor`:

razor

```
@page "/consume-component-3"
@using ComponentLibrary

<h1>Consume component (<code>additionalStyles.css</code> example)</h1>

<ExtraStyles />
```

Link to the library's stylesheet in the app's `<head>` markup (location of <head> content):

Blazor Web Apps:

HTML

```
<link href="@Assets["_content/ComponentLibrary/additionalStyles.css"]"
rel="stylesheet">
```

Standalone Blazor WebAssembly apps:

HTML

```
<link href="_content/ComponentLibrary/additionalStyles.css"
rel="stylesheet">
```

Make routable components available from the RCL

To make routable components in the RCL available for direct requests, the RCL's assembly must be disclosed to the app's router.

Open the app's `App` component (`App.razor`). Assign an Assembly collection to the AdditionalAssemblies parameter of the Router component to include the RCL's assembly. In the following example, the `ComponentLibrary.Component1` component is used to discover the RCL's assembly.

razor

```
AdditionalAssemblies="new[] { typeof(ComponentLibrary.Component1).Assembly
}"
```

For more information, see ASP.NET Core Blazor routing and navigation.

Create an RCL with static assets in the `wwwroot` folder

An RCL's static assets are available to any app that consumes the library.

Place static assets in the `wwwroot` folder of the RCL and reference the static assets with the following path in the app: `_content/{PACKAGE ID}/{PATH AND FILE NAME}`. The `{PACKAGE ID}` placeholder is the library's package ID. The package ID defaults to the project's assembly name if `<PackageId>` isn't specified in the project file. The `{PATH AND FILE NAME}` placeholder is path and file name under `wwwroot`. This path format is also used in the app for static assets supplied by NuGet packages added to the RCL.

The following example demonstrates the use of RCL static assets with an RCL named `ComponentLibrary` and a Blazor app that consumes the RCL. The app has a project reference for the `ComponentLibrary` RCL.

The following Jeep® image is used in this section's example. If you implement the example shown in this section, right-click the image to save it locally.

`wwwroot/jeep-yj.png` in the `ComponentLibrary` RCL:

Add the following `JeepYJ` component to the RCL.

`JeepYJ.razor` in the `ComponentLibrary` RCL:

razor

```
<h3>ComponentLibrary.JeepYJ</h3>

<p>
    <img alt="Jeep YJ&reg;" src="_content/ComponentLibrary/jeep-yj.png" />
</p>
```

Add the following `Jeep` component to the app that consumes the `ComponentLibrary` RCL. The `Jeep` component uses:

- The Jeep YJ® image from the `ComponentLibrary` RCL's `wwwroot` folder.
- The `JeepYJ` component from the RCL.

`Jeep.razor`:

razor

```
@page "/jeep"
@using ComponentLibrary

<div style="float:left;margin-right:10px">
    <h3>Direct use</h3>

    <p>
        <img alt="Jeep YJ&reg;" src="_content/ComponentLibrary/jeep-yj.png"
/>
    </p>
</div>

<JeepYJ />

<p>
```

```
    <em>Jeep</em> and <em>Jeep YJ</em> are registered trademarks of
    <a href="https://www.stellantis.com">FCA US LLC (Stellantis NV)</a>.
</p>
```

Rendered `Jeep` component:

For more information, see Reusable Razor UI in class libraries with ASP.NET Core.

Create an RCL with JavaScript files collocated with components

Collocation of JavaScript (JS) files for Razor components is a convenient way to organize scripts in an app.

Razor components of Blazor apps collocate JS files using the `.razor.js` extension and are publicly addressable using the path to the file in the project:

`{PATH}/{COMPONENT}.razor.js`

- The `{PATH}` placeholder is the path to the component.
- The `{COMPONENT}` placeholder is the component.

When the app is published, the framework automatically moves the script to the web root. Scripts are moved to `bin/Release/{TARGET FRAMEWORK MONIKER}/publish/wwwroot/{PATH}/{COMPONENT}.razor.js`, where the placeholders are:

- `{TARGET FRAMEWORK MONIKER}` is the Target Framework Moniker (TFM).
- `{PATH}` is the path to the component.
- `{COMPONENT}` is the component name.

No change is required to the script's relative URL, as Blazor takes care of placing the JS file in published static assets for you.

This section and the following examples are primarily focused on explaining JS file collocation. The first example demonstrates a collocated JS file with an ordinary JS function. The second example demonstrates the use of a module to load a function, which is the recommended approach for most production apps. Calling JS from .NET is fully covered in Call JavaScript functions from .NET methods in ASP.NET Core Blazor, where there are further explanations of the Blazor JS API with additional examples. Component disposal, which is present in the second example, is covered in ASP.NET Core Razor component lifecycle.

The following `JsCollocation1` component loads a script via a HeadContent component and calls a JS function with IJSRuntime.InvokeAsync. The `{PATH}` placeholder is the path to the component.

> **ⓘ Important**
>
> If you use the following code for a demonstration in a test app, change the `{PATH}` placeholder to the path of the component (example: `Components/Pages` in .NET 8 or later or `Pages` in .NET 7 or earlier). In a Blazor Web App (.NET 8 or later), the component requires an interactive render mode applied either globally to the app or to the component definition.

Add the following script after the Blazor script (location of the Blazor start script):

HTML

```
<script src="{PATH}/JsCollocation1.razor.js"></script>
```

`JsCollocation1` component (`{PATH}/JsCollocation1.razor`):

razor

```
@page "/js-collocation-1"
@inject IJSRuntime JS

<PageTitle>JS Collocation 1</PageTitle>

<h1>JS Collocation Example 1</h1>

<button @onclick="ShowPrompt">Call showPrompt1</button>

@if (!string.IsNullOrEmpty(result))
```

```
{
    <p>
        Hello @result!
    </p>
}

@code {
    private string? result;

    public async void ShowPrompt()
    {
        result = await JS.InvokeAsync<string>(
            "showPrompt1", "What's your name?");
        StateHasChanged();
    }
}
```

The collocated JS file is placed next to the `JsCollocation1` component file with the file name `JsCollocation1.razor.js`. In the `JsCollocation1` component, the script is referenced at the path of the collocated file. In the following example, the `showPrompt1` function accepts the user's name from a Window prompt() and returns it to the `JsCollocation1` component for display.

`{PATH}/JsCollocation1.razor.js`:

JavaScript

```
function showPrompt1(message) {
  return prompt(message, 'Type your name here');
}
```

The preceding approach isn't recommended for general use in production apps because the approach pollutes the client with global functions. A better approach for production apps is to use JS modules. The same general principles apply to loading a JS module from a collocated JS file, as the next example demonstrates.

The following `JsCollocation2` component's `OnAfterRenderAsync` method loads a JS module into `module`, which is an IJSObjectReference of the component class. `module` is used to call the `showPrompt2` function. The `{PATH}` placeholder is the path to the component.

> **ⓘ Important**
>
> If you use the following code for a demonstration in a test app, change the `{PATH}` placeholder to the path of the component. In a Blazor Web App (.NET 8 or later),

the component requires an interactive render mode applied either globally to the app or to the component definition.

`JsCollocation2` component (`{PATH}/JsCollocation2.razor`):

razor

```
@page "/js-collocation-2"
@implements IAsyncDisposable
@inject IJSRuntime JS

<PageTitle>JS Collocation 2</PageTitle>

<h1>JS Collocation Example 2</h1>

<button @onclick="ShowPrompt">Call showPrompt2</button>

@if (!string.IsNullOrEmpty(result))
{
    <p>
        Hello @result!
    </p>
}

@code {
    private IJSObjectReference? module;
    private string? result;

    protected async override Task OnAfterRenderAsync(bool firstRender)
    {
        if (firstRender)
        {
            /*
                Change the {PATH} placeholder in the next line to the path
of
                the collocated JS file in the app. Examples:

                ./Components/Pages/JsCollocation2.razor.js (.NET 8 or later)
                ./Pages/JsCollocation2.razor.js (.NET 7 or earlier)
            */
            module = await JS.InvokeAsync<IJSObjectReference>("import",
                "./{PATH}/JsCollocation2.razor.js");
        }
    }

    public async void ShowPrompt()
    {
        if (module is not null)
        {
            result = await module.InvokeAsync<string>(
                "showPrompt2", "What's your name?");
            StateHasChanged();
```

```
        }
    }

    async ValueTask IAsyncDisposable.DisposeAsync()
    {
        if (module is not null)
        {
            await module.DisposeAsync();
        }
    }
}
```

`{PATH}/JsCollocation2.razor.js`:

JavaScript

```
export function showPrompt2(message) {
  return prompt(message, 'Type your name here');
}
```

Use of scripts and modules for collocated JS in a Razor class library (RCL) is only supported for Blazor's JS interop mechanism based on the IJSRuntime interface. If you're implementing JavaScript [JSImport]/[JSExport] interop, see JavaScript JSImport/JSExport interop with ASP.NET Core Blazor.

For scripts or modules provided by a Razor class library (RCL) using IJSRuntime-based JS interop, the following path is used:

`./_content/{PACKAGE ID}/{PATH}/{COMPONENT}.{EXTENSION}.js`

- The path segment for the current directory (`./`) is required in order to create the correct static asset path to the JS file.
- The `{PACKAGE ID}` placeholder is the RCL's package identifier (or library name for a class library referenced by the app).
- The `{PATH}` placeholder is the path to the component. If a Razor component is located at the root of the RCL, the path segment isn't included.
- The `{COMPONENT}` placeholder is the component name.
- The `{EXTENSION}` placeholder matches the extension of component, either `razor` or `cshtml`.

In the following Blazor app example:

- The RCL's package identifier is `AppJS`.
- A module's scripts are loaded for the `JsCollocation3` component (`JsCollocation3.razor`).

- The `JsCollocation3` component is in the `Components/Pages` folder of the RCL.

C#

```
module = await JS.InvokeAsync<IJSObjectReference>("import",
    "./_content/AppJS/Components/Pages/JsCollocation3.razor.js");
```

Client-side browser compatibility analyzer

Client-side apps target the full .NET API surface area, but not all .NET APIs are supported on WebAssembly due to browser sandbox constraints. Unsupported APIs throw PlatformNotSupportedException when running on WebAssembly. A platform compatibility analyzer warns the developer when the app uses APIs that aren't supported by the app's target platforms. For client-side apps, this means checking that APIs are supported in browsers. Annotating .NET framework APIs for the compatibility analyzer is an on-going process, so not all .NET framework API is currently annotated.

Blazor Web Apps that enable Interactive WebAssembly components, Blazor WebAssembly apps, and RCL projects *automatically* enable browser compatibility checks by adding `browser` as a supported platform with the `SupportedPlatform` MSBuild item. Library developers can manually add the `SupportedPlatform` item to a library's project file to enable the feature:

XML

```
<ItemGroup>
  <SupportedPlatform Include="browser" />
</ItemGroup>
```

When authoring a library, indicate that a particular API isn't supported in browsers by specifying `browser` to UnsupportedOSPlatformAttribute:

C#

```
using System.Runtime.Versioning;

...

[UnsupportedOSPlatform("browser")]
private static string GetLoggingDirectory()
{
    ...
}
```

For more information, see Annotating APIs as unsupported on specific platforms (dotnet/designs GitHub repository).

JavaScript isolation in JavaScript modules

Blazor enables JavaScript isolation in standard JavaScript modules. JavaScript isolation provides the following benefits:

- Imported JavaScript no longer pollutes the global namespace.
- Consumers of the library and components aren't required to manually import the related JavaScript.

For more information, see Call JavaScript functions from .NET methods in ASP.NET Core Blazor.

Avoid trimming JavaScript-invokable .NET methods

Runtime relinking trims class instance JavaScript-invokable .NET methods unless they're explicitly preserved. For more information, see Call .NET methods from JavaScript functions in ASP.NET Core Blazor.

Build, pack, and ship to NuGet

Because Razor class libraries that contain Razor components are standard .NET libraries, packing and shipping them to NuGet is no different from packing and shipping any library to NuGet. Packing is performed using the dotnet pack command in a command shell:

.NET CLI

```
dotnet pack
```

Upload the package to NuGet using the dotnet nuget push command in a command shell.

ASP.NET Core Razor class libraries (RCLs) with static server-side rendering (static SSR)

Article • 09/27/2024

This article provides guidance for component library authors considering support for static server-side rendering (static SSR).

Blazor encourages the development of an ecosystem of open-source and commercial component libraries, formally called *Razor class libraries (RCLs)*. Developers might also create reusable components for sharing components privately across apps within their own companies. Ideally, components are developed for compatibility with as many hosting models and rendering modes as possible. Static SSR introduces additional restrictions that can be more challenging to support than interactive rendering modes.

Understand the capabilities and restrictions of static SSR

Static SSR is a mode in which components run when the server handles an incoming HTTP request. Blazor renders the component as HTML, which is included in the response. Once the response is sent, the server-side component and renderer state is discarded, so all that remains is HTML in the browser.

The benefit of this mode is cheaper, more scalable hosting, because no ongoing server resources are required to hold component state, no ongoing connection must be maintained between browser and server, and no WebAssembly payload is required in the browser.

All existing components can still be used with static SSR. However, the cost of this mode is that event handlers, such as `@onclick`†, can't be run for the following reasons:

- There's no .NET code in the browser to run them.
- The server has immediately discarded any component and renderer state that would be needed to execute event handlers or to rerender the same component instances.

†There's a special exception for the `@onsubmit` event handler for forms, which is always functional, regardless of render mode.

This is equivalent to how components behave during prerendering, before a Blazor circuit or the .NET WebAssembly runtime is started.

For components whose only role is to produce read-only DOM content, these behaviors for static SSR are completely sufficient. However, library authors must consider what approach to take when including interactive components in their libraries.

Options for component authors

There are three main approaches:

- **Don't use interactive behaviors** (Basic)

  For components whose only role is to produce read-only DOM content, the developer isn't required to take any special action. These components naturally work with any render mode.

  Examples:
  - A "user card" component that loads data corresponding to a person and renders it in a stylized UI with a photo, job title, and other details.
  - A "video" component that acts as a wrapper around the HTML `<video>` element, making it more convenient to use in a Razor component.

- **Require interactive rendering** (Basic)

  You can choose to require that your component is only used with interactive rendering. This limits the applicability of your component, but means that you may freely rely on arbitrary event handlers. Even then, you should still avoid declaring a specific `@rendermode` and permit the app author who consumes your library to select one.

  Examples:
  - A video editing component in which users may splice and re-order segments of video. Even if there was a way to represent these edit operations with plain HTML buttons and form posts, the user experience would be unacceptable without true interactivity.
  - A collaborative document editor that must show the activities of other users in real time.

- **Use interactive behaviors, but design for static SSR and progressive enhancement** (Advanced)

Many interactive behaviors can be implemented using only HTML capabilities. With a good understanding of HTML and CSS, you can often produce a useful baseline of functionality that works with static SSR. You can still declare event handlers that implement more advanced, optional behaviors, which only work in interactive render modes.

Examples:

- A grid component. Under static SSR, the component may only support displaying data and navigating between pages (implemented with `<a>` links). When used with interactive rendering, the component may add live sorting and filtering.
- A tabset component. As long as navigation between tabs is achieved using `<a>` links and state is held only in URL query parameters, the component can work without `@onclick`.
- An advanced file upload component. Under static SSR, the component may behave as a native `<input type=file>`. When used with interactive rendering, the component could also display upload progress.
- A stock ticker. Under static SSR, the component may display the stock quote at the time the HTML was rendered. When used with interactive rendering, the component may then update the stock price in real time.

For any of these strategies, there's also the option of implementing interactive features with JavaScript.

To choose among these approaches, reusable Razor component authors must make a cost/benefit tradeoff. Your component is more useful and has a broader potential user base if it supports all render modes, including static SSR. However, it takes more work to design and implement a component that supports and takes best advantage of each render mode.

When to use the `@rendermode` directive

In most cases, reusable component authors should **not** specify a render mode, even when interactivity is required. This is because the component author doesn't know whether the app enables support for InteractiveServer, InteractiveWebAssembly, or both with InteractiveAuto. By not specifying a `@rendermode`, the component author leaves the choice to the app developer.

Even if the component author thinks that interactivity is required, there may still be cases where an app author considers it sufficient to use static SSR alone. For example, a map component with drag and zoom interactivity may seem to require interactivity.

However, some scenarios may only call for rendering a static map image and avoiding drag/zoom features.

The only reason why a reusable component author should use the `@rendermode` directive on their component is if the implementation is fundamentally coupled to one specific render mode and would certainly cause an error if used in a different mode. Consider a component with a core purpose of interacting directly with the host OS using Windows or Linux-specific APIs. It might be impossible to use such a component on WebAssembly. If so, it's reasonable to declare `@rendermode InteractiveServer` for the component.

Streaming rendering

Reusable Razor components are free to declare `@attribute [StreamRendering]` for streaming rendering ([StreamRendering] attribute API). This results in incremental UI updates during static SSR. Since the same data-loading patterns produce incremental UI updates during interactive rendering, regardless of the presence of the `[StreamRendering]` attribute, the component can behave correctly in all cases. Even in cases where streaming static SSR is suppressed on the server, the component still renders its correct final state.

Using links across render modes

Reusable Razor components may use links and enhanced navigation. HTML `<a>` tags should produce equivalent behaviors with or without an interactive Router component and whether or not enhanced navigation is enabled/disabled at an ancestor level in the DOM.

Using forms across render modes

Reusable Razor components may include forms (either `<form>` or `<EditForm>`), as these can be implemented to work equivalently across both static and interactive render modes.

Consider the following example:

razor

```
<EditForm Enhance FormName="NewProduct" Model="Model"
OnValidSubmit="SaveProduct">
    <DataAnnotationsValidator />
```

```
    <ValidationSummary />

    <p><label>Name: <InputText @bind-Value="Item.Name" /></label></p>

    <button type="submit">Submit</button>
</EditForm>

@code {
    [SupplyParameterFromForm]
    private Product? Model { get; set; }

    protected override void OnInitialized() => Model ??= new();

    private async Task Save()
    {
        ...
    }
}
```

The Enhance, FormName, and SupplyParameterFromFormAttribute APIs are only used during static SSR and are ignored during interactive rendering. The form works correctly during both interactive and static SSR.

Avoid APIs that are specific to static SSR

HttpContext is only available during static SSR, so don't rely on HttpContext when creating components that work across render modes. The HttpContext API doesn't make sense to use during interactive rendering either because there's no active HTTP request in flight at those times. It's meaningless to think about setting a HTTP status code or writing to the HTTP response.

Reusable components are free to receive an HttpContext when available, as follows:

C#

```
[CascadingParameter]
public HttpContext? Context { get; set; }
```

The value is `null` during interactive rendering and is only set during static SSR.

In many cases, there are better alternatives than using HttpContext. If you need to know the current URL or to perform a redirection, the APIs on NavigationManager work with all render modes. If you need to know the user's authentication state, use Blazor's AuthenticationStateProvider service (AuthenticationStateProvider documentation) over using HttpContext.User.

Use Razor components in JavaScript apps and SPA frameworks

Article • 11/06/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article covers how to render Razor components from JavaScript, use Blazor custom elements, and generate Angular and React components.

> **Note**
>
> We recommend using the `blazor.server.js` (Blazor Server) and `blazor.webassembly.js` (Blazor WebAssembly) scripts when integrating Razor components into an existing JavaScript app until better support for the `blazor.web.js` (Blazor Web App) script is added in the future. For more information, see RegisterCustomElement stopped working in Blazor 8 (dotnet/aspnetcore #53920).

Angular sample apps

- CustomElementsBlazorSample (Blazor Server) (javiercn/CustomElementsBlazorSample, branch: blazor-server): Blazor Server is supported in .NET 8. To migrate this .NET 7 sample to .NET 8, see Migrate from ASP.NET Core 7.0 to 8.0.
- CustomElementsBlazorSample (Blazor WebAssembly) (javiercn/CustomElementsBlazorSample, branch: blazor-wasm): To migrate this .NET 7 sample to .NET 8, see Migrate from ASP.NET Core 7.0 to 8.0.

Render Razor components from JavaScript

Razor components can be dynamically-rendered from JavaScript (JS) for existing JS apps.

The example in this section renders the following Razor component into a page via JS.

`Quote.razor`:

razor

```razor
<div class="m-5 p-5">
    <h2>Quote</h2>
    <p>@Text</p>
</div>

@code {
    [Parameter]
    public string? Text { get; set; }
}
```

In the `Program` file, add the namespace for the location of the component.

Call RegisterForJavaScript on the app's root component collection to register a Razor component as a root component for JS rendering.

RegisterForJavaScript includes an overload that accepts the name of a JS function that executes initialization logic (`javaScriptInitializer`). The JS function is called once per component registration immediately after the Blazor app starts and before any components are rendered. This function can be used for integration with JS technologies, such as HTML custom elements or a JS-based SPA framework.

One or more initializer functions can be created and called by different component registrations. The typical use case is to reuse the same initializer function for multiple components, which is expected if the initializer function is configuring integration with custom elements or another JS-based SPA framework.

> **ⓘ Important**
>
> Don't confuse the `javaScriptInitializer` parameter of RegisterForJavaScript with JavaScript initializers. The name of the parameter and the JS initializers feature is coincidental.

The following example demonstrates the dynamic registration of the preceding `Quote` component with "`quote`" as the identifier.

- In a Blazor Server app, modify the call to AddServerSideBlazor in the `Program` file:

  C#

  ```
  builder.Services.AddServerSideBlazor(options =>
  {
      options.RootComponents.RegisterForJavaScript<Quote>(identifier:
  "quote",
          javaScriptInitializer: "initializeComponent");
  });
  ```

- In a Blazor WebAssembly app, call RegisterForJavaScript on RootComponents in the client-side `Program` file:

  C#

  ```
  builder.RootComponents.RegisterForJavaScript<Quote>(identifier:
  "quote",
      javaScriptInitializer: "initializeComponent");
  ```

Attach the initializer function with `name` and `parameters` function parameters to the `window` object. For demonstration purposes, the following `initializeComponent` function logs the name and parameters of the registered component.

`wwwroot/jsComponentInitializers.js`:

JavaScript

```
window.initializeComponent = (name, parameters) => {
  console.log({ name: name, parameters: parameters });
}
```

Render the component from JS into a container element using the registered identifier, passing component parameters as needed.

In the following example:

- The `Quote` component (`quote` identifier) is rendered into the `quoteContainer` element when the `showQuote` function is called.
- A quote string is passed to the component's `Text` parameter.

`wwwroot/scripts.js`:

JavaScript

```
window.showQuote = async () => {
  let targetElement = document.getElementById('quoteContainer');
  await Blazor.rootComponents.add(targetElement, 'quote',
  {
    text: "Crow: I have my doubts that this movie is actually 'starring' " +
      "anybody. More like, 'camera is generally pointed at.'"
  });
}

const btn = document.querySelector("#showQuoteBtn");
btn.addEventListener("click", showQuote);
```

After the Blazor script is loaded, load the preceding scripts into the JS app:

HTML

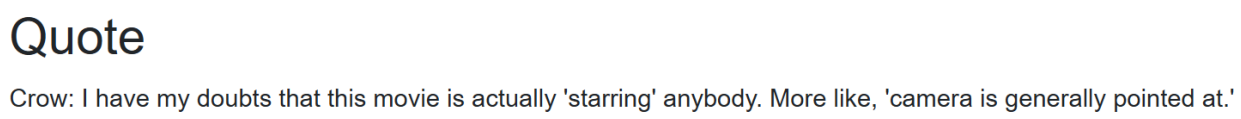
```
<script src="_framework/{BLAZOR SCRIPT}"></script>
<script src="jsComponentInitializers.js"></script>
<script src="scripts.js"></script>
```

In the preceding example, the `{BLAZOR SCRIPT}` placeholder is the Blazor script.

In HTML, place the target container element (`quoteContainer`). For the demonstration in this section, a button triggers rendering the `Quote` component by calling the `showQuote` JS function:

HTML

```
<button id="showQuoteBtn">Show Quote</button>



<div id="quoteContainer"></div>
```

On initialization before any components are rendered, the browser's developer tools console logs the `Quote` component's identifier (`name`) and parameters (`parameters`) when `initializeComponent` is called:

Console

```
Object { name: "quote", parameters: (1) […] }
  name: "quote"
  parameters: Array [ {…} ]
    0: Object { name: "Text", type: "string" }
    length: 1
```

When the **Show Quote** button is selected, the `Quote` component is rendered with the quote stored in `Text` displayed:

Quote ©1988-1999 Satellite of Love LLC: *Mystery Science Theater 3000* (Trace Beaulieu (Crow))

> **Note**
>
> `rootComponents.add` returns an instance of the component. Call `dispose` on the instance to release it:
>
> JavaScript
>
> ```
> const rootComponent = await window.Blazor.rootComponents.add(...);
>
> ...
>
> rootComponent.dispose();
> ```

The preceding example dynamically renders the root component when the `showQuote()` JS function is called. To render a root component into a container element when Blazor starts, use a JavaScript initializer to render the component, as the following example demonstrates.

The following example builds on the preceding example, using the `Quote` component, the root component registration in the `Program` file, and the initialization of `jsComponentInitializers.js`. The `showQuote()` function (and the `script.js` file) aren't used.

In HTML, place the target container element, `quoteContainer2` for this example:

HTML

```
<div id="quoteContainer2"></div>
```

Using a JavaScript initializer, add the root component to the target container element.

`wwwroot/{PACKAGE ID/ASSEMBLY NAME}.lib.module.js`:

JavaScript

```
export function afterStarted(blazor) {
  let targetElement = document.getElementById('quoteContainer2');
  blazor.rootComponents.add(targetElement, 'quote',
    {
      text: "Crow: I have my doubts that this movie is actually 'starring' "
+
          "anybody. More like, 'camera is generally pointed at.'"
    });
}
```

> **Note**
>
> For the call to `rootComponents.add`, use the `blazor` parameter (lowercase `b`) provided by the Blazor start event. Although the registration is valid when using the `Blazor` object (uppercase `B`), the preferred approach is to use the parameter.

For an advanced example with additional features, see the example in the `BasicTestApp` of the ASP.NET Core reference source (`dotnet/aspnetcore` GitHub repository):

- JavaScriptRootComponents.razor
- wwwroot/js/jsRootComponentInitializers.js
- wwwroot/index.html

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Blazor custom elements

Use Blazor custom elements to dynamically render Razor components from other SPA frameworks, such as Angular or React.

Blazor custom elements:

- Use standard HTML interfaces to implement custom HTML elements.
- Eliminate the need to manually manage the state and lifecycle of root Razor components using JavaScript APIs.

- Are useful for gradually introducing Razor components into existing projects written in other SPA frameworks.

Custom elements don't support child content or templated components.

Element name

Per the HTML specification, custom element tag names must adopt kebab case:

❌ `mycounter`
❌ `MY-COUNTER`
❌ `MyCounter`
✔ `my-counter`
✔ `my-cool-counter`

Package

Add a package reference for Microsoft.AspNetCore.Components.CustomElements to the app's project file.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

Example component

The following examples are based on the `Counter` component from the Blazor project template.

`Counter.razor`:

razor

```razor
@page "/counter"

<PageTitle>Counter</PageTitle>

<h1>Counter</h1>

<p role="status">Current count: @currentCount</p>
```

```razor
<button class="btn btn-primary" @onclick="IncrementCount">Click me</button>

@code {
    private int currentCount = 0;

    private void IncrementCount() => currentCount++;
}
```

Blazor Server registration

Take the following steps to register a root component as a custom element in a Blazor Server app.

Add the Microsoft.AspNetCore.Components.Web namespace to the top of the `Program` file:

C#

```
using Microsoft.AspNetCore.Components.Web;
```

Add a namespace for the app's components. In the following example, the app's namespace is `BlazorSample` and the components are located in the `Pages` folder:

C#

```
using BlazorSample.Pages;
```

Modify the call to AddServerSideBlazor. Specify the custom element with RegisterCustomElement on the RootComponents circuit option. The following example registers the `Counter` component with the custom HTML element `my-counter`:

C#

```
builder.Services.AddServerSideBlazor(options =>
{
    options.RootComponents.RegisterCustomElement<Counter>("my-counter");
});
```

Blazor WebAssembly registration

Take the following steps to register a root component as a custom element in a Blazor WebAssembly app.

Add the Microsoft.AspNetCore.Components.Web namespace to the top of the `Program` file:

```
C#

using Microsoft.AspNetCore.Components.Web;
```

Add a namespace for the app's components. In the following example, the app's namespace is `BlazorSample` and the components are located in the `Pages` folder:

```
C#

using BlazorSample.Pages;
```

Call RegisterCustomElement on RootComponents. The following example registers the `Counter` component with the custom HTML element `my-counter`:

```
C#

builder.RootComponents.RegisterCustomElement<Counter>("my-counter");
```

Use the registered custom element

Use the custom element with any web framework. For example, the preceding `my-counter` custom HTML element that renders the app's `Counter` component is used in a React app with the following markup:

```
HTML

<my-counter></my-counter>
```

For a complete example of how to create custom elements with Blazor, see the CustomElementsComponent component in the reference source.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Pass parameters

Pass parameters to your Razor component either as HTML attributes or as JavaScript properties on the DOM element.

The following `Counter` component uses an `IncrementAmount` parameter to set the increment amount of the **Click me** button.

`Counter.razor`:

razor

```razor
@page "/counter"

<h1>Counter</h1>

<p role="status">Current count: @currentCount</p>

<button class="btn btn-primary" @onclick="IncrementCount">Click me</button>

@code {
    private int currentCount = 0;

    [Parameter]
    public int IncrementAmount { get; set; } = 1;

    private void IncrementCount()
    {
        currentCount += IncrementAmount;
    }
}
```

Render the `Counter` component with the custom element and pass a value to the `IncrementAmount` parameter as an HTML attribute. The attribute name adopts kebab-case syntax (`increment-amount`, not `IncrementAmount`):

HTML

```html
<my-counter increment-amount="10"></my-counter>
```

Alternatively, you can set the parameter's value as a JavaScript property on the element object. The property name adopts camel case syntax (`incrementAmount`, not `IncrementAmount`):

JavaScript

```
const elem = document.querySelector("my-counter");
elem.incrementAmount = 10;
```

You can update parameter values at any time using either attribute or property syntax.

Supported parameter types:

- Using JavaScript property syntax, you can pass objects of any JSON-serializable type.
- Using HTML attributes, you are limited to passing objects of string, boolean, or numerical types.

Generate Angular and React components

Generate framework-specific JavaScript (JS) components from Razor components for web frameworks, such as Angular or React. This capability isn't included with .NET, but is enabled by the support for rendering Razor components from JS. The JS component generation sample on GitHub demonstrates how to generate Angular and React components from Razor components. See the GitHub sample app's `README.md` file for additional information.

> ⚠ **Warning**
>
> The Angular and React component features are currently **experimental, unsupported, and subject to change or be removed at any time**. We welcome your feedback on how well this particular approach meets your requirements.

Render Razor components outside of ASP.NET Core

Article • 02/09/2024

Razor components can be rendered outside of the context of an HTTP request. You can render Razor components as HTML directly to a string or stream independently of the ASP.NET Core hosting environment. This is convenient for scenarios where you want to generate HTML fragments, such as for generating email content, generating static site content, or for building a content templating engine.

In the following example, a Razor component is rendered to an HTML string from a console app:

In a command shell, create a new console app project:

.NET CLI

```
dotnet new console -o ConsoleApp1
cd ConsoleApp1
```

In a command shell in the `ConsoleApp1` folder, add package references for Microsoft.AspNetCore.Components.Web and Microsoft.Extensions.Logging to the console app:

.NET CLI

```
dotnet add package Microsoft.AspNetCore.Components.Web
dotnet add package Microsoft.Extensions.Logging
```

In the console app's project file (`ConsoleApp1.csproj`), update the console app project to use the Razor SDK:

diff

```
- <Project Sdk="Microsoft.NET.Sdk">
+ <Project Sdk="Microsoft.NET.Sdk.Razor">
```

Add the following `RenderMessage` component to the project.

`RenderMessage.razor`:

razor

```
<h1>Render Message</h1>

<p>@Message</p>

@code {
    [Parameter]
    public string Message { get; set; }
}
```

Update the `Program` file:

- Set up dependency injection (IServiceCollection/BuildServiceProvider) and logging (AddLogging/ILoggerFactory).
- Create an HtmlRenderer and render the `RenderMessage` component by calling RenderComponentAsync.

Any calls to RenderComponentAsync must be made in the context of calling `InvokeAsync` on a component dispatcher. A component dispatcher is available from the HtmlRenderer.Dispatcher property.

C#

```
using Microsoft.AspNetCore.Components;
using Microsoft.AspNetCore.Components.Web;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Logging;
using ConsoleApp1;

IServiceCollection services = new ServiceCollection();
services.AddLogging();

IServiceProvider serviceProvider = services.BuildServiceProvider();
ILoggerFactory loggerFactory =
serviceProvider.GetRequiredService<ILoggerFactory>();

await using var htmlRenderer = new HtmlRenderer(serviceProvider,
loggerFactory);

var html = await htmlRenderer.Dispatcher.InvokeAsync(async () =>
{
    var dictionary = new Dictionary<string, object?>
    {
        { "Message", "Hello from the Render Message component!" }
    };

    var parameters = ParameterView.FromDictionary(dictionary);
    var output = await htmlRenderer.RenderComponentAsync<RenderMessage>
(parameters);

    return output.ToHtmlString();
```

```
});

Console.WriteLine(html);
```

> **Note**
>
> Pass **ParameterView.Empty** to **RenderComponentAsync** when rendering the component without passing parameters.

Alternatively, you can write the HTML to a TextWriter by calling `output.WriteHtmlTo(textWriter)`.

The task returned by RenderComponentAsync completes when the component is fully rendered, including completing any asynchronous lifecycle methods. If you want to observe the rendered HTML earlier, call BeginRenderingComponent instead. Then, wait for the component rendering to complete by awaiting HtmlRootComponent.QuiescenceTask on the returned HtmlRootComponent instance.

ASP.NET Core Blazor globalization and localization

Article • 10/14/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article explains how to render globalized and localized content to users in different cultures and languages.

Globalization and localization

For globalization, Blazor provides number and date formatting. For localization, Blazor renders content using the .NET Resources system.

A limited set of ASP.NET Core's localization features are supported:

✔ IStringLocalizer and IStringLocalizer<T> are supported in Blazor apps.

✘ IHtmlLocalizer, IViewLocalizer, and Data Annotations localization are ASP.NET Core MVC features and *not supported* in Blazor apps.

This article describes how to use Blazor's globalization and localization features based on:

- The Accept-Language header, which is set by the browser based on a user's language preferences in browser settings.
- A culture set by the app not based on the value of the Accept-Language header. The setting can be static for all users or dynamic based on app logic. When the setting is based on the user's preference, the setting is usually saved for reload on future visits.

For additional general information, see the following resources:

- Globalization and localization in ASP.NET Core
- .NET Fundamentals: Globalization

- .NET Fundamentals: Localization

Often, the terms *language* and *culture* are used interchangeably when dealing with globalization and localization concepts.

In this article, *language* refers to selections made by a user in their browser's settings. The user's language selections are submitted in browser requests in the Accept-Language header. Browser settings usually use the word "language" in the UI.

Culture pertains to members of .NET and Blazor API. For example, a user's request can include the Accept-Language header specifying a *language* from the user's perspective, but the app ultimately sets the CurrentCulture ("culture") property from the language that the user requested. API usually uses the word "culture" in its member names.

The guidance in this article doesn't cover setting the page's HTML language attribute (<html lang="...">), which accessiblity tools use. You can set the value statically by assigning a language to the `lang` attribute of the `<html>` tag or to `document.documentElement.lang` in JavaScript. You can dynamically set the value of `document.documentElement.lang` with JS interop.

> **Note**
>
> The code examples in this article adopt nullable reference types (NRTs) and .NET compiler null-state static analysis, which are supported in ASP.NET Core in .NET 6 or later. When targeting ASP.NET Core 5.0 or earlier, remove the null type designation (`?`) from the article's examples.

Globalization

The @bind attribute directive applies formats and parses values for display based on the user's first preferred language that the app supports. @bind supports the @bind:culture parameter to provide a System.Globalization.CultureInfo for parsing and formatting a value.

The current culture can be accessed from the System.Globalization.CultureInfo.CurrentCulture property.

CultureInfo.InvariantCulture is used for the following field types (`<input type="{TYPE}" />`, where the `{TYPE}` placeholder is the type):

- `date`

- `number`

The preceding field types:

- Are displayed using their appropriate browser-based formatting rules.
- Can't contain free-form text.
- Provide user interaction characteristics based on the browser's implementation.

Blazor provides built-in support to render values in the current culture. Therefore, specifying a culture with @bind:culture isn't recommended when using the `date` and `number` field types.

The following field types have specific formatting requirements and aren't supported by all of the major browsers, so they aren't supported by Blazor:

- `datetime-local`
- `month`
- `week`

For current browser support of the preceding types, see Can I use.

.NET globalization and International Components for Unicode (ICU) support (Blazor WebAssembly)

Blazor WebAssembly uses a reduced globalization API and set of built-in International Components for Unicode (ICU) locales. For more information, see .NET globalization and ICU: ICU on WebAssembly.

To load a custom ICU data file to control the app's locales, see WASM Globalization Icu. Currently, manually building the custom ICU data file is required. .NET tooling to ease the process of creating the file is planned for .NET 9 in November, 2024.

Invariant globalization

This section only applies to client-side Blazor scenarios.

If the app doesn't require localization, configure the app to support the invariant culture, which is generally based on United States English (`en-US`). Using invariant globalization reduces the app's download size and results in faster app startup. Set the `InvariantGlobalization` property to `true` in the app's project file (`.csproj`):

XML

```xml
<PropertyGroup>
  <InvariantGlobalization>true</InvariantGlobalization>
</PropertyGroup>
```

Alternatively, configure invariant globalization with the following approaches:

- In `runtimeconfig.json`:

  JSON

  ```json
  {
    "runtimeOptions": {
      "configProperties": {
        "System.Globalization.Invariant": true
      }
    }
  }
  ```

- With an environment variable:
  - Key: `DOTNET_SYSTEM_GLOBALIZATION_INVARIANT`
  - Value: `true` or `1`

For more information, see Runtime configuration options for globalization (.NET documentation).

Timezone information

This section only applies to client-side Blazor scenarios.

Adopting invariant globalization only results in using non-localized timezone names. To trim timezone code and data, which reduces the app's download size and results in faster app startup, apply the `<InvariantTimezone>` MSBuild property with a value of `true` in the app's project file:

XML

```xml
<PropertyGroup>
  <InvariantTimezone>true</InvariantTimezone>
</PropertyGroup>
```

> ⓘ Note

<BlazorEnableTimeZoneSupport> overrides an earlier `<InvariantTimezone>` setting. We recommend removing the `<BlazorEnableTimeZoneSupport>` setting.

Demonstration component

The following `CultureExample1` component can be used to demonstrate Blazor globalization and localization concepts covered by this article.

`CultureExample1.razor`:

razor

```
@page "/culture-example-1"
@using System.Globalization

<h1>Culture Example 1</h1>

<ul>
    <li><b>CurrentCulture</b>: @CultureInfo.CurrentCulture</li>
    <li><b>CurrentUICulture</b>: @CultureInfo.CurrentUICulture</li>
</ul>

<h2>Rendered values</h2>

<ul>
    <li><b>Date</b>: @dt</li>
    <li><b>Number</b>: @number.ToString("N2")</li>
</ul>

<h2><code>&lt;input&gt;</code> elements that don't set a <code>type</code>
</h2>

<p>
    The following <code>&lt;input&gt;</code> elements use
    <code>CultureInfo.CurrentCulture</code>.
</p>

<ul>
    <li><label><b>Date:</b> <input @bind="dt" /></label></li>
    <li><label><b>Number:</b> <input @bind="number" /></label></li>
</ul>

<h2><code>&lt;input&gt;</code> elements that set a <code>type</code></h2>

<p>
    The following <code>&lt;input&gt;</code> elements use
    <code>CultureInfo.InvariantCulture</code>.
</p>

<ul>
```

```
    <li><label><b>Date:</b> <input type="date" @bind="dt" /></label></li>
    <li><label><b>Number:</b> <input type="number" @bind="number" /></label>
</li>
</ul>

@code {
    private DateTime dt = DateTime.Now;
    private double number = 1999.69;
}
```

The number string format (`N2`) in the preceding example (`.ToString("N2")`) is a standard .NET numeric format specifier. The `N2` format is supported for all numeric types, includes a group separator, and renders up to two decimal places.

Optionally, add a menu item to the navigation in the `NavMenu` component (`NavMenu.razor`) for the `CultureExample1` component.

Dynamically set the culture from the `Accept-Language` header

Add the Microsoft.Extensions.Localization package to the app.

The Accept-Language header is set by the browser and controlled by the user's language preferences in browser settings. In browser settings, a user sets one or more preferred languages in order of preference. The order of preference is used by the browser to set quality values (`q`, 0-1) for each language in the header. The following example specifies United States English, English, and Costa Rican Spanish with a preference for United States English or English:

Accept-Language: en-US,en;q=0.9,es-CR;q=0.8

The app's culture is set by matching the first requested language that matches a supported culture of the app.

In ***client-side development***, set the `BlazorWebAssemblyLoadAllGlobalizationData` property to `true` in the client-side app's project file (`.csproj`):

XML

```
<PropertyGroup>

<BlazorWebAssemblyLoadAllGlobalizationData>true</BlazorWebAssemblyLoadAllGlo
balizationData>
</PropertyGroup>
```

> **Note**
>
> If the app's specification requires limiting the supported cultures to an explicit list, see the Dynamically set the client-side culture by user preference section of this article.

Apps are localized using Localization Middleware. Add localization services to the app with AddLocalization.

Add the following line to the `Program` file where services are registered:

```
C#

builder.Services.AddLocalization();
```

In ***server-side development***, specify the app's supported cultures before any middleware that might check the request culture. Generally, place Request Localization Middleware immediately before calling MapRazorComponents. The following example configures supported cultures for United States English and Costa Rican Spanish:

```
C#

app.UseRequestLocalization(new RequestLocalizationOptions()
    .AddSupportedCultures(new[] { "en-US", "es-CR" })
    .AddSupportedUICultures(new[] { "en-US", "es-CR" }));
```

For information on ordering the Localization Middleware in the middleware pipeline of the `Program` file, see ASP.NET Core Middleware.

Use the `CultureExample1` component shown in the Demonstration component section to study how globalization works. Issue a request with United States English (`en-US`). Switch to Costa Rican Spanish (`es-CR`) in the browser's language settings. Request the webpage again.

> **Note**
>
> Some browsers force you to use the default language setting for both requests and the browser's own UI settings. This can make changing the language back to one that you understand difficult because all of the setting UI screens might end up in a language that you can't read. A browser such as Opera is a good choice for

testing because it permits you to set a default language for webpage requests but leave the browser's settings UI in your language.

When the culture is United States English (`en-US`), the rendered component uses month/day date formatting (`6/7`), 12-hour time (`AM`/`PM`), and comma separators in numbers with a dot for the decimal value (`1,999.69`):

- **Date**: 6/7/2021 6:45:22 AM
- **Number**: 1,999.69

When the culture is Costa Rican Spanish (`es-CR`), the rendered component uses day/month date formatting (`7/6`), 24-hour time, and period separators in numbers with a comma for the decimal value (`1.999,69`):

- **Date**: 7/6/2021 6:49:38
- **Number**: 1.999,69

Statically set the client-side culture

Set the `BlazorWebAssemblyLoadAllGlobalizationData` property to `true` in the app's project file (`.csproj`):

XML

```
<PropertyGroup>

<BlazorWebAssemblyLoadAllGlobalizationData>true</BlazorWebAssemblyLoadAllGlo
balizationData>
</PropertyGroup>
```

The app's culture can be set in JavaScript when Blazor starts with the `applicationCulture` Blazor start option. The following example configures the app to launch using the United States English (`en-US`) culture.

Prevent Blazor autostart by adding `autostart="false"` to Blazor's <script> tag:

HTML

```
<script src="{BLAZOR SCRIPT}" autostart="false"></script>
```

In the preceding example, the `{BLAZOR SCRIPT}` placeholder is the Blazor script path and file name. For the location of the script, see ASP.NET Core Blazor project structure.

Add the following `<script>` block after Blazor's <script> tag and before the closing `</body>` tag:

Blazor Web App:

HTML

```
<script>
  Blazor.start({
    webAssembly: {
      applicationCulture: 'en-US'
    }
  });
</script>
```

Standalone Blazor WebAssembly:

HTML

```
<script>
  Blazor.start({
    applicationCulture: 'en-US'
  });
</script>
```

The value for `applicationCulture` must conform to the BCP-47 language tag format. For more information on Blazor startup, see ASP.NET Core Blazor startup.

An alternative to setting the culture Blazor's start option is to set the culture in C# code. Set CultureInfo.DefaultThreadCurrentCulture and CultureInfo.DefaultThreadCurrentUICulture in the `Program` file to the same culture.

Add the System.Globalization namespace to the `Program` file:

C#

```
using System.Globalization;
```

Add the culture settings before the line that builds and runs the WebAssemblyHostBuilder (`await builder.Build().RunAsync();`):

C#

```
CultureInfo.DefaultThreadCurrentCulture = new CultureInfo("en-US");
CultureInfo.DefaultThreadCurrentUICulture = new CultureInfo("en-US");
```

> **Note**
>
> Currently, Blazor WebAssembly apps only load resources based on DefaultThreadCurrentCulture. For more information, see Blazor WASM only relies on the current culture (current UI culture isn't respected) (dotnet/aspnetcore #56824).

Use the `CultureExample1` component shown in the Demonstration component section to study how globalization works. Issue a request with United States English (`en-US`). Switch to Costa Rican Spanish (`es-CR`) in the browser's language settings. Request the webpage again. When the requested language is Costa Rican Spanish, the app's culture remains United States English (`en-US`).

Statically set the server-side culture

Server-side apps are localized using Localization Middleware. Add localization services to the app with AddLocalization.

In the `Program` file:

```
C#

builder.Services.AddLocalization();
```

Specify the static culture in the `Program` file before any middleware that might check the request culture. Generally, place Request Localization Middleware immediately before MapRazorComponents. The following example configures United States English:

```
C#

app.UseRequestLocalization("en-US");
```

The culture value for UseRequestLocalization must conform to the BCP-47 language tag format.

For information on ordering the Localization Middleware in the middleware pipeline of the `Program` file, see ASP.NET Core Middleware.

Use the `CultureExample1` component shown in the Demonstration component section to study how globalization works. Issue a request with United States English (`en-US`). Switch to Costa Rican Spanish (`es-CR`) in the browser's language settings. Request the

webpage again. When the requested language is Costa Rican Spanish, the app's culture remains United States English (`en-US`).

Dynamically set the client-side culture by user preference

Examples of locations where an app might store a user's preference include in browser local storage (common for client-side scenarios), in a localization cookie or database (common for server-side scenarios), or in an external service attached to an external database and accessed by a web API. The following example demonstrates how to use browser local storage.

Add the Microsoft.Extensions.Localization package to the app.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

Set the `BlazorWebAssemblyLoadAllGlobalizationData` property to `true` in the project file:

XML

```
<PropertyGroup>

<BlazorWebAssemblyLoadAllGlobalizationData>true</BlazorWebAssemblyLoadAllGlobalizationData>
</PropertyGroup>
```

The app's culture for client-side rendering is set using the Blazor framework's API. A user's culture selection can be persisted in browser local storage.

Provide JS functions after Blazor's <script> tag to get and set the user's culture selection with browser local storage:

HTML

```
<script>
  window.blazorCulture = {
    get: () => window.localStorage['BlazorCulture'],
    set: (value) => window.localStorage['BlazorCulture'] = value
```

```
  };
</script>
```

> **Note**
>
> The preceding example pollutes the client with global functions. For a better approach in production apps, see JavaScript isolation in JavaScript modules.

Add the namespaces for System.Globalization and Microsoft.JSInterop to the top of the `Program` file:

C#

```
using System.Globalization;
using Microsoft.JSInterop;
```

Remove the following line:

diff

```
- await builder.Build().RunAsync();
```

Replace the preceding line with the following code. The code adds Blazor's localization service to the app's service collection with AddLocalization and uses JS interop to call into JS and retrieve the user's culture selection from local storage. If local storage doesn't contain a culture for the user, the code sets a default value of United States English (`en-US`).

C#

```
builder.Services.AddLocalization();

var host = builder.Build();

const string defaultCulture = "en-US";

var js = host.Services.GetRequiredService<IJSRuntime>();
var result = await js.InvokeAsync<string>("blazorCulture.get");
var culture = CultureInfo.GetCultureInfo(result ?? defaultCulture);

if (result == null)
{
    await js.InvokeVoidAsync("blazorCulture.set", defaultCulture);
}

CultureInfo.DefaultThreadCurrentCulture = culture;
```

```
CultureInfo.DefaultThreadCurrentUICulture = culture;

await host.RunAsync();
```

> ⓘ Note
>
> Currently, Blazor WebAssembly apps only load resources based on DefaultThreadCurrentCulture. For more information, see Blazor WASM only relies on the current culture (current UI culture isn't respected) (dotnet/aspnetcore #56824).

The following `CultureSelector` component shows how to perform the following actions:

- Set the user's culture selection into browser local storage via JS interop.
- Reload the component that they requested (`forceLoad: true`), which uses the updated culture.

`CultureSelector.razor`:

razor

```
@using System.Globalization
@inject IJSRuntime JS
@inject NavigationManager Navigation

<p>
    <label>
        Select your locale:
        <select @bind="selectedCulture"
@bind:after="ApplySelectedCultureAsync">
            @foreach (var culture in supportedCultures)
            {
                <option value="@culture">@culture.DisplayName</option>
            }
        </select>
    </label>
</p>

@code
{
    private CultureInfo[] supportedCultures = new[]
    {
        new CultureInfo("en-US"),
        new CultureInfo("es-CR"),
    };

    private CultureInfo? selectedCulture;

    protected override void OnInitialized()
```

```
    {
        selectedCulture = CultureInfo.CurrentCulture;
    }

    private async Task ApplySelectedCultureAsync()
    {
        if (CultureInfo.CurrentCulture != selectedCulture)
        {
            await JS.InvokeVoidAsync("blazorCulture.set",
selectedCulture!.Name);

            Navigation.NavigateTo(Navigation.Uri, forceLoad: true);
        }
    }
}
```

> ⓘ Note
>
> For more information on IJSInProcessRuntime, see Call JavaScript functions from .NET methods in ASP.NET Core Blazor.

Inside the closing tag of the `</main>` element in the `MainLayout` component (`MainLayout.razor`), add the `CultureSelector` component:

razor

```
<article class="bottom-row px-4">
    <CultureSelector />
</article>
```

Use the `CultureExample1` component shown in the Demonstration component section to study how the preceding example works.

Dynamically set the server-side culture by user preference

Examples of locations where an app might store a user's preference include in browser local storage (common for client-side scenarios), in a localization cookie or database (common for server-side scenarios), or in an external service attached to an external database and accessed by a web API. The following example demonstrates how to use a localization cookie.

> ⓘ Note

The following example assumes that the app adopts ***global*** interactivity by specifying the interactive server-side rendering (interactive SSR) on the `Routes` component in the `App` component (`Components/App.razor`):

razor

```
<Routes @rendermode="InteractiveServer" />
```

If the app adopts ***per-page/component*** interactivity, see the remarks at the end of this section to modify the render modes of the example's components.

Add the Microsoft.Extensions.Localization package to the app.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

Server-side apps are localized using Localization Middleware. Add localization services to the app with AddLocalization.

In the `Program` file:

C#

```
builder.Services.AddLocalization();
```

Set the app's default and supported cultures with RequestLocalizationOptions.

Before the call to MapRazorComponents in the request processing pipeline, place the following code:

C#

```
var supportedCultures = new[] { "en-US", "es-CR" };
var localizationOptions = new RequestLocalizationOptions()
    .SetDefaultCulture(supportedCultures[0])
    .AddSupportedCultures(supportedCultures)
    .AddSupportedUICultures(supportedCultures);

app.UseRequestLocalization(localizationOptions);
```

For information on ordering the Localization Middleware in the middleware pipeline, see ASP.NET Core Middleware.

The following example shows how to set the current culture in a cookie that can be read by the Localization Middleware.

The following namespaces are required for the `App` component:

- System.Globalization
- Microsoft.AspNetCore.Localization

Add the following to the top of the `App` component file (`Components/App.razor`):

razor

```
@using System.Globalization
@using Microsoft.AspNetCore.Localization
```

Add the following `@code` block to the bottom of the `App` component file:

razor

```
@code {
    [CascadingParameter]
    public HttpContext? HttpContext { get; set; }

    protected override void OnInitialized()
    {
        HttpContext?.Response.Cookies.Append(
            CookieRequestCultureProvider.DefaultCookieName,
            CookieRequestCultureProvider.MakeCookieValue(
                new RequestCulture(
                    CultureInfo.CurrentCulture,
                    CultureInfo.CurrentUICulture)));
    }
}
```

For information on ordering the Localization Middleware in the middleware pipeline, see ASP.NET Core Middleware.

If the app isn't configured to process controller actions:

- Add MVC services by calling AddControllers on the service collection in the `Program` file:

  C#

```
builder.Services.AddControllers();
```

- Add controller endpoint routing in the `Program` file by calling MapControllers on the IEndpointRouteBuilder (`app`):

```
C#

app.MapControllers();
```

To provide UI to allow a user to select a culture, use a *redirect-based approach* with a localization cookie. The app persists the user's selected culture via a redirect to a controller. The controller sets the user's selected culture into a cookie and redirects the user back to the original URI. The process is similar to what happens in a web app when a user attempts to access a secure resource, where the user is redirected to a sign-in page and then redirected back to the original resource.

`Controllers/CultureController.cs`:

```
C#

using Microsoft.AspNetCore.Localization;
using Microsoft.AspNetCore.Mvc;

[Route("[controller]/[action]")]
public class CultureController : Controller
{
    public IActionResult Set(string culture, string redirectUri)
    {
        if (culture != null)
        {
            HttpContext.Response.Cookies.Append(
                CookieRequestCultureProvider.DefaultCookieName,
                CookieRequestCultureProvider.MakeCookieValue(
                    new RequestCulture(culture, culture)));
        }

        return LocalRedirect(redirectUri);
    }
}
```

> ⚠ **Warning**

Use the LocalRedirect action result, as shown in the preceding example, to prevent open redirect attacks. For more information, see Prevent open redirect attacks in ASP.NET Core.

The following `CultureSelector` component shows how to call the `Set` method of the `CultureController` with the new culture. The component is placed in the `Shared` folder for use throughout the app.

`CultureSelector.razor`:

razor

```
@using System.Globalization
@inject IJSRuntime JS
@inject NavigationManager Navigation

<p>
    <label>
        Select your locale:
        <select @bind="selectedCulture"
@bind:after="ApplySelectedCultureAsync">
            @foreach (var culture in supportedCultures)
            {
                <option value="@culture">@culture.DisplayName</option>
            }
        </select>
    </label>
</p>

@code
{
    private CultureInfo[] supportedCultures = new[]
    {
        new CultureInfo("en-US"),
        new CultureInfo("es-CR"),
    };

    private CultureInfo? selectedCulture;

    protected override void OnInitialized()
    {
        selectedCulture = CultureInfo.CurrentCulture;
    }

    private async Task ApplySelectedCultureAsync()
    {
        if (CultureInfo.CurrentCulture != selectedCulture)
        {
            var uri = new Uri(Navigation.Uri)
                .GetComponents(UriComponents.PathAndQuery,
UriFormat.Unescaped);
```

```
            var cultureEscaped = Uri.EscapeDataString(selectedCulture.Name);
            var uriEscaped = Uri.EscapeDataString(uri);

            Navigation.NavigateTo(
                $"Culture/Set?culture={cultureEscaped}&redirectUri=
{uriEscaped}",
                forceLoad: true);
        }
    }
}
```

Add the `CultureSelector` component to the `MainLayout` component. Place the following markup inside the closing `</main>` tag in the `Components/Layout/MainLayout.razor` file:

razor

```
<article class="bottom-row px-4">
    <CultureSelector />
</article>
```

Use the `CultureExample1` component shown in the Demonstration component section to study how the preceding example works.

The preceding example assumes that the app adopts ***global*** interactivity by specifying the Interactive Server render mode on the `Routes` component in the `App` component (`Components/App.razor`):

razor

```
<Routes @rendermode="InteractiveServer" />
```

If the app adopts ***per-page/component*** interactivity, make the following changes:

- Add the Interactive Server render mode to the top of the `CultureExample1` component file (`Components/Pages/CultureExample1.razor`):

  razor

  ```
  @rendermode InteractiveServer
  ```

- In the app's main layout (`Components/Layout/MainLayout.razor`), apply the Interactive Server render mode to the `CultureSelector` component:

  razor

```
<CultureSelector @rendermode="InteractiveServer" />
```

Dynamically set the culture in a Blazor Web App by user preference

This section applies to Blazor Web Apps that adopt Auto (Server and WebAssembly) interactivity.

Examples of locations where an app might store a user's preference include in browser local storage (common for client-side scenarios), in a localization cookie or database (common for server-side scenarios), both local storage and a localization cookie (Blazor Web Apps with server and WebAssembly components), or in an external service attached to an external database and accessed by a web API. The following example demonstrates how to use browser local storage for client-side rendered (CSR) components and a localization cookie for server-side rendered (SSR) components.

Updates to the `.Client` project

Add the Microsoft.Extensions.Localization package to the `.Client` project.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

Set the `BlazorWebAssemblyLoadAllGlobalizationData` property to `true` in the `.Client` project file:

XML

```
<PropertyGroup>

<BlazorWebAssemblyLoadAllGlobalizationData>true</BlazorWebAssemblyLoadAllGlobalizationData>
</PropertyGroup>
```

Add the namespaces for System.Globalization and Microsoft.JSInterop to the top of the `.Client` project's `Program` file:

C#

```
using System.Globalization;
using Microsoft.JSInterop;
```

Remove the following line:

diff

```
- await builder.Build().RunAsync();
```

Replace the preceding line with the following code. The code adds Blazor's localization service to the app's service collection with AddLocalization and uses JS interop to call into JS and retrieve the user's culture selection from local storage. If local storage doesn't contain a culture for the user, the code sets a default value of United States English (`en-US`).

C#

```
builder.Services.AddLocalization();

var host = builder.Build();

const string defaultCulture = "en-US";

var js = host.Services.GetRequiredService<IJSRuntime>();
var result = await js.InvokeAsync<string>("blazorCulture.get");
var culture = CultureInfo.GetCultureInfo(result ?? defaultCulture);

if (result == null)
{
    await js.InvokeVoidAsync("blazorCulture.set", defaultCulture);
}

CultureInfo.DefaultThreadCurrentCulture = culture;
CultureInfo.DefaultThreadCurrentUICulture = culture;

await host.RunAsync();
```

> ⓘ **Note**
>
> Currently, Blazor WebAssembly apps only load resources based on DefaultThreadCurrentCulture. For more information, see Blazor WASM only relies on the current culture (current UI culture isn't respected) (dotnet/aspnetcore #56824).

Add the following `CultureSelector` component to the `.Client` project.

The component adopts the following approaches to work for either SSR or CSR components:

- The display name of each available culture in the dropdown list is provided by a dictionary because client-side globalization data include localized text of culture display names that server-side globalization data provides. For example, server-side localization displays `English (United States)` when `en-US` is the culture and `Ingles ()` when a different culture is used. Because localization of the culture display names isn't available with Blazor WebAssembly globalization, the display name for United States English on the client for any loaded culture is just `en-US`. Using a custom dictionary permits the component to at least display full English culture names.
- When user changes the culture, JS interop sets the culture in local browser storage and a controller action updates the localization cookie with the culture. The controller is added to the app later in the Server project updates section.

`Pages/CultureSelector.razor`:

razor

```
@using System.Globalization
@inject IJSRuntime JS
@inject NavigationManager Navigation

<p>
    <label>
        Select your locale:
        <select @bind="@selectedCulture"
@bind:after="ApplySelectedCultureAsync">
            @foreach (var culture in supportedCultures)
            {
                <option value="@culture">@cultureDict[culture.Name]</option>
            }
        </select>
    </label>
</p>

@code
{
    private Dictionary<string, string> cultureDict =
        new()
        {
            { "en-US", "English (United States)" },
            { "es-CR", "Spanish (Costa Rica)" }
        };

    private CultureInfo[] supportedCultures = new[]
```

```
    {
        new CultureInfo("en-US"),
        new CultureInfo("es-CR"),
    };

    private CultureInfo? selectedCulture;

    protected override void OnInitialized()
    {
        selectedCulture = CultureInfo.CurrentCulture;
    }

    private async Task ApplySelectedCultureAsync()
    {
        if (CultureInfo.CurrentCulture != selectedCulture)
        {
            await JS.InvokeVoidAsync("blazorCulture.set",
selectedCulture!.Name);

            var uri = new Uri(Navigation.Uri)
                .GetComponents(UriComponents.PathAndQuery,
UriFormat.Unescaped);
            var cultureEscaped = Uri.EscapeDataString(selectedCulture.Name);
            var uriEscaped = Uri.EscapeDataString(uri);

            Navigation.NavigateTo(
                $"Culture/Set?culture={cultureEscaped}&redirectUri=
{uriEscaped}",
                forceLoad: true);
        }
    }
}
```

> **Note**
>
> For more information on IJSInProcessRuntime, see Call JavaScript functions from .NET methods in ASP.NET Core Blazor.

In the `.Client` project, place the following `CultureClient` component to study how globalization works for CSR components.

`Pages/CultureClient.razor`:

razor

```
@page "/culture-client"
@rendermode InteractiveWebAssembly
@using System.Globalization

<PageTitle>Culture Client</PageTitle>
```

```
<h1>Culture Client</h1>

<ul>
    <li><b>CurrentCulture</b>: @CultureInfo.CurrentCulture</li>
    <li><b>CurrentUICulture</b>: @CultureInfo.CurrentUICulture</li>
</ul>

<h2>Rendered values</h2>

<ul>
    <li><b>Date</b>: @dt</li>
    <li><b>Number</b>: @number.ToString("N2")</li>
</ul>

<h2><code>&lt;input&gt;</code> elements that don't set a <code>type</code>
</h2>

<p>
    The following <code>&lt;input&gt;</code> elements use
    <code>CultureInfo.CurrentCulture</code>.
</p>

<ul>
    <li><label><b>Date:</b> <input @bind="dt" /></label></li>
    <li><label><b>Number:</b> <input @bind="number" /></label></li>
</ul>

<h2><code>&lt;input&gt;</code> elements that set a <code>type</code></h2>

<p>
    The following <code>&lt;input&gt;</code> elements use
    <code>CultureInfo.InvariantCulture</code>.
</p>

<ul>
    <li><label><b>Date:</b> <input type="date" @bind="dt" /></label></li>
    <li><label><b>Number:</b> <input type="number" @bind="number" /></label>
</li>
</ul>

@code {
    private DateTime dt = DateTime.Now;
    private double number = 1999.69;
}
```

Server project updates

Add the Microsoft.Extensions.Localization package to the server project.

> **Note**

For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

Server-side apps are localized using Localization Middleware. Add localization services to the app with AddLocalization.

In the server project's `Program` file where services are registered:

C#

```
builder.Services.AddLocalization();
```

Set the app's default and supported cultures with RequestLocalizationOptions.

Before the call to MapRazorComponents in the request processing pipeline, place the following code:

C#

```
var supportedCultures = new[] { "en-US", "es-CR" };
var localizationOptions = new RequestLocalizationOptions()
    .SetDefaultCulture(supportedCultures[0])
    .AddSupportedCultures(supportedCultures)
    .AddSupportedUICultures(supportedCultures);

app.UseRequestLocalization(localizationOptions);
```

The following example shows how to set the current culture in a cookie that can be read by the Localization Middleware.

The following namespaces are required for the `App` component:

- System.Globalization
- Microsoft.AspNetCore.Localization

Add the following to the top of the `App` component file (`Components/App.razor`):

razor

```
@using System.Globalization
@using Microsoft.AspNetCore.Localization
```

The app's culture for client-side rendering is set using the Blazor framework's API. A user's culture selection can be persisted in browser local storage for CSR components.

After the Blazor's <script> tag, provide JS functions to get and set the user's culture selection with browser local storage:

HTML

```
<script>
  window.blazorCulture = {
    get: () => window.localStorage['BlazorCulture'],
    set: (value) => window.localStorage['BlazorCulture'] = value
  };
</script>
```

> **Note**
>
> The preceding example pollutes the client with global functions. For a better approach in production apps, see JavaScript isolation in JavaScript modules.

Add the following `@code` block to the bottom of the `App` component file:

razor

```
@code {
    [CascadingParameter]
    public HttpContext? HttpContext { get; set; }

    protected override void OnInitialized()
    {
        HttpContext?.Response.Cookies.Append(
            CookieRequestCultureProvider.DefaultCookieName,
            CookieRequestCultureProvider.MakeCookieValue(
                new RequestCulture(
                    CultureInfo.CurrentCulture,
                    CultureInfo.CurrentUICulture)));
    }
}
```

If the server project isn't configured to process controller actions:

- Add MVC services by calling AddControllers on the service collection in the `Program` file:

  C#

  ```
  builder.Services.AddControllers();
  ```

- Add controller endpoint routing in the `Program` file by calling MapControllers on the IEndpointRouteBuilder (`app`):

  C#

  ```
  app.MapControllers();
  ```

To allow a user to select a culture for SSR components, use a *redirect-based approach* with a localization cookie. The app persists the user's selected culture via a redirect to a controller. The controller sets the user's selected culture into a cookie and redirects the user back to the original URI. The process is similar to what happens in a web app when a user attempts to access a secure resource, where the user is redirected to a sign-in page and then redirected back to the original resource.

`Controllers/CultureController.cs`:

C#

```
using Microsoft.AspNetCore.Localization;
using Microsoft.AspNetCore.Mvc;

[Route("[controller]/[action]")]
public class CultureController : Controller
{
    public IActionResult Set(string culture, string redirectUri)
    {
        if (culture != null)
        {
            HttpContext.Response.Cookies.Append(
                CookieRequestCultureProvider.DefaultCookieName,
                CookieRequestCultureProvider.MakeCookieValue(
                    new RequestCulture(culture, culture)));
        }

        return LocalRedirect(redirectUri);
    }
}
```

> ⚠ **Warning**
>
> Use the LocalRedirect action result, as shown in the preceding example, to prevent open redirect attacks. For more information, see Prevent open redirect attacks in ASP.NET Core.

Add the `CultureSelector` component to the `MainLayout` component. Place the following markup inside the closing `</main>` tag in the `Components/Layout/MainLayout.razor` file:

razor

```razor
<article class="bottom-row px-4">
    <CultureSelector @rendermode="InteractiveAuto" />
</article>
```

Use the `CultureExample1` component shown in the Demonstration component section to study how the preceding example works.

In the server project, place the following `CultureServer` component to study how globalization works for SSR components.

`Components/Pages/CultureServer.razor`:

razor

```razor
@page "/culture-server"
@rendermode InteractiveServer
@using System.Globalization

<PageTitle>Culture Server</PageTitle>

<h1>Culture Server</h1>

<ul>
    <li><b>CurrentCulture</b>: @CultureInfo.CurrentCulture</li>
    <li><b>CurrentUICulture</b>: @CultureInfo.CurrentUICulture</li>
</ul>

<h2>Rendered values</h2>

<ul>
    <li><b>Date</b>: @dt</li>
    <li><b>Number</b>: @number.ToString("N2")</li>
</ul>

<h2><code>&lt;input&gt;</code> elements that don't set a <code>type</code>
</h2>

<p>
    The following <code>&lt;input&gt;</code> elements use
    <code>CultureInfo.CurrentCulture</code>.
</p>

<ul>
    <li><label><b>Date:</b> <input @bind="dt" /></label></li>
    <li><label><b>Number:</b> <input @bind="number" /></label></li>
</ul>
```

```
<h2><code>&lt;input&gt;</code> elements that set a <code>type</code></h2>

<p>
    The following <code>&lt;input&gt;</code> elements use
    <code>CultureInfo.InvariantCulture</code>.
</p>

<ul>
    <li><label><b>Date:</b> <input type="date" @bind="dt" /></label></li>
    <li><label><b>Number:</b> <input type="number" @bind="number" /></label>
</li>
</ul>

@code {
    private DateTime dt = DateTime.Now;
    private double number = 1999.69;
}
```

Add both the `CultureClient` and `CultureServer` components to the sidebar navigation in `Components/Layout/NavMenu.razor`:

razor

```
<div class="nav-item px-3">
    <NavLink class="nav-link" href="culture-server">
        <span class="bi bi-list-nested-nav-menu" aria-hidden="true"></span>
Culture (Server)
    </NavLink>
</div>
<div class="nav-item px-3">
    <NavLink class="nav-link" href="culture-client">
        <span class="bi bi-list-nested-nav-menu" aria-hidden="true"></span>
Culture (Client)
    </NavLink>
</div>
```

Interactive Auto components

The guidance in this section also works for components that adopt the Interactive Auto render mode:

razor

```
@rendermode InteractiveAuto
```

Localization

If the app doesn't already support dynamic culture selection, add the Microsoft.Extensions.Localization package to the app.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

Client-side localization

Set the `BlazorWebAssemblyLoadAllGlobalizationData` property to `true` in the app's project file (`.csproj`):

```xml
<PropertyGroup>

<BlazorWebAssemblyLoadAllGlobalizationData>true</BlazorWebAssemblyLoadAllGlobalizationData>
</PropertyGroup>
```

In the `Program` file, add namespace the namespace for System.Globalization to the top of the file:

```csharp
using System.Globalization;
```

Add Blazor's localization service to the app's service collection with AddLocalization:

```csharp
builder.Services.AddLocalization();
```

Server-side localization

Use Localization Middleware to set the app's culture.

If the app doesn't already support dynamic culture selection:

- Add localization services to the app with AddLocalization.

- Specify the app's default and supported cultures in the `Program` file. The following example configures supported cultures for United States English and Costa Rican Spanish.

```
C#

builder.Services.AddLocalization();
```

Place Request Localization Middleware before any middleware that might check the request culture. Generally, place the middleware immediately before calling MapRazorComponents:

```
C#

var supportedCultures = new[] { "en-US", "es-CR" };
var localizationOptions = new RequestLocalizationOptions()
    .SetDefaultCulture(supportedCultures[0])
    .AddSupportedCultures(supportedCultures)
    .AddSupportedUICultures(supportedCultures);

app.UseRequestLocalization(localizationOptions);
```

For information on ordering the Localization Middleware in the middleware pipeline, see ASP.NET Core Middleware.

If the app should localize resources based on storing a user's culture setting, use a localization culture cookie. Use of a cookie ensures that the WebSocket connection can correctly propagate the culture. If localization schemes are based on the URL path or query string, the scheme might not be able to work with WebSockets, thus fail to persist the culture. Therefore, the recommended approach is to use a localization culture cookie. See the Dynamically set the server-side culture by user preference section of this article to see an example Razor expression that persists the user's culture selection.

Example of localized resources

The example of localized resources in this section works with the prior examples in this article where the app's supported cultures are English (`en`) as a default locale and Spanish (`es`) as a user-selectable or browser-specified alternate locale.

Create a resource file for each locale. In the following example, resources are created for a `Greeting` string in English and Spanish:

- English (`en`): `Hello, World!`

- Spanish (`es`): `¡Hola, Mundo!`

> **Note**
>
> The following resource file can be added in Visual Studio by right-clicking the `Pages` folder and selecting **Add** > **New Item** > **Resources File**. Name the file `CultureExample2.resx`. When the editor appears, provide data for a new entry. Set the **Name** to `Greeting` and **Value** to `Hello, World!`. Save the file.
>
> If using Visual Studio Code, we recommend installing Tim Heuer's ResX Viewer and Editor. Add an empty `CultureExample2.resx` file to the `Pages` folder. The extension automatically takes over managing the file in the UI. Select the **Add New Resource** button. Follow the instructions to add an entry for `Greeting` (key), `Hello, World!` (value), and `None` (comment). Save the file. If you close and re-open the file, you can see the `Greeting` resource.
>
> Tim Heuer's ResX Viewer and Editor isn't owned or maintained by Microsoft and isn't covered by any Microsoft Support Agreement or license.

The following demonstrates a typical resource file. You can manually place resource files into the app's `Pages` folder if you prefer not to use built-in tooling with an integrated development environment (IDE), such as Visual Studio's built-in resource file editor or Visual Studio Code with an extension for creating and editing resource files.

`Pages/CultureExample2.resx`:

XML

```
<?xml version="1.0" encoding="utf-8"?>
<root>

              <xsd:sequence>
                <xsd:element name="value" type="xsd:string" minOccurs="0" />
              </xsd:sequence>
              <xsd:attribute name="name" use="required" type="xsd:string" />
              <xsd:attribute name="type" type="xsd:string" />
              <xsd:attribute name="mimetype" type="xsd:string" />
              <xsd:attribute ref="xml:space" />
            </xsd:complexType>
          </xsd:element>
```

```
          <xsd:element name="assembly">
            <xsd:complexType>
              <xsd:attribute name="alias" type="xsd:string" />
              <xsd:attribute name="name" type="xsd:string" />
            </xsd:complexType>
          </xsd:element>
          <xsd:element name="data">
            <xsd:complexType>
              <xsd:sequence>
                <xsd:element name="value" type="xsd:string" minOccurs="0"
msdata:Ordinal="1" />
                <xsd:element name="comment" type="xsd:string" minOccurs="0"
msdata:Ordinal="2" />
              </xsd:sequence>
              <xsd:attribute name="name" type="xsd:string" use="required"
msdata:Ordinal="1" />
              <xsd:attribute name="type" type="xsd:string"
msdata:Ordinal="3" />
              <xsd:attribute name="mimetype" type="xsd:string"
msdata:Ordinal="4" />
              <xsd:attribute ref="xml:space" />
            </xsd:complexType>
          </xsd:element>
          <xsd:element name="resheader">
            <xsd:complexType>
              <xsd:sequence>
                <xsd:element name="value" type="xsd:string" minOccurs="0"
msdata:Ordinal="1" />
              </xsd:sequence>
              <xsd:attribute name="name" type="xsd:string" use="required" />
            </xsd:complexType>
          </xsd:element>
        </xsd:choice>
      </xsd:complexType>
    </xsd:element>
  </xsd:schema>
  <resheader name="resmimetype">
    <value>text/microsoft-resx</value>
  </resheader>
  <resheader name="version">
    <value>2.0</value>
  </resheader>
  <resheader name="reader">
    <value>System.Resources.ResXResourceReader, System.Windows.Forms,
Version=4.0.0.0, Culture=neutral, PublicKeyToken=b77a5c561934e089</value>
  </resheader>
  <resheader name="writer">
    <value>System.Resources.ResXResourceWriter, System.Windows.Forms,
Version=4.0.0.0, Culture=neutral, PublicKeyToken=b77a5c561934e089</value>
  </resheader>
  <data name="Greeting" xml:space="preserve">
    <value>¡Hola, Mundo!</value>
  </data>
</root>
```

The following component demonstrates the use of the localized `Greeting` string with IStringLocalizer<T>. The Razor markup `@Loc["Greeting"]` in the following example localizes the string keyed to the `Greeting` value, which is set in the preceding resource files.

Add the namespace for Microsoft.Extensions.Localization to the app's `_Imports.razor` file:

razor

```
@using Microsoft.Extensions.Localization
```

`CultureExample2.razor`:

razor

```
@page "/culture-example-2"
@using System.Globalization
@inject IStringLocalizer<CultureExample2> Loc

<h1>Culture Example 2</h1>

<ul>
    <li><b>CurrentCulture</b>: @CultureInfo.CurrentCulture</li>
    <li><b>CurrentUICulture</b>: @CultureInfo.CurrentUICulture</li>
</ul>

<h2>Greeting</h2>

<p>
    @Loc["Greeting"]
</p>

<p>
    @greeting
</p>

@code {
    private string? greeting;

    protected override void OnInitialized()
    {
        greeting = Loc["Greeting"];
    }
}
```

Optionally, add a menu item for the `CultureExample2` component to the navigation in the `NavMenu` component (`NavMenu.razor`).

WebAssembly culture provider reference source

To further understand how the Blazor framework processes localization, see the WebAssemblyCultureProvider class in the ASP.NET Core reference source.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Shared resources

To create localization shared resources, adopt the following approach.

- Create a dummy class with an arbitrary class name. In the following example:
  - The app uses the `BlazorSample` namespace, and localization assets use the `BlazorSample.Localization` namespace.
  - The dummy class is named `SharedResource`.
  - The class file is placed in a `Localization` folder at the root of the app.

  `Localization/SharedResource.cs`:

  C#

  ```
  namespace BlazorSample.Localization;

  public class SharedResource
  {
  }
  ```

- Create the shared resource files with a **Build Action** of `Embedded resource`. In the following example:

  - The files are placed in the `Localization` folder with the dummy `SharedResource` class (`Localization/SharedResource.cs`).

    - Name the resource files to match the name of the dummy class. The following example files include a default localization file and a file for Spanish (`es`) localization.
    - `Localization/SharedResource.resx`
    - `Localization/SharedResource.es.resx`

    > ⚠ **Warning**
    >
    > When following the approach in this section, you can't simultaneously set LocalizationOptions.ResourcesPath and use IStringLocalizerFactory.Create to load resources.

- To reference the dummy class for an injected IStringLocalizer<T> in a Razor component, either place an @using directive for the localization namespace or include the localization namespace in the dummy class reference. In the following examples:
    - The first example states the `Localization` namespace for the `SharedResource` dummy class with an @using directive.
    - The second example states the `SharedResource` dummy class's namespace explicitly.

    In a Razor component, use ***either*** of the following approaches:

    razor

    ```
    @using Localization
    @inject IStringLocalizer<SharedResource> Loc
    ```

    razor

    ```
    @inject IStringLocalizer<Localization.SharedResource> Loc
    ```

For additional guidance, see Globalization and localization in ASP.NET Core.

Location override using "Sensors" pane in developer tools

When using the location override using the **Sensors** pane in Google Chrome or Microsoft Edge developer tools, the fallback language is reset after prerendering. Avoid

setting the language using the **Sensors** pane when testing. Set the language using the browser's language settings.

For more information, see Blazor Localization does not work with InteractiveServer (dotnet/aspnetcore #53707).

ASP.NET Core Blazor forms overview

Article • 10/21/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article explains how to use forms in Blazor.

Input components and forms

The Blazor framework supports forms and provides built-in input components:

- Bound to an object or model that can use data annotations.
  - HTML forms with the `<form>` element.
  - EditForm components.
- Built-in input components.

> **ⓘ Note**
>
> Unsupported ASP.NET Core validation features are covered in the Unsupported validation features section.

The Microsoft.AspNetCore.Components.Forms namespace provides:

- Classes for managing form elements, state, and validation.
- Access to built-in Input* components.

A project created from the Blazor project template includes the namespace in the app's `_Imports.razor` file, which makes the namespace available to the app's Razor components.

Standard HTML forms are supported. Create a form using the normal HTML `<form>` tag and specify an `@onsubmit` handler for handling the submitted form request.

`StarshipPlainForm.razor`:

razor

```razor
@page "/starship-plain-form"
@inject ILogger<StarshipPlainForm> Logger

<form method="post" @onsubmit="Submit" @formname="starship-plain-form">
    <AntiforgeryToken />
    <div>
        <label>
            Identifier:
            <InputText @bind-Value="Model!.Id" />
        </label>
    </div>
    <div>
        <button type="submit">Submit</button>
    </div>
</form>

@code {
    [SupplyParameterFromForm]
    private Starship? Model { get; set; }

    protected override void OnInitialized() => Model ??= new();

    private void Submit() => Logger.LogInformation("Id = {Id}", Model?.Id);

    public class Starship
    {
        public string? Id { get; set; }
    }
}
```

In the preceding `StarshipPlainForm` component:

- The form is rendered where the `<form>` element appears. The form is named with the @formname directive attribute, which uniquely identifies the form to the Blazor framework.
- The model is created in the component's `@code` block and held in a public property (`Model`). The `[SupplyParameterFromForm]` attribute indicates that the value of the associated property should be supplied from the form data. Data in the request that matches the property's name is bound to the property.
- The InputText component is an input component for editing string values. The `@bind-Value` directive attribute binds the `Model.Id` model property to the InputText component's Value property.
- The `Submit` method is registered as a handler for the `@onsubmit` callback. The handler is called when the form is submitted by the user.

> **ⓘ Important**

Always use the **@formname** directive attribute with a unique form name.

Blazor enhances page navigation and form handling by intercepting the request in order to apply the response to the existing DOM, preserving as much of the rendered form as possible. The enhancement avoids the need to fully load the page and provides a much smoother user experience, similar to a single-page app (SPA), although the component is rendered on the server. For more information, see ASP.NET Core Blazor routing and navigation.

Streaming rendering is supported for plain HTML forms.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

The preceding example includes antiforgery support by including an AntiforgeryToken component in the form. Antiforgery support is explained further in the Antiforgery support section of this article.

To submit a form based on another element's DOM events, for example `oninput` or `onblur`, use JavaScript to submit the form (submit (MDN documentation)).

Instead of using plain forms in Blazor apps, a form is typically defined with Blazor's built-in form support using the framework's EditForm component. The following Razor component demonstrates typical elements, components, and Razor code to render a webform using an EditForm component.

`Starship1.razor`:

razor

```razor
@page "/starship-1"
@inject ILogger<Starship1> Logger

<EditForm Model="Model" OnSubmit="Submit" FormName="Starship1">
    <div>
        <label>
            Identifier:
            <InputText @bind-Value="Model!.Id" />
        </label>
```

```
    </div>
    <div>
        <button type="submit">Submit</button>
    </div>
</EditForm>

@code {
    [SupplyParameterFromForm]
    private Starship? Model { get; set; }

    protected override void OnInitialized() => Model ??= new();

    private void Submit() => Logger.LogInformation("Id = {Id}", Model?.Id);

    public class Starship
    {
        public string? Id { get; set; }
    }
}
```

In the preceding `Starship1` component:

- The EditForm component is rendered where the `<EditForm>` element appears. The form is named with the @formname directive attribute, which uniquely identifies the form to the Blazor framework.
- The model is created in the component's `@code` block and held in a public property (`Model`). The property is assigned to the EditForm.Model parameter. The `[SupplyParameterFromForm]` attribute indicates that the value of the associated property should be supplied from the form data. Data in the request that matches the property's name is bound to the property.
- The InputText component is an input component for editing string values. The `@bind-Value` directive attribute binds the `Model.Id` model property to the InputText component's Value property.
- The `Submit` method is registered as a handler for the OnSubmit callback. The handler is called when the form is submitted by the user.

> **ⓘ Important**
>
> Always use the **@formname** directive attribute with a unique form name.

Blazor enhances page navigation and form handling for EditForm components. For more information, see ASP.NET Core Blazor routing and navigation.

Streaming rendering is supported for EditForm.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

†For more information on property binding, see ASP.NET Core Blazor data binding.

In the next example, the preceding component is modified to create the form in the `Starship2` component:

- OnSubmit is replaced with OnValidSubmit, which processes assigned event handler if the form is valid when submitted by the user.
- A ValidationSummary component is added to display validation messages when the form is invalid on form submission.
- The data annotations validator (DataAnnotationsValidator component†) attaches validation support using data annotations:
  - If the `<input>` form field is left blank when the **`Submit`** button is selected, an error appears in the validation summary (ValidationSummary component‡) ("`The Id field is required.`") and `Submit` is **not** called.
  - If the `<input>` form field contains more than ten characters when the **`Submit`** button is selected, an error appears in the validation summary ("`Id is too long.`"). `Submit` is **not** called.
  - If the `<input>` form field contains a valid value when the **`Submit`** button is selected, `Submit` is called.

†The DataAnnotationsValidator component is covered in the Validator component section. ‡The ValidationSummary component is covered in the Validation Summary and Validation Message components section.

`Starship2.razor`:

razor

```razor
@page "/starship-2"
@using System.ComponentModel.DataAnnotations
@inject ILogger<Starship2> Logger

<EditForm Model="Model" OnValidSubmit="Submit" FormName="Starship2">
    <DataAnnotationsValidator />
    <ValidationSummary />
```

```
    <label>
        Identifier:
        <InputText @bind-Value="Model!.Id" />
    </label>
    <button type="submit">Submit</button>
</EditForm>

@code {
    [SupplyParameterFromForm]
    private Starship? Model { get; set; }

    protected override void OnInitialized() => Model ??= new();

    private void Submit() => Logger.LogInformation("Id = {Id}", Model?.Id);

    public class Starship
    {
        [Required]
        [StringLength(10, ErrorMessage = "Id is too long.")]
        public string? Id { get; set; }
    }
}
```

Handle form submission

The EditForm provides the following callbacks for handling form submission:

- Use OnValidSubmit to assign an event handler to run when a form with valid fields is submitted.
- Use OnInvalidSubmit to assign an event handler to run when a form with invalid fields is submitted.
- Use OnSubmit to assign an event handler to run regardless of the form fields' validation status. The form is validated by calling EditContext.Validate in the event handler method. If Validate returns `true`, the form is valid.

Clear a form or field

Reset a form by clearing its model back its default state, which can be performed inside or outside of an EditForm's markup:

razor

```
<button @onclick="ClearForm">Clear form</button>

...
```

```
private void ClearForm() => Model = new();
```

Alternatively, use an explicit Razor expression:

razor

```
<button @onclick="@(() => Model = new())">Clear form</button>
```

Reset a field by clearing its model value back to its default state:

razor

```
<button @onclick="ResetId">Reset Identifier</button>

...

private void ResetId() => Model!.Id = string.Empty;
```

Alternatively, use an explicit Razor expression:

razor

```
<button @onclick="@(() => Model!.Id = string.Empty)">Reset
Identifier</button>
```

There's no need to call StateHasChanged in the preceding examples because StateHasChanged is automatically called by the Blazor framework to rerender the component after an event handler is invoked. If an event handler isn't used to invoke the methods that clear a form or field, then developer code should call StateHasChanged to rerender the component.

Antiforgery support

Antiforgery services are automatically added to Blazor apps when AddRazorComponents is called in the `Program` file.

The app uses Antiforgery Middleware by calling UseAntiforgery in its request processing pipeline in the `Program` file. UseAntiforgery is called after the call to UseRouting. If there are calls to UseRouting and UseEndpoints, the call to UseAntiforgery must go between them. A call to UseAntiforgery must be placed after calls to UseAuthentication and UseAuthorization.

The AntiforgeryToken component renders an antiforgery token as a hidden field, and the `[RequireAntiforgeryToken]` attribute enables antiforgery protection. If an antiforgery check fails, a 400 - Bad Request response is thrown and the form isn't processed.

For forms based on EditForm, the AntiforgeryToken component and `[RequireAntiforgeryToken]` attribute are automatically added to provide antiforgery protection.

For forms based on the HTML `<form>` element, manually add the AntiforgeryToken component to the form:

razor

```razor
<form method="post" @onsubmit="Submit" @formname="starshipForm">
    <AntiforgeryToken />
    <input id="send" type="submit" value="Send" />
</form>

@if (submitted)
{
    <p>Form submitted!</p>
}

@code{
    private bool submitted = false;

    private void Submit() => submitted = true;
}
```

> ⚠ **Warning**
>
> For forms based on either **EditForm** or the HTML `<form>` element, antiforgery protection can be disabled by passing `required: false` to the `[RequireAntiforgeryToken]` attribute. The following example disables antiforgery and is ***not recommended*** for public apps:
>
> razor
>
> ```razor
> @using Microsoft.AspNetCore.Antiforgery
> @attribute [RequireAntiforgeryToken(required: false)]
> ```

For more information, see ASP.NET Core Blazor authentication and authorization.

Mitigate overposting attacks

Statically-rendered server-side forms, such as those typically used in components that create and edit records in a database with a form model, can be vulnerable to an *overposting* attack, also known as a *mass assignment* attack. An overposting attack occurs when a malicious user issues an HTML form POST to the server that processes data for properties that aren't part of the rendered form and that the developer doesn't wish to allow users to modify. The term "overposting" literally means that the malicious user has *over*-POSTed with the form.

Overposting isn't a concern when the model doesn't include restricted properties for create and update operations. However, it's important to keep overposting in mind when working with static SSR-based Blazor forms that you maintain.

To mitigate overposting, we recommend using a separate view model/data transfer object (DTO) for the form and database with create (insert) and update operations. When the form is submitted, only properties of the view model/DTO are used by the component and C# code to modify the database. Any extra data included by a malicious user is discarded, so the malicious user is prevented from conducting an overposting attack.

Enhanced form handling

Enhance navigation for form POST requests with the Enhance parameter for EditForm forms or the `data-enhance` attribute for HTML forms (`<form>`):

razor

```
<EditForm ... Enhance ...>
    ...
</EditForm>
```

HTML

```
<form ... data-enhance ...>
    ...
</form>
```

❌ You can't set enhanced navigation on a form's ancestor element to enable enhanced form handling.

HTML

```
<div ... data-enhance ...>
    <form ...>
        <!-- NOT enhanced -->
```

```
    </form>
</div>
```

Enhanced form posts only work with Blazor endpoints. Posting an enhanced form to non-Blazor endpoint results in an error.

To disable enhanced form handling:

- For an EditForm, remove the Enhance parameter from the form element (or set it to `false`: `Enhance="false"`).
- For an HTML `<form>`, remove the `data-enhance` attribute from form element (or set it to `false`: `data-enhance="false"`).

Blazor's enhanced navigation and form handing may undo dynamic changes to the DOM if the updated content isn't part of the server rendering. To preserve the content of an element, use the `data-permanent` attribute.

In the following example, the content of the `<div>` element is updated dynamically by a script when the page loads:

HTML

```
<div data-permanent>
    ...
</div>
```

To disable enhanced navigation and form handling globally, see ASP.NET Core Blazor startup.

For guidance on using the `enhancedload` event to listen for enhanced page updates, see ASP.NET Core Blazor routing and navigation.

Examples

Examples don't adopt enhanced form handling for form POST requests, but all of the examples can be updated to adopt the enhanced features by following the guidance in the Enhanced form handling section.

To demonstrate how forms work with data annotations validation, example components rely on System.ComponentModel.DataAnnotations API. If you wish to avoid an extra line of code in components that use data annotations, make the namespace available throughout the app's components with the imports file (`_Imports.razor`):

```
```

razor

```
@using System.ComponentModel.DataAnnotations
```

Form examples reference aspects of the Star Trek universe. Star Trek is a copyright ©1966-2023 of CBS Studios and Paramount.

Client-side validation requires a circuit

In Blazor Web Apps, client-side validation requires an active Blazor SignalR circuit. Client-side validation isn't available to forms in components that have adopted static server-side rendering (static SSR). Forms that adopt static SSR are validated on the server after the form is submitted.

Unsupported validation features

All of the data annotation built-in validators are supported in Blazor except for the [Remote] validation attribute.

jQuery validation isn't supported in Razor components. We recommend any of the following approaches:

- Follow the guidance in ASP.NET Core Blazor forms validation for either:
  - Server-side validation in a Blazor Web App that adopts an interactive render mode.
  - Client-side validation in a standalone Blazor Web Assembly app.
- Use native HTML validation attributes (see Client-side form validation (MDN documentation)).
- Adopt a third-party validation JavaScript library.

For statically-rendered forms on the server, a new mechanism for client-side validation is under consideration for .NET 10 in late 2025. For more information, see Create server rendered forms with client validation using Blazor without a circuit (dotnet/aspnetcore #51040).

ASP.NET Core Blazor input components

Article • 10/18/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article describes Blazor's built-in input components.

Input components

The Blazor framework provides built-in input components to receive and validate user input. The built-in input components in the following table are supported in an EditForm with an EditContext.

The components in the table are also supported outside of a form in Razor component markup. Inputs are validated when they're changed and when a form is submitted.

Expand table

Input component	Rendered as...
InputCheckbox	`<input type="checkbox">`
InputDate<TValue>	`<input type="date">`
InputFile	`<input type="file">`
InputNumber<TValue>	`<input type="number">`
InputRadio<TValue>	`<input type="radio">`
InputRadioGroup<TValue>	Group of child InputRadio<TValue>
InputSelect<TValue>	`<select>`
InputText	`<input>`
InputTextArea	`<textarea>`

For more information on the InputFile component, see ASP.NET Core Blazor file uploads.

All of the input components, including EditForm, support arbitrary attributes. Any attribute that doesn't match a component parameter is added to the rendered HTML element.

Input components provide default behavior for validating when a field is changed:

- For input components in a form with an EditContext, the default validation behavior includes updating the field CSS class to reflect the field's state as valid or invalid with validation styling of the underlying HTML element.
- For controls that don't have an EditContext, the default validation reflects the valid or invalid state but doesn't provide validation styling to the underlying HTML element.

Some components include useful parsing logic. For example, InputDate<TValue> and InputNumber<TValue> handle unparseable values gracefully by registering unparseable values as validation errors. Types that can accept null values also support nullability of the target field (for example, `int?` for a nullable integer).

The InputNumber<TValue> component supports the type="range" attribute, which creates a range input that supports model binding and form validation, typically rendered as a slider or dial control rather than a text box:

```razor
<InputNumber @bind-Value="..." max="..." min="..." step="..." type="range"
/>
```

For more information on the InputFile component, see ASP.NET Core Blazor file uploads.

Example form

The following `Starship` type, which is used in several of this article's examples and examples in other *Forms* node articles, defines a diverse set of properties with data annotations:

- `Id` is required because it's annotated with the RequiredAttribute. `Id` requires a value of at least one character but no more than 16 characters using the StringLengthAttribute.
- `Description` is optional because it isn't annotated with the RequiredAttribute.
- `Classification` is required.

- The `MaximumAccommodation` property defaults to zero but requires a value from one to 100,000 per its RangeAttribute.
- `IsValidatedDesign` requires that the property have a `true` value, which matches a selected state when the property is bound to a checkbox in the UI (`<input type="checkbox">`).
- `ProductionDate` is a DateTime and required.

`Starship.cs`:

C#

```
using System.ComponentModel.DataAnnotations;

namespace BlazorSample;

public class Starship
{
    [Required]
    [StringLength(16, ErrorMessage = "Identifier too long (16 character
limit).")]
    public string? Id { get; set; }

    public string? Description { get; set; }

    [Required]
    public string? Classification { get; set; }

    [Range(1, 100000, ErrorMessage = "Accommodation invalid (1-100000).")]
    public int MaximumAccommodation { get; set; }

    [Required]
    [Range(typeof(bool), "true", "true", ErrorMessage = "Approval
required.")]
    public bool IsValidatedDesign { get; set; }

    [Required]
    public DateTime ProductionDate { get; set; }
}
```

The following form accepts and validates user input using:

- The properties and validation defined in the preceding `Starship` model.
- Several of Blazor's built-in input components.

When the model property for the ship's classification (`Classification`) is set, the option matching the model is checked. For example, `checked="@(Model!.Classification == "Exploration")"` for the classification of an exploration ship. The reason for explicitly setting the checked option is that the value of a `<select>` element is only present in the

browser. If the form is rendered on the server after it's submitted, any state from the client is overridden with state from the server, which doesn't ordinarily mark an option as checked. By setting the checked option from the model property, the classification always reflects the model's state. This preserves the classification selection across form submissions that result in the form rerendering on the server. In situations where the form isn't rerendered on the server, such as when the Interactive Server render mode is applied directly to the component, explicit assignment of the checked option from the model isn't necessary because Blazor preserves the state for the `<select>` element on the client.

`Starship3.razor`:

razor

```razor
@page "/starship-3"
@inject ILogger<Starship3> Logger

<h1>Starfleet Starship Database</h1>

<h2>New Ship Entry Form</h2>

<EditForm Model="Model" OnValidSubmit="Submit" FormName="Starship3">
    <DataAnnotationsValidator />
    <ValidationSummary />
    <div>
        <label>
            Identifier:
            <InputText @bind-Value="Model!.Id" />
        </label>
    </div>
    <div>
        <label>
            Description (optional):
            <InputTextArea @bind-Value="Model!.Description" />
        </label>
    </div>
    <div>
        <label>
            Primary Classification:
            <InputSelect @bind-Value="Model!.Classification">
                <option value="">
                    Select classification ...
                </option>
                <option checked="@(Model!.Classification == "Exploration")"
                    value="Exploration">
                    Exploration
                </option>
                <option checked="@(Model!.Classification == "Diplomacy")"
                    value="Diplomacy">
                    Diplomacy
                </option>
```

```
                <option checked="@(Model!.Classification == "Defense")"
                    value="Defense">
                    Defense
                </option>
            </InputSelect>
        </label>
    </div>
    <div>
        <label>
            Maximum Accommodation:
            <InputNumber @bind-Value="Model!.MaximumAccommodation" />
        </label>
    </div>
    <div>
        <label>
            Engineering Approval:
            <InputCheckbox @bind-Value="Model!.IsValidatedDesign" />
        </label>
    </div>
    <div>
        <label>
            Production Date:
            <InputDate @bind-Value="Model!.ProductionDate" />
        </label>
    </div>
    <div>
        <button type="submit">Submit</button>
    </div>
</EditForm>

@code {
    [SupplyParameterFromForm]
    private Starship? Model { get; set; }

    protected override void OnInitialized() =>
        Model ??= new() { ProductionDate = DateTime.UtcNow };

    private void Submit()
    {
        Logger.LogInformation("Id = {Id} Description = {Description} " +
            "Classification = {Classification} MaximumAccommodation = " +
            "{MaximumAccommodation} IsValidatedDesign = " +
            "{IsValidatedDesign} ProductionDate = {ProductionDate}",
            Model?.Id, Model?.Description, Model?.Classification,
            Model?.MaximumAccommodation, Model?.IsValidatedDesign,
            Model?.ProductionDate);
    }
}
```

The EditForm in the preceding example creates an EditContext based on the assigned `Starship` instance (`Model="..."`) and handles a valid form. The next example demonstrates how to assign an EditContext to a form and validate when the form is submitted.

In the following example:

- A shortened version of the earlier `Starfleet Starship Database` form (`Starship3` component) is used that only accepts a value for the starship's Id. The other `Starship` properties receive valid default values when an instance of the `Starship` type is created.
- The `Submit` method executes when the **`Submit`** button is selected.
- The form is validated by calling EditContext.Validate in the `Submit` method.
- Logging is executed depending on the validation result.

`Starship4.razor`:

razor

```razor
@page "/starship-4"
@inject ILogger<Starship4> Logger

<EditForm EditContext="editContext" OnSubmit="Submit" FormName="Starship4">
    <DataAnnotationsValidator />
    <div>
        <label>
            Identifier:
            <InputText @bind-Value="Model!.Id" />
        </label>
    </div>
    <div>
        <button type="submit">Submit</button>
    </div>
</EditForm>

@code {
    private EditContext? editContext;

    [SupplyParameterFromForm]
    private Starship? Model { get; set; }

    protected override void OnInitialized()
    {
        Model ??=
            new()
                {
                    Id = "NCC-1701",
                    Classification = "Exploration",
                    MaximumAccommodation = 150,
                    IsValidatedDesign = true,
                    ProductionDate = new DateTime(2245, 4, 11)
                };
        editContext = new(Model);
    }

    private void Submit()
```

```
    {
        if (editContext != null && editContext.Validate())
        {
            Logger.LogInformation("Submit: Form is valid");
        }
        else
        {
            Logger.LogInformation("Submit: Form is INVALID");
        }
    }
}
```

> ⓘ Note
>
> Changing the EditContext after it's assigned is **not** supported.

Multiple option selection with the `InputSelect` component

Binding supports multiple option selection with the InputSelect<TValue> component. The @onchange event provides an array of the selected options via event arguments (ChangeEventArgs). The value must be bound to an array type, and binding to an array type makes the multiple attribute optional on the InputSelect<TValue> tag.

In the following example, the user must select at least two starship classifications but no more than three classifications.

`Starship5.razor`:

razor

```
@page "/starship-5"
@using System.ComponentModel.DataAnnotations
@inject ILogger<Starship5> Logger

<h1>Bind Multiple <code>InputSelect</code> Example</h1>

<EditForm EditContext="editContext" OnValidSubmit="Submit"
FormName="Starship5">
    <DataAnnotationsValidator />
    <ValidationSummary />
    <div>
        <label>
            Select classifications (Minimum: 2, Maximum: 3):
            <InputSelect @bind-Value="Model!.SelectedClassification">
                <option
value="@Classification.Exploration">Exploration</option>
```

```
                <option value="@Classification.Diplomacy">Diplomacy</option>
                <option value="@Classification.Defense">Defense</option>
                <option value="@Classification.Research">Research</option>
            </InputSelect>
        </label>
    </div>
    <div>
        <button type="submit">Submit</button>
    </div>
</EditForm>

@if (Model?.SelectedClassification?.Length > 0)
{
    <div>@string.Join(", ", Model.SelectedClassification)</div>
}

@code {
    private EditContext? editContext;

    [SupplyParameterFromForm]
    private Starship? Model { get; set; }

    protected override void OnInitialized()
    {
        Model = new();
        editContext = new(Model);
    }

    private void Submit() => Logger.LogInformation("Submit: Processing
form");

    private class Starship
    {
        [Required]
        [MinLength(2, ErrorMessage = "Select at least two
classifications.")]
        [MaxLength(3, ErrorMessage = "Select no more than three
classifications.")]
        public Classification[]? SelectedClassification { get; set; } =
            new[] { Classification.None };
    }

    private enum Classification { None, Exploration, Diplomacy, Defense,
Research }
}
```

For information on how empty strings and `null` values are handled in data binding, see the Binding InputSelect options to C# object null values section.

Binding `InputSelect` options to C# object `null` values

For information on how empty strings and `null` values are handled in data binding, see ASP.NET Core Blazor data binding.

Display name support

Several built-in components support display names with the InputBase<TValue>.DisplayName parameter.

In the `Starfleet Starship Database` form (`Starship3` component) of the Example form section, the production date of a new starship doesn't specify a display name:

razor

```
<label>
    Production Date:
    <InputDate @bind-Value="Model!.ProductionDate" />
</label>
```

If the field contains an invalid date when the form is submitted, the error message doesn't display a friendly name. The field name, "`ProductionDate`" doesn't have a space between "`Production`" and "`Date`" when it appears in the validation summary:

> The ProductionDate field must be a date.

Set the DisplayName property to a friendly name with a space between the words "`Production`" and "`Date`":

razor

```
<label>
    Production Date:
    <InputDate @bind-Value="Model!.ProductionDate"
        DisplayName="Production Date" />
</label>
```

The validation summary displays the friendly name when the field's value is invalid:

> The Production Date field must be a date.

Error message template support

InputDate<TValue> and InputNumber<TValue> support error message templates:

- InputDate<TValue>.ParsingErrorMessage
- InputNumber<TValue>.ParsingErrorMessage

In the `Starfleet Starship Database` form (`Starship3` component) of the Example form section with a friendly display name assigned, the `Production Date` field produces an error message using the following default error message template:

```
css

The {0} field must be a date.
```

The position of the `{0}` placeholder is where the value of the DisplayName property appears when the error is displayed to the user.

```
razor

<label>
    Production Date:
    <InputDate @bind-Value="Model!.ProductionDate"
        DisplayName="Production Date" />
</label>
```

> The Production Date field must be a date.

Assign a custom template to ParsingErrorMessage to provide a custom message:

```
razor

<label>
    Production Date:
    <InputDate @bind-Value="Model!.ProductionDate"
        DisplayName="Production Date"
        ParsingErrorMessage="The {0} field has an incorrect date value." />
</label>
```

> The Production Date field has an incorrect date value.

ASP.NET Core Blazor forms binding

Article • 10/18/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article explains how to use binding in Blazor forms.

`EditForm` / `EditContext` model

An EditForm creates an EditContext based on the assigned object as a cascading value for other components in the form. The EditContext tracks metadata about the edit process, including which form fields have been modified and the current validation messages. Assigning to either an EditForm.Model or an EditForm.EditContext can bind a form to data.

Model binding

Assignment to EditForm.Model:

razor

```
<EditForm ... Model="Model" ...>
    ...
</EditForm>

@code {
    [SupplyParameterFromForm]
    private Starship? Model { get; set; }

    protected override void OnInitialized() => Model ??= new();
}
```

Context binding

Assignment to EditForm.EditContext:

razor

```razor
<EditForm ... EditContext="editContext" ...>
    ...
</EditForm>

@code {
    private EditContext? editContext;

    [SupplyParameterFromForm]
    private Starship? Model { get; set; }

    protected override void OnInitialized()
    {
        Model ??= new();
        editContext = new(Model);
    }
}
```

Assign **either** an EditContext **or** a Model to an EditForm. If both are assigned, a runtime error is thrown.

Supported types

Binding supports:

- Primitive types
- Collections
- Complex types
- Recursive types
- Types with constructors
- Enums

You can also use the [DataMember] and [IgnoreDataMember] attributes to customize model binding. Use these attributes to rename properties, ignore properties, and mark properties as required.

Additional binding options

Additional model binding options are available from RazorComponentsServiceOptions when calling AddRazorComponents:

- MaxFormMappingCollectionSize: Maximum number of elements allowed in a form collection.

- MaxFormMappingRecursionDepth: Maximum depth allowed when recursively mapping form data.
- MaxFormMappingErrorCount: Maximum number of errors allowed when mapping form data.
- MaxFormMappingKeySize: Maximum size of the buffer used to read form data keys.

The following demonstrates the default values assigned by the framework:

C#

```
builder.Services.AddRazorComponents(options =>
{
    options.FormMappingUseCurrentCulture = true;
    options.MaxFormMappingCollectionSize = 1024;
    options.MaxFormMappingErrorCount = 200;
    options.MaxFormMappingKeySize = 1024 * 2;
    options.MaxFormMappingRecursionDepth = 64;
}).AddInteractiveServerComponents();
```

Form names

Use the FormName parameter to assign a form name. Form names must be unique to bind model data. The following form is named `RomulanAle`:

razor

```
<EditForm ... FormName="RomulanAle" ...>
    ...
</EditForm>
```

Supplying a form name:

- Is required for all forms that are submitted by statically-rendered server-side components.
- Isn't required for forms that are submitted by interactively-rendered components, which includes forms in Blazor WebAssembly apps and components with an interactive render mode. However, we recommend supplying a unique form name for every form to prevent runtime form posting errors if interactivity is ever dropped for a form.

The form name is only checked when the form is posted to an endpoint as a traditional HTTP POST request from a statically-rendered server-side component. The framework

doesn't throw an exception at the point of rendering a form, but only at the point that an HTTP POST arrives and doesn't specify a form name.

There's an unnamed (empty string) form scope above the app's root component, which suffices when there are no form name collisions in the app. If form name collisions are possible, such as when including a form from a library and you have no control of the form name used by the library's developer, provide a form name scope with the FormMappingScope component in the Blazor Web App's main project.

In the following example, the `HelloFormFromLibrary` component has a form named `Hello` and is in a library.

`HelloFormFromLibrary.razor`:

razor

```razor
<EditForm FormName="Hello" Model="this" OnSubmit="Submit">
    <InputText @bind-Value="Name" />
    <button type="submit">Submit</button>
</EditForm>

@if (submitted)
{
    <p>Hello @Name from the library's form!</p>
}

@code {
    bool submitted = false;

    [SupplyParameterFromForm]
    private string? Name { get; set; }

    private void Submit() => submitted = true;
}
```

The following `NamedFormsWithScope` component uses the library's `HelloFormFromLibrary` component and also has a form named `Hello`. The FormMappingScope component's scope name is `ParentContext` for any forms supplied by the `HelloFormFromLibrary` component. Although both of the forms in this example have the form name (`Hello`), the form names don't collide and events are routed to the correct form for form POST events.

`NamedFormsWithScope.razor`:

razor

```razor
@page "/named-forms-with-scope"

<div>Hello form from a library</div>

<FormMappingScope Name="ParentContext">
    <HelloFormFromLibrary />
</FormMappingScope>

<div>Hello form using the same form name</div>

<EditForm FormName="Hello" Model="this" OnSubmit="Submit">
    <InputText @bind-Value="Name" />
    <button type="submit">Submit</button>
</EditForm>

@if (submitted)
{
    <p>Hello @Name from the app form!</p>
}

@code {
    bool submitted = false;

    [SupplyParameterFromForm]
    private string? Name { get; set; }

    private void Submit() => submitted = true;
}
```

Supply a parameter from the form (`[SupplyParameterFromForm]`)

The `[SupplyParameterFromForm]` attribute indicates that the value of the associated property should be supplied from the form data for the form. Data in the request that matches the name of the property is bound to the property. Inputs based on `InputBase<TValue>` generate form value names that match the names Blazor uses for model binding. Unlike component parameter properties (`[Parameter]`), properties annotated with `[SupplyParameterFromForm]` aren't required to be marked `public`.

You can specify the following form binding parameters to the [SupplyParameterFromForm] attribute:

- Name: Gets or sets the name for the parameter. The name is used to determine the prefix to use to match the form data and decide whether or not the value needs to be bound.

- FormName: Gets or sets the name for the handler. The name is used to match the parameter to the form by form name to decide whether or not the value needs to be bound.

The following example independently binds two forms to their models by form name.

`Starship6.razor`:

razor

```
@page "/starship-6"
@inject ILogger<Starship6> Logger

<EditForm Model="Model1" OnSubmit="Submit1" FormName="Holodeck1">
    <div>
        <label>
            Holodeck 1 Identifier:
            <InputText @bind-Value="Model1!.Id" />
        </label>
    </div>
    <div>
        <button type="submit">Submit</button>
    </div>
</EditForm>

<EditForm Model="Model2" OnSubmit="Submit2" FormName="Holodeck2">
    <div>
        <label>
            Holodeck 2 Identifier:
            <InputText @bind-Value="Model2!.Id" />
        </label>
    </div>
    <div>
        <button type="submit">Submit</button>
    </div>
</EditForm>

@code {
    [SupplyParameterFromForm(FormName = "Holodeck1")]
    private Holodeck? Model1 { get; set; }

    [SupplyParameterFromForm(FormName = "Holodeck2")]
    private Holodeck? Model2 { get; set; }

    protected override void OnInitialized()
    {
        Model1 ??= new();
        Model2 ??= new();
    }

    private void Submit1() => Logger.LogInformation("Submit1: Id={Id}",
Model1?.Id);
```

```
    private void Submit2() => Logger.LogInformation("Submit2: Id={Id}",
Model2?.Id);

    public class Holodeck
    {
        public string? Id { get; set; }
    }
}
```

Nest and bind forms

The following guidance demonstrates how to nest and bind child forms.

The following ship details class (`ShipDetails`) holds a description and length for a subform.

`ShipDetails.cs`:

C#

```
namespace BlazorSample;

public class ShipDetails
{
    public string? Description { get; set; }
    public int? Length { get; set; }
}
```

The following `Ship` class names an identifier (`Id`) and includes the ship details.

`Ship.cs`:

C#

```
namespace BlazorSample
{
    public class Ship
    {
        public string? Id { get; set; }
        public ShipDetails Details { get; set; } = new();
    }
}
```

The following subform is used for editing values of the `ShipDetails` type. This is implemented by inheriting Editor<T> at the top of the component. Editor<T> ensures

that the child component generates the correct form field names based on the model (`T`), where `T` in the following example is `ShipDetails`.

`StarshipSubform.razor`:

razor

```razor
@inherits Editor<ShipDetails>

<div>
    <label>
        Description:
        <InputText @bind-Value="Value!.Description" />
    </label>
</div>
<div>
    <label>
        Length:
        <InputNumber @bind-Value="Value!.Length" />
    </label>
</div>
```

The main form is bound to the `Ship` class. The `StarshipSubform` component is used to edit ship details, bound as `Model!.Details`.

`Starship7.razor`:

razor

```razor
@page "/starship-7"
@inject ILogger<Starship7> Logger

<EditForm Model="Model" OnSubmit="Submit" FormName="Starship7">
    <div>
        <label>
            Identifier:
            <InputText @bind-Value="Model!.Id" />
        </label>
    </div>
    <StarshipSubform @bind-Value="Model!.Details" />
    <div>
        <button type="submit">Submit</button>
    </div>
</EditForm>

@code {
    [SupplyParameterFromForm]
    private Ship? Model { get; set; }

    protected override void OnInitialized() => Model ??= new();
```

```
    private void Submit() =>
        Logger.LogInformation("Id = {Id} Desc = {Description} Length =
{Length}",
            Model?.Id, Model?.Details?.Description, Model?.Details?.Length);
}
```

Initialize form data with static SSR

When a component adopts static SSR, the OnInitialized{Async} lifecycle method and the OnParametersSet{Async} lifecycle method fire when the component is initially rendered and on every form POST to the server. To initialize form model values, confirm if the model already has data before assigning new model values in `OnParametersSet{Async}`, as the following example demonstrates.

`StarshipInit.razor`:

razor

```
@page "/starship-init"
@inject ILogger<StarshipInit> Logger

<EditForm Model="Model" OnValidSubmit="Submit" FormName="StarshipInit">
    <div>
        <label>
            Identifier:
            <InputText @bind-Value="Model!.Id" />
        </label>
    </div>
    <div>
        <button type="submit">Submit</button>
    </div>
</EditForm>

@code {
    [SupplyParameterFromForm]
    private Starship? Model { get; set; }

    protected override void OnInitialized() => Model ??= new();

    protected override void OnParametersSet()
    {
        if (Model!.Id == default)
        {
            LoadData();
        }
    }

    private void LoadData()
    {
        Model!.Id = "Set by LoadData";
```

```
    }

    private void Submit()
    {
        Logger.LogInformation("Id = {Id}", Model?.Id);
    }

    public class Starship
    {
        public string? Id { get; set; }
    }
}
```

Advanced form mapping error scenarios

The framework instantiates and populates the FormMappingContext for a form, which is the context associated with a given form's mapping operation. Each mapping scope (defined by a FormMappingScope component) instantiates FormMappingContext. Each time a `[SupplyParameterFromForm]` asks the context for a value, the framework populates the FormMappingContext with the attempted value and any mapping errors.

Developers aren't expected to interact with FormMappingContext directly, as it's mainly a source of data for InputBase<TValue>, EditContext, and other internal implementations to show mapping errors as validation errors. In advanced custom scenarios, developers can access FormMappingContext directly as a `[CascadingParameter]` to write custom code that consumes the attempted values and mapping errors.

Custom input components

For custom input processing scenarios, the following subsections demonstrate custom input components:

- Input component based on InputBase<T>: The component inherits from InputBase<TValue>, which provides a base implementation for binding, callbacks, and validation. Components that inherit from InputBase<TValue> must be used in a Blazor form (EditForm).
- Input component with full developer control: The component takes full control of input processing. The component's code must manage binding, callbacks, and validation. The component can be used inside or outside of a Blazor form.

We recommend that you derive your custom input components from InputBase<TValue> unless specific requirements prevent you from doing so. The

InputBase<TValue> class is actively maintained by the ASP.NET Core team, ensuring it stays up-to-date with the latest Blazor features and framework changes.

Input component based on `InputBase<T>`

The following example component:

- Inherits from InputBase<TValue>. Components that inherit from InputBase<TValue> must be used in a Blazor form (EditForm).
- Takes boolean input from a checkbox.
- Sets the background color of its container `<div>` based on the checkbox's state, which occurs when the `AfterChange` method executes after binding (`@bind:after`).
- Is required to override the base class's `TryParseValueFromString` method but doesn't process string input data because a checkbox doesn't provide string data. Example implementations of `TryParseValueFromString` for other types of input components that process string input are available in the ASP.NET Core reference source.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

`EngineeringApprovalInputDerived.razor`:

razor

```razor
@using System.Diagnostics.CodeAnalysis
@inherits InputBase<bool>

<div class="@divCssClass">
    <label>
        Engineering Approval:
        <input @bind="CurrentValue" @bind:after="AfterChange"
class="@CssClass"
            type="checkbox" />
    </label>
</div>

@code {
    private string? divCssClass;
```

```
    private void AfterChange()
    {
        divCssClass = CurrentValue ? "bg-success text-white" : null;
    }

    protected override bool TryParseValueFromString(
        string? value, out bool result,
        [NotNullWhen(false)] out string? validationErrorMessage)
            => throw new NotSupportedException(
                "This component does not parse string inputs. " +
                $"Bind to the '{nameof(CurrentValue)}' property, " +
                $"not '{nameof(CurrentValueAsString)}'.");
}
```

To use the preceding component in the starship example form (Starship3.razor/Starship.cs), replace the `<div>` block for the engineering approval field with an `EngineeringApprovalInputDerived` component instance bound to the model's `IsValidatedDesign` property:

diff

```
- <div>
-     <label>
-         Engineering Approval:
-         <InputCheckbox @bind-Value="Model!.IsValidatedDesign" />
-     </label>
- </div>
+ <EngineeringApprovalInputDerived @bind-Value="Model!.IsValidatedDesign" />
```

Input component with full developer control

The following example component:

- Doesn't inherit from InputBase<TValue>. The component takes full control of input processing, including binding, callbacks, and validation. The component can be used inside or outside of a Blazor form (EditForm).
- Takes boolean input from a checkbox.
- Changes the background color if the checkbox is checked.

Code in the component includes:

- The `Value` property is used with two-way binding to get or set the value of the input. `ValueChanged` is the callback that updates the bound value.

- When used in a Blazor form:
  - The EditContext is a cascading value.

    - `fieldCssClass` styles the field based on the result of EditContext validation.
    - `ValueExpression` is an expression (`Expression<Func<T>>`) assigned by the framework that identifies the bound value.
    - FieldIdentifier uniquely identifies a single field that can be edited, usually corresponding to a model property. The field identifier is created with the expression that identifies the bound value (`ValueExpression`).

- In the `OnChange` event handler:
    - The value of the checkbox input is obtained from InputFileChangeEventArgs.
    - The background color and text color of the container `<div>` element are set.
    - EventCallback.InvokeAsync invokes the delegate associated with the binding and dispatches an event notification to consumers that the value has changed.
    - If the component is used in an EditForm (the `EditContext` property isn't `null`), EditContext.NotifyFieldChanged is called to trigger validation.

`EngineeringApprovalInputStandalone.razor`:

razor

```
@using System.Globalization
@using System.Linq.Expressions

<div class="@divCssClass">
    <label>
        Engineering Approval:
        <input class="@fieldCssClass" @onchange="OnChange" type="checkbox"
            value="@Value" />
    </label>
</div>

@code {
    private string? divCssClass;
    private FieldIdentifier fieldIdentifier;
    private string? fieldCssClass =>
EditContext?.FieldCssClass(fieldIdentifier);

    [CascadingParameter]
    private EditContext? EditContext { get; set; }

    [Parameter]
    public bool? Value { get; set; }

    [Parameter]
    public EventCallback<bool> ValueChanged { get; set; }

    [Parameter]
    public Expression<Func<bool>>? ValueExpression { get; set; }

    protected override void OnInitialized()
```

```
    {
        fieldIdentifier = FieldIdentifier.Create(ValueExpression!);
    }

    private async Task OnChange(ChangeEventArgs args)
    {
        BindConverter.TryConvertToBool(args.Value,
CultureInfo.CurrentCulture,
            out var value);

        divCssClass = value ? "bg-success text-white" : null;

        await ValueChanged.InvokeAsync(value);
        EditContext?.NotifyFieldChanged(fieldIdentifier);
    }
}
```

To use the preceding component in the starship example form (Starship3.razor/Starship.cs), replace the `<div>` block for the engineering approval field with a `EngineeringApprovalInputStandalone` component instance bound to the model's `IsValidatedDesign` property:

diff

```
- <div>
-     <label>
-         Engineering Approval:
-         <InputCheckbox @bind-Value="Model!.IsValidatedDesign" />
-     </label>
- </div>
+ <EngineeringApprovalInputStandalone @bind-Value="Model!.IsValidatedDesign"
/>
```

The `EngineeringApprovalInputStandalone` component is also functional outside of an EditForm:

razor

```
<EngineeringApprovalInputStandalone @bind-Value="ValidDesign" />

<div>
    <b>ValidDesign:</b> @ValidDesign
</div>

@code {
    private bool ValidDesign { get; set; }
}
```

Radio buttons

The example in this section is based on the `Starfleet Starship Database` form (`Starship3` component) of the Example form section of this article.

Add the following enum types to the app. Create a new file to hold them or add them to the `Starship.cs` file.

C#

```
public class ComponentEnums
{
    public enum Manufacturer { SpaceX, NASA, ULA, VirginGalactic, Unknown }
    public enum Color { ImperialRed, SpacecruiserGreen, StarshipBlue,
VoyagerOrange }
    public enum Engine { Ion, Plasma, Fusion, Warp }
}
```

Make the `ComponentEnums` class accessible to the:

- `Starship` model in `Starship.cs` (for example, `using static ComponentEnums;`).
- `Starfleet Starship Database` form (`Starship3.razor`) (for example, `@using static ComponentEnums`).

Use InputRadio<TValue> components with the InputRadioGroup<TValue> component to create a radio button group. In the following example, properties are added to the `Starship` model described in the Example form section of the *Input components* article:

C#

```
[Required]
[Range(typeof(Manufacturer), nameof(Manufacturer.SpaceX),
    nameof(Manufacturer.VirginGalactic), ErrorMessage = "Pick a
manufacturer.")]
public Manufacturer Manufacturer { get; set; } = Manufacturer.Unknown;

[Required, EnumDataType(typeof(Color))]
public Color? Color { get; set; } = null;

[Required, EnumDataType(typeof(Engine))]
public Engine? Engine { get; set; } = null;
```

Update the `Starfleet Starship Database` form (`Starship3` component) of the Example form section of the *Input components* article. Add the components to produce:

- A radio button group for the ship manufacturer.

- A nested radio button group for engine and ship color.

> **Note**
>
> Nested radio button groups aren't often used in forms because they can result in a disorganized layout of form controls that may confuse users. However, there are cases when they make sense in UI design, such as in the following example that pairs recommendations for two user inputs, ship engine and ship color. One engine and one color are required by the form's validation. The form's layout uses nested InputRadioGroup<TValue>s to pair engine and color recommendations. However, the user can combine any engine with any color to submit the form.

> **Note**
>
> Be sure to make the `ComponentEnums` class available to the component for the following example:

razor

```
@using static ComponentEnums
```

razor

```
<fieldset>
    <legend>Manufacturer</legend>
    <InputRadioGroup @bind-Value="Model!.Manufacturer">
        @foreach (var manufacturer in Enum.GetValues<Manufacturer>())
        {
            <div>
                <label>
                    <InputRadio Value="manufacturer" />
                    @manufacturer
                </label>
            </div>
        }
    </InputRadioGroup>
</fieldset>

<fieldset>
    <legend>Engine and Color</legend>
    <p>
        Engine and color pairs are recommended, but any
        combination of engine and color is allowed.
    </p>
    <InputRadioGroup Name="engine" @bind-Value="Model!.Engine">
        <InputRadioGroup Name="color" @bind-Value="Model!.Color">
```

```
            <div style="margin-bottom:5px">
                <div>
                    <label>
                        <InputRadio Name="engine" Value="Engine.Ion" />
                        Ion
                    </label>
                </div>
                <div>
                    <label>
                        <InputRadio Name="color" Value="Color.ImperialRed"
/>
                        Imperial Red
                    </label>
                </div>
            </div>
            <div style="margin-bottom:5px">
                <div>
                    <label>
                        <InputRadio Name="engine" Value="Engine.Plasma" />
                        Plasma
                    </label>
                </div>
                <div>
                    <label>
                        <InputRadio Name="color"
Value="Color.SpacecruiserGreen" />
                        Spacecruiser Green
                    </label>
                </div>
            </div>
            <div style="margin-bottom:5px">
                <div>
                    <label>
                        <InputRadio Name="engine" Value="Engine.Fusion" />
                        Fusion
                    </label>
                </div>
                <div>
                    <label>
                        <InputRadio Name="color" Value="Color.StarshipBlue"
/>
                        Starship Blue
                    </label>
                </div>
            </div>
            <div style="margin-bottom:5px">
                <div>
                    <label>
                        <InputRadio Name="engine" Value="Engine.Warp" />
                        Warp
                    </label>
                </div>
                <div>
                    <label>
                        <InputRadio Name="color" Value="Color.VoyagerOrange"
```

```
/>
                        Voyager Orange
                    </label>
                </div>
            </div>
        </InputRadioGroup>
    </InputRadioGroup>
</fieldset>
```

> **Note**
>
> If `Name` is omitted, InputRadio<TValue> components are grouped by their most recent ancestor.

If you implemented the preceding Razor markup in the `Starship3` component of the Example form section of the *Input components* article, update the logging for the `Submit` method:

C#

```
Logger.LogInformation("Id = {Id} Description = {Description} " +
    "Classification = {Classification} MaximumAccommodation = " +
    "{MaximumAccommodation} IsValidatedDesign = " +
    "{IsValidatedDesign} ProductionDate = {ProductionDate} " +
    "Manufacturer = {Manufacturer}, Engine = {Engine}, " +
    "Color = {Color}",
    Model?.Id, Model?.Description, Model?.Classification,
    Model?.MaximumAccommodation, Model?.IsValidatedDesign,
    Model?.ProductionDate, Model?.Manufacturer, Model?.Engine,
    Model?.Color);
```

ASP.NET Core Blazor forms validation

Article • 10/18/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article explains how to use validation in Blazor forms.

Form validation

In basic form validation scenarios, an EditForm instance can use declared EditContext and ValidationMessageStore instances to validate form fields. A handler for the OnValidationRequested event of the EditContext executes custom validation logic. The handler's result updates the ValidationMessageStore instance.

Basic form validation is useful in cases where the form's model is defined within the component hosting the form, either as members directly on the component or in a subclass. Use of a validator component is recommended where an independent model class is used across several components.

In Blazor Web Apps, client-side validation requires an active Blazor SignalR circuit. Client-side validation isn't available to forms in components that have adopted static server-side rendering (static SSR). Forms that adopt static SSR are validated on the server after the form is submitted.

In the following component, the `HandleValidationRequested` handler method clears any existing validation messages by calling ValidationMessageStore.Clear before validating the form.

`Starship8.razor`:

razor

```
@page "/starship-8"
@implements IDisposable
@inject ILogger<Starship8> Logger
```

```razor
<h2>Holodeck Configuration</h2>

<EditForm EditContext="editContext" OnValidSubmit="Submit"
FormName="Starship8">
    <div>
        <label>
            <InputCheckbox @bind-Value="Model!.Subsystem1" />
            Safety Subsystem
        </label>
    </div>
    <div>
        <label>
            <InputCheckbox @bind-Value="Model!.Subsystem2" />
            Emergency Shutdown Subsystem
        </label>
    </div>
    <div>
        <ValidationMessage For="() => Model!.Options" />
    </div>
    <div>
        <button type="submit">Update</button>
    </div>
</EditForm>

@code {
    private EditContext? editContext;

    [SupplyParameterFromForm]
    private Holodeck? Model { get; set; }

    private ValidationMessageStore? messageStore;

    protected override void OnInitialized()
    {
        Model ??= new();
        editContext = new(Model);
        editContext.OnValidationRequested += HandleValidationRequested;
        messageStore = new(editContext);
    }

    private void HandleValidationRequested(object? sender,
        ValidationRequestedEventArgs args)
    {
        messageStore?.Clear();

        // Custom validation logic
        if (!Model!.Options)
        {
            messageStore?.Add(() => Model.Options, "Select at least one.");
        }
    }

    private void Submit() => Logger.LogInformation("Submit: Processing
form");
```

```
    public class Holodeck
    {
        public bool Subsystem1 { get; set; }
        public bool Subsystem2 { get; set; }
        public bool Options => Subsystem1 || Subsystem2;
    }

    public void Dispose()
    {
        if (editContext is not null)
        {
            editContext.OnValidationRequested -= HandleValidationRequested;
        }
    }
}
```

Data Annotations Validator component and custom validation

The DataAnnotationsValidator component attaches data annotations validation to a cascaded EditContext. Enabling data annotations validation requires the DataAnnotationsValidator component. To use a different validation system than data annotations, use a custom implementation instead of the DataAnnotationsValidator component. The framework implementations for DataAnnotationsValidator are available for inspection in the reference source:

- DataAnnotationsValidator
- AddDataAnnotationsValidation.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Blazor performs two types of validation:

- *Field validation* is performed when the user tabs out of a field. During field validation, the DataAnnotationsValidator component associates all reported validation results with the field.

- *Model validation* is performed when the user submits the form. During model validation, the DataAnnotationsValidator component attempts to determine the field based on the member name that the validation result reports. Validation results that aren't associated with an individual member are associated with the model rather than a field.

Validator components

Validator components support form validation by managing a ValidationMessageStore for a form's EditContext.

The Blazor framework provides the DataAnnotationsValidator component to attach validation support to forms based on validation attributes (data annotations). You can create custom validator components to process validation messages for different forms on the same page or the same form at different steps of form processing (for example, client validation followed by server validation). The validator component example shown in this section, `CustomValidation`, is used in the following sections of this article:

- Business logic validation with a validator component
- Server validation with a validator component

Of the data annotation built-in validators, only the [Remote] validation attribute isn't supported in Blazor.

> **Note**
>
> Custom data annotation validation attributes can be used instead of custom validator components in many cases. Custom attributes applied to the form's model activate with the use of the **DataAnnotationsValidator** component. When used with server validation, any custom attributes applied to the model must be executable on the server. For more information, see the **Custom validation attributes** section.

Create a validator component from ComponentBase:

- The form's EditContext is a cascading parameter of the component.
- When the validator component is initialized, a new ValidationMessageStore is created to maintain a current list of form errors.
- The message store receives errors when developer code in the form's component calls the `DisplayErrors` method. The errors are passed to the `DisplayErrors`

method in a Dictionary<string, List<string>>. In the dictionary, the key is the name of the form field that has one or more errors. The value is the error list.

- Messages are cleared when any of the following have occurred:
  - Validation is requested on the EditContext when the OnValidationRequested event is raised. All of the errors are cleared.
  - A field changes in the form when the OnFieldChanged event is raised. Only the errors for the field are cleared.
  - The `ClearErrors` method is called by developer code. All of the errors are cleared.

Update the namespace in the following class to match your app's namespace.

`CustomValidation.cs`:

C#

```
using Microsoft.AspNetCore.Components;
using Microsoft.AspNetCore.Components.Forms;

namespace BlazorSample;

public class CustomValidation : ComponentBase
{
    private ValidationMessageStore? messageStore;

    [CascadingParameter]
    private EditContext? CurrentEditContext { get; set; }

    protected override void OnInitialized()
    {
        if (CurrentEditContext is null)
        {
            throw new InvalidOperationException(
                $"{nameof(CustomValidation)} requires a cascading " +
                $"parameter of type {nameof(EditContext)}. " +
                $"For example, you can use {nameof(CustomValidation)} " +
                $"inside an {nameof(EditForm)}.");
        }

        messageStore = new(CurrentEditContext);

        CurrentEditContext.OnValidationRequested += (s, e) =>
            messageStore?.Clear();
        CurrentEditContext.OnFieldChanged += (s, e) =>
            messageStore?.Clear(e.FieldIdentifier);
    }

    public void DisplayErrors(Dictionary<string, List<string>> errors)
    {
        if (CurrentEditContext is not null)
        {
```

```
            foreach (var err in errors)
            {
                messageStore?.Add(CurrentEditContext.Field(err.Key),
err.Value);
            }

            CurrentEditContext.NotifyValidationStateChanged();
        }
    }

    public void ClearErrors()
    {
        messageStore?.Clear();
        CurrentEditContext?.NotifyValidationStateChanged();
    }
}
```

ⓘ Important

Specifying a namespace is **required** when deriving from ComponentBase. Failing to specify a namespace results in a build error:

> Tag helpers cannot target tag name '<global namespace>.{CLASS NAME}' because it contains a ' ' character.

The `{CLASS NAME}` placeholder is the name of the component class. The custom validator example in this section specifies the example namespace `BlazorSample`.

ⓘ Note

Anonymous lambda expressions are registered event handlers for OnValidationRequested and OnFieldChanged in the preceding example. It isn't necessary to implement IDisposable and unsubscribe the event delegates in this scenario. For more information, see ASP.NET Core Razor component lifecycle.

Business logic validation with a validator component

For general business logic validation, use a validator component that receives form errors in a dictionary.

Basic validation is useful in cases where the form's model is defined within the component hosting the form, either as members directly on the component or in a subclass. Use of a validator component is recommended where an independent model class is used across several components.

In the following example:

- A shortened version of the `Starfleet Starship Database` form (`Starship3` component) of the Example form section of the *Input components* article is used that only accepts the starship's classification and description. Data annotation validation isn't triggered on form submission because the DataAnnotationsValidator component isn't included in the form.
- The `CustomValidation` component from the Validator components section of this article is used.
- The validation requires a value for the ship's description (`Description`) if the user selects the "`Defense`" ship classification (`Classification`).

When validation messages are set in the component, they're added to the validator's ValidationMessageStore and shown in the EditForm's validation summary.

`Starship9.razor`:

razor

```
@page "/starship-9"
@inject ILogger<Starship9> Logger

<h1>Starfleet Starship Database</h1>

<h2>New Ship Entry Form</h2>

<EditForm Model="Model" OnValidSubmit="Submit" FormName="Starship9">
    <CustomValidation @ref="customValidation" />
    <ValidationSummary />
    <div>
        <label>
            Primary Classification:
            <InputSelect @bind-Value="Model!.Classification">
                <option value="">
                    Select classification ...
                </option>
                <option checked="@(Model!.Classification == "Exploration")"
                    value="Exploration">
                    Exploration
                </option>
                <option checked="@(Model!.Classification == "Diplomacy")"
                    value="Diplomacy">
                    Diplomacy
                </option>
```

```
                <option checked="@(Model!.Classification == "Defense")"
                    value="Defense">
                    Defense
                </option>
            </InputSelect>
        </label>
    </div>
    <div>
        <label>
            Description (optional):
            <InputTextArea @bind-Value="Model!.Description" />
        </label>
    </div>
    <div>
        <button type="submit">Submit</button>
    </div>
</EditForm>

@code {
    private CustomValidation? customValidation;

    [SupplyParameterFromForm]
    private Starship? Model { get; set; }

    protected override void OnInitialized() =>
        Model ??= new() { ProductionDate = DateTime.UtcNow };

    private void Submit()
    {
        customValidation?.ClearErrors();

        var errors = new Dictionary<string, List<string>>();

        if (Model!.Classification == "Defense" &&
                string.IsNullOrEmpty(Model.Description))
        {
            errors.Add(nameof(Model.Description),
                new() { "For a 'Defense' ship classification, " +
                "'Description' is required." });
        }

        if (errors.Any())
        {
            customValidation?.DisplayErrors(errors);
        }
        else
        {
            Logger.LogInformation("Submit called: Processing the form");
        }
    }
}
```

> ⓘ Note

As an alternative to using validation components, data annotation validation attributes can be used. Custom attributes applied to the form's model activate with the use of the DataAnnotationsValidator component. When used with server validation, the attributes must be executable on the server. For more information, see the Custom validation attributes section.

Server validation with a validator component

This section is focused on Blazor Web App scenarios, but the approach for any type of app that uses server validation with web API adopts the same general approach.

Server validation is supported in addition to client validation:

- Process client validation in the form with the DataAnnotationsValidator component.
- When the form passes client validation (OnValidSubmit is called), send the EditContext.Model to a backend server API for form processing.
- Process model validation on the server.
- The server API includes both the built-in framework data annotations validation and custom validation logic supplied by the developer. If validation passes on the server, process the form and send back a success status code (200 - OK). If validation fails, return a failure status code (400 - Bad Request) and the field validation errors.
- Either disable the form on success or display the errors.

Basic validation is useful in cases where the form's model is defined within the component hosting the form, either as members directly on the component or in a subclass. Use of a validator component is recommended where an independent model class is used across several components.

The following example is based on:

- A Blazor Web App with Interactive WebAssembly components created from the Blazor Web App project template.
- The `Starship` model (`Starship.cs`) of the Example form section of the *Input components* article.
- The `CustomValidation` component shown in the Validator components section.

Place the `Starship` model (`Starship.cs`) into a shared class library project so that both the client and server projects can use the model. Add or update the namespace to match the namespace of the shared app (for example, `namespace BlazorSample.Shared`).

Since the model requires data annotations, confirm that the shared class library uses the shared framework or add the System.ComponentModel.Annotations package to the shared project.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

In the main project of the Blazor Web App, add a controller to process starship validation requests and return failed validation messages. Update the namespaces in the last `using` statement for the shared class library project and the `namespace` for the controller class. In addition to client and server data annotations validation, the controller validates that a value is provided for the ship's description (`Description`) if the user selects the `Defense` ship classification (`Classification`).

The validation for the `Defense` ship classification only occurs on the server in the controller because the upcoming form doesn't perform the same validation client-side when the form is submitted to the server. Server validation without client validation is common in apps that require private business logic validation of user input on the server. For example, private information from data stored for a user might be required to validate user input. Private data obviously can't be sent to the client for client validation.

> **Note**
>
> The `StarshipValidation` controller in this section uses Microsoft Identity 2.0. The Web API only accepts tokens for users that have the "`API.Access`" scope for this API. Additional customization is required if the API's scope name is different from `API.Access`.
>
> For more information on security, see:
>
> - ASP.NET Core Blazor authentication and authorization (and the other articles in the Blazor *Security and Identity* node)
> - Microsoft identity platform documentation

`Controllers/StarshipValidation.cs`:

C#

```
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Mvc;
using BlazorSample.Shared;

namespace BlazorSample.Server.Controllers;

[Authorize]
[ApiController]
[Route("[controller]")]
public class StarshipValidationController(
    ILogger<StarshipValidationController> logger)
    : ControllerBase
{
    static readonly string[] scopeRequiredByApi = new[] { "API.Access" };

    [HttpPost]
    public async Task<IActionResult> Post(Starship model)
    {
        HttpContext.VerifyUserHasAnyAcceptedScope(scopeRequiredByApi);

        try
        {
            if (model.Classification == "Defense" &&
                string.IsNullOrEmpty(model.Description))
            {
                ModelState.AddModelError(nameof(model.Description),
                    "For a 'Defense' ship " +
                    "classification, 'Description' is required.");
            }
            else
            {
                logger.LogInformation("Processing the form asynchronously");

                // async ...

                return Ok(ModelState);
            }
        }
        catch (Exception ex)
        {
            logger.LogError("Validation Error: {Message}", ex.Message);
        }

        return BadRequest(ModelState);
    }
}
```

Confirm or update the namespace of the preceding controller (`BlazorSample.Server.Controllers`) to match the app's controllers' namespace.

When a model binding validation error occurs on the server, an ApiController (ApiControllerAttribute) normally returns a default bad request response with a ValidationProblemDetails. The response contains more data than just the validation errors, as shown in the following example when all of the fields of the `Starfleet Starship Database` form aren't submitted and the form fails validation:

JSON

```
{
  "title": "One or more validation errors occurred.",
  "status": 400,
  "errors": {
    "Id": ["The Id field is required."],
    "Classification": ["The Classification field is required."],
    "IsValidatedDesign": ["This form disallows unapproved ships."],
    "MaximumAccommodation": ["Accommodation invalid (1-100000)."]
  }
}
```

> **Note**
>
> To demonstrate the preceding JSON response, you must either disable the form's client validation to permit empty field form submission or use a tool to send a request directly to the server API, such as Firefox Browser Developer.

If the server API returns the preceding default JSON response, it's possible for the client to parse the response in developer code to obtain the children of the `errors` node for forms validation error processing. It's inconvenient to write developer code to parse the file. Parsing the JSON manually requires producing a Dictionary<string, List<string>> of errors after calling ReadFromJsonAsync. Ideally, the server API should only return the validation errors, as the following example shows:

JSON

```
{
  "Id": ["The Id field is required."],
  "Classification": ["The Classification field is required."],
  "IsValidatedDesign": ["This form disallows unapproved ships."],
  "MaximumAccommodation": ["Accommodation invalid (1-100000)."]
}
```

To modify the server API's response to make it only return the validation errors, change the delegate that's invoked on actions that are annotated with ApiControllerAttribute in the `Program` file. For the API endpoint (`/StarshipValidation`), return a

BadRequestObjectResult with the ModelStateDictionary. For any other API endpoints, preserve the default behavior by returning the object result with a new ValidationProblemDetails.

Add the Microsoft.AspNetCore.Mvc namespace to the top of the `Program` file in the main project of the Blazor Web App:

```
C#

using Microsoft.AspNetCore.Mvc;
```

In the `Program` file, add or update the following AddControllersWithViews extension method and add the following call to ConfigureApiBehaviorOptions:

```
C#

builder.Services.AddControllersWithViews()
    .ConfigureApiBehaviorOptions(options =>
    {
        options.InvalidModelStateResponseFactory = context =>
        {
            if (context.HttpContext.Request.Path == "/StarshipValidation")
            {
                return new BadRequestObjectResult(context.ModelState);
            }
            else
            {
                return new BadRequestObjectResult(
                    new ValidationProblemDetails(context.ModelState));
            }
        };
    });
```

If you're adding controllers to the main project of the Blazor Web App for the first time, map controller endpoints when you place the preceding code that registers services for controllers. The following example uses default controller routes:

```
C#

app.MapDefaultControllerRoute();
```

> **Note**
>
> The preceding example explicitly registers controller services by calling AddControllersWithViews to automatically mitigate Cross-Site Request Forgery

(XSRF/CSRF) attacks. If you merely use AddControllers, antiforgery isn't enabled automatically.

For more information on controller routing and validation failure error responses, see the following resources:

- Routing to controller actions in ASP.NET Core
- Handle errors in ASP.NET Core controller-based web APIs

In the `.Client` project, add the `CustomValidation` component shown in the Validator components section. Update the namespace to match the app (for example, `namespace BlazorSample.Client`).

In the `.Client` project, the `Starfleet Starship Database` form is updated to show server validation errors with help of the `CustomValidation` component. When the server API returns validation messages, they're added to the `CustomValidation` component's ValidationMessageStore. The errors are available in the form's EditContext for display by the form's validation summary.

In the following component, update the namespace of the shared project (`@using BlazorSample.Shared`) to the shared project's namespace. Note that the form requires authorization, so the user must be signed into the app to navigate to the form.

`Starship10.razor`:

> **Note**
>
> Forms based on EditForm automatically enable antiforgery support. The controller should use AddControllersWithViews to register controller services and automatically enable antiforgery support for the web API.

razor

```
@page "/starship-10"
@rendermode InteractiveWebAssembly
@using System.Net
@using System.Net.Http.Json
@using Microsoft.AspNetCore.Authorization
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@using BlazorSample.Shared
@attribute [Authorize]
@inject HttpClient Http
@inject ILogger<Starship10> Logger
```

```
<h1>Starfleet Starship Database</h1>

<h2>New Ship Entry Form</h2>

<EditForm FormName="Starship10" Model="Model" OnValidSubmit="Submit">
    <DataAnnotationsValidator />
    <CustomValidation @ref="customValidation" />
    <ValidationSummary />
    <div>
        <label>
            Identifier:
            <InputText @bind-Value="Model!.Id" disabled="@disabled" />
        </label>
    </div>
    <div>
        <label>
            Description (optional):
            <InputTextArea @bind-Value="Model!.Description"
                disabled="@disabled" />
        </label>
    </div>
    <div>
        <label>
            Primary Classification:
            <InputSelect @bind-Value="Model!.Classification"
disabled="@disabled">
                <option value="">Select classification ...</option>
                <option value="Exploration">Exploration</option>
                <option value="Diplomacy">Diplomacy</option>
                <option value="Defense">Defense</option>
            </InputSelect>
        </label>
    </div>
    <div>
        <label>
            Maximum Accommodation:
            <InputNumber @bind-Value="Model!.MaximumAccommodation"
                disabled="@disabled" />
        </label>
    </div>
    <div>
        <label>
            Engineering Approval:
            <InputCheckbox @bind-Value="Model!.IsValidatedDesign"
                disabled="@disabled" />
        </label>
    </div>
    <div>
        <label>
            Production Date:
            <InputDate @bind-Value="Model!.ProductionDate"
disabled="@disabled" />
        </label>
    </div>
    <div>
```

```
        <button type="submit" disabled="@disabled">Submit</button>
    </div>
    <div style="@messageStyles">
        @message
    </div>
</EditForm>

@code {
    private CustomValidation? customValidation;
    private bool disabled;
    private string? message;
    private string messageStyles = "visibility:hidden";

    [SupplyParameterFromForm]
    private Starship? Model { get; set; }

    protected override void OnInitialized() =>
        Model ??= new() { ProductionDate = DateTime.UtcNow };

    private async Task Submit(EditContext editContext)
    {
        customValidation?.ClearErrors();

        try
        {
            var response = await Http.PostAsJsonAsync<Starship>(
                "StarshipValidation", (Starship)editContext.Model);

            var errors = await response.Content
                .ReadFromJsonAsync<Dictionary<string, List<string>>>() ??
                new Dictionary<string, List<string>>();

            if (response.StatusCode == HttpStatusCode.BadRequest &&
                errors.Any())
            {
                customValidation?.DisplayErrors(errors);
            }
            else if (!response.IsSuccessStatusCode)
            {
                throw new HttpRequestException(
                    $"Validation failed. Status Code:
{response.StatusCode}");
            }
            else
            {
                disabled = true;
                messageStyles = "color:green";
                message = "The form has been processed.";
            }
        }
        catch (AccessTokenNotAvailableException ex)
        {
            ex.Redirect();
        }
        catch (Exception ex)
```

```
        {
            Logger.LogError("Form processing error: {Message}", ex.Message);
            disabled = true;
            messageStyles = "color:red";
            message = "There was an error processing the form.";
        }
    }
}
```

The `.Client` project of a Blazor Web App must also register an HttpClient for HTTP POST requests to a backend web API controller. Confirm or add the following to the `.Client` project's `Program` file:

C#

```
builder.Services.AddScoped(sp =>
    new HttpClient { BaseAddress = new
Uri(builder.HostEnvironment.BaseAddress) });
```

The preceding example sets the base address with `builder.HostEnvironment.BaseAddress` (IWebAssemblyHostEnvironment.BaseAddress), which gets the base address for the app and is typically derived from the `<base>` tag's `href` value in the host page.

> **Note**
>
> As an alternative to the use of a validation component, data annotation validation attributes can be used. Custom attributes applied to the form's model activate with the use of the DataAnnotationsValidator component. When used with server validation, the attributes must be executable on the server. For more information, see the Custom validation attributes section.

`InputText` based on the input event

Use the InputText component to create a custom component that uses the `oninput` event (input) instead of the `onchange` event (change). Use of the `input` event triggers field validation on each keystroke.

The following `CustomInputText` component inherits the framework's `InputText` component and sets event binding to the `oninput` event (input).

`CustomInputText.razor`:

razor

```razor
@inherits InputText

<input @attributes="AdditionalAttributes"
       class="@CssClass"
       @bind="CurrentValueAsString"
       @bind:event="oninput" />
```

The `CustomInputText` component can be used anywhere InputText is used. The following component uses the shared `CustomInputText` component.

`Starship11.razor`:

razor

```razor
@page "/starship-11"
@using System.ComponentModel.DataAnnotations
@inject ILogger<Starship11> Logger

<EditForm Model="Model" OnValidSubmit="Submit" FormName="Starship11">
    <DataAnnotationsValidator />
    <ValidationSummary />
    <div>
        <label>
            Identifier:
            <CustomInputText @bind-Value="Model!.Id" />
        </label>
    </div>
    <div>
        <button type="submit">Submit</button>
    </div>
</EditForm>

<div>
    CurrentValue: @Model?.Id
</div>

@code {
    [SupplyParameterFromForm]
    private Starship? Model { get; set; }

    protected override void OnInitialized() => Model ??= new();

    private void Submit() => Logger.LogInformation("Submit: Processing
form");

    public class Starship
    {
        [Required]
        [StringLength(10, ErrorMessage = "Id is too long.")]
        public string? Id { get; set; }
```

```
    }
}
```

Validation Summary and Validation Message components

The ValidationSummary component summarizes all validation messages, which is similar to the Validation Summary Tag Helper:

razor

```
<ValidationSummary />
```

Output validation messages for a specific model with the `Model` parameter:

razor

```
<ValidationSummary Model="Model" />
```

The ValidationMessage<TValue> component displays validation messages for a specific field, which is similar to the Validation Message Tag Helper. Specify the field for validation with the For attribute and a lambda expression naming the model property:

razor

```
<ValidationMessage For="@(() => Model!.MaximumAccommodation)" />
```

The ValidationMessage<TValue> and ValidationSummary components support arbitrary attributes. Any attribute that doesn't match a component parameter is added to the generated `<div>` or `<ul>` element.

Control the style of validation messages in the app's stylesheet (`wwwroot/css/app.css` or `wwwroot/css/site.css`). The default `validation-message` class sets the text color of validation messages to red:

css

```
.validation-message {
    color: red;
}
```

Determine if a form field is valid

Use EditContext.IsValid to determine if a field is valid without obtaining validation messages.

❌ Supported, but not recommended:

```
C#

var isValid = !editContext.GetValidationMessages(fieldIdentifier).Any();
```

✔ Recommended:

```
C#

var isValid = editContext.IsValid(fieldIdentifier);
```

Custom validation attributes

To ensure that a validation result is correctly associated with a field when using a custom validation attribute, pass the validation context's MemberName when creating the ValidationResult.

`CustomValidator.cs`:

```
C#

using System;
using System.ComponentModel.DataAnnotations;

public class CustomValidator : ValidationAttribute
{
    protected override ValidationResult IsValid(object value,
        ValidationContext validationContext)
    {
        ...

        return new ValidationResult("Validation message to user.",
            new[] { validationContext.MemberName });
    }
}
```

Inject services into custom validation attributes through the ValidationContext. The following example demonstrates a salad chef form that validates user input with dependency injection (DI).

The `SaladChef` class indicates the approved starship ingredient list for a Ten Forward salad.

`SaladChef.cs`:

```
C#

namespace BlazorSample;

public class SaladChef
{
    public string[] SaladToppers = { "Horva", "Kanda Root", "Krintar",
"Plomeek",
        "Syto Bean" };
}
```

Register `SaladChef` in the app's DI container in the `Program` file:

```
C#

builder.Services.AddTransient<SaladChef>();
```

The `IsValid` method of the following `SaladChefValidatorAttribute` class obtains the `SaladChef` service from DI to check the user's input.

`SaladChefValidatorAttribute.cs`:

```
C#

using System.ComponentModel.DataAnnotations;

namespace BlazorSample;

public class SaladChefValidatorAttribute : ValidationAttribute
{
    protected override ValidationResult? IsValid(object? value,
        ValidationContext validationContext)
    {
        var saladChef = validationContext.GetRequiredService<SaladChef>();

        if (saladChef.SaladToppers.Contains(value?.ToString()))
        {
            return ValidationResult.Success;
        }

        return new ValidationResult("Is that a Vulcan salad topper?! " +
            "The following toppers are available for a Ten Forward salad: "
+
            string.Join(", ", saladChef.SaladToppers));
```

```
    }
}
```

The following component validates user input by applying the `SaladChefValidatorAttribute` (`[SaladChefValidator]`) to the salad ingredient string (`SaladIngredient`).

`Starship12.razor`:

razor

```razor
@page "/starship-12"
@inject SaladChef SaladChef

<EditForm Model="this" autocomplete="off" FormName="Starship12">
    <DataAnnotationsValidator />
    <div>
        <label>
            Salad topper (@saladToppers):
            <input @bind="SaladIngredient" />
        </label>
    </div>
    <div>
        <button type="submit">Submit</button>
    </div>
    <ul>
        @foreach (var message in context.GetValidationMessages())
        {
            <li class="validation-message">@message</li>
        }
    </ul>
</EditForm>

@code {
    private string? saladToppers;

    [SaladChefValidator]
    public string? SaladIngredient { get; set; }

    protected override void OnInitialized() =>
        saladToppers ??= string.Join(", ", SaladChef.SaladToppers);
}
```

Custom validation CSS class attributes

Custom validation CSS class attributes are useful when integrating with CSS frameworks, such as Bootstrap.

To specify custom validation CSS class attributes, start by providing CSS styles for custom validation. In the following example, valid (`validField`) and invalid (`invalidField`) styles are specified.

Add the following CSS classes to the app's stylesheet:

```css
.validField {
    border-color: lawngreen;
}

.invalidField {
    background-color: tomato;
}
```

Create a class derived from FieldCssClassProvider that checks for field validation messages and applies the appropriate valid or invalid style.

`CustomFieldClassProvider.cs`:

```C#
using Microsoft.AspNetCore.Components.Forms;

public class CustomFieldClassProvider : FieldCssClassProvider
{
    public override string GetFieldCssClass(EditContext editContext,
        in FieldIdentifier fieldIdentifier)
    {
        var isValid = editContext.IsValid(fieldIdentifier);

        return isValid ? "validField" : "invalidField";
    }
}
```

Set the `CustomFieldClassProvider` class as the Field CSS Class Provider on the form's EditContext instance with SetFieldCssClassProvider.

`Starship13.razor`:

```razor
@page "/starship-13"
@using System.ComponentModel.DataAnnotations
@inject ILogger<Starship13> Logger

<EditForm EditContext="editContext" OnValidSubmit="Submit"
```

```
FormName="Starship13">
    <DataAnnotationsValidator />
    <ValidationSummary />
    <div>
        <label>
            Identifier:
            <InputText @bind-Value="Model!.Id" />
        </label>
    </div>
    <div>
        <button type="submit">Submit</button>
    </div>
</EditForm>

@code {
    private EditContext? editContext;

    [SupplyParameterFromForm]
    private Starship? Model { get; set; }

    protected override void OnInitialized()
    {
        Model ??= new();
        editContext = new(Model);
        editContext.SetFieldCssClassProvider(new
CustomFieldClassProvider());
    }

    private void Submit() => Logger.LogInformation("Submit: Processing
form");

    public class Starship
    {
        [Required]
        [StringLength(10, ErrorMessage = "Id is too long.")]
        public string? Id { get; set; }
    }
}
```

The preceding example checks the validity of all form fields and applies a style to each field. If the form should only apply custom styles to a subset of the fields, make `CustomFieldClassProvider` apply styles conditionally. The following `CustomFieldClassProvider2` example only applies a style to the `Name` field. For any fields with names not matching `Name`, `string.Empty` is returned, and no style is applied. Using reflection, the field is matched to the model member's property or field name, not an `id` assigned to the HTML entity.

`CustomFieldClassProvider2.cs`:

```
C#
```

```
using Microsoft.AspNetCore.Components.Forms;

public class CustomFieldClassProvider2 : FieldCssClassProvider
{
    public override string GetFieldCssClass(EditContext editContext,
        in FieldIdentifier fieldIdentifier)
    {
        if (fieldIdentifier.FieldName == "Name")
        {
            var isValid = editContext.IsValid(fieldIdentifier);

            return isValid ? "validField" : "invalidField";
        }

        return string.Empty;
    }
}
```

> **Note**
>
> Matching the field name in the preceding example is case sensitive, so a model property member designated "`Name`" must match a conditional check on "`Name`":
>
> - ✔ `fieldId.FieldName == "Name"`
> - ✘ `fieldId.FieldName == "name"`
> - ✘ `fieldId.FieldName == "NAME"`
> - ✘ `fieldId.FieldName == "nAmE"`

Add an additional property to `Model`, for example:

C#

```
[StringLength(10, ErrorMessage = "Description is too long.")]
public string? Description { get; set; }
```

Add the `Description` to the `CustomValidationForm` component's form:

razor

```
<InputText @bind-Value="Model!.Description" />
```

Update the EditContext instance in the component's `OnInitialized` method to use the new Field CSS Class Provider:

C#

```
editContext?.SetFieldCssClassProvider(new CustomFieldClassProvider2());
```

Because a CSS validation class isn't applied to the `Description` field, it isn't styled. However, field validation runs normally. If more than 10 characters are provided, the validation summary indicates the error:

> Description is too long.

In the following example:

- The custom CSS style is applied to the `Name` field.
- Any other fields apply logic similar to Blazor's default logic and using Blazor's default field CSS validation styles, `modified` with `valid` or `invalid`. Note that for the default styles, you don't need to add them to the app's stylesheet if the app is based on a Blazor project template. For apps not based on a Blazor project template, the default styles can be added to the app's stylesheet:

  CSS

  ```
  .valid.modified:not([type=checkbox]) {
      outline: 1px solid #26b050;
  }

  .invalid {
      outline: 1px solid red;
  }
  ```

`CustomFieldClassProvider3.cs`:

C#

```
using Microsoft.AspNetCore.Components.Forms;

public class CustomFieldClassProvider3 : FieldCssClassProvider
{
    public override string GetFieldCssClass(EditContext editContext,
        in FieldIdentifier fieldIdentifier)
    {
        var isValid = editContext.IsValid(fieldIdentifier);

        if (fieldIdentifier.FieldName == "Name")
        {
            return isValid ? "validField" : "invalidField";
        }
```

```
        else
        {
            if (editContext.IsModified(fieldIdentifier))
            {
                return isValid ? "modified valid" : "modified invalid";
            }
            else
            {
                return isValid ? "valid" : "invalid";
            }
        }
    }
}
```

Update the EditContext instance in the component's `OnInitialized` method to use the preceding Field CSS Class Provider:

C#

```
editContext.SetFieldCssClassProvider(new CustomFieldClassProvider3());
```

Using `CustomFieldClassProvider3`:

- The `Name` field uses the app's custom validation CSS styles.
- The `Description` field uses logic similar to Blazor's logic and Blazor's default field CSS validation styles.

Class-level validation with `IValidatableObject`

Class-level validation with IValidatableObject (API documentation) is supported for Blazor form models. IValidatableObject validation only executes when the form is submitted and only if all other validation succeeds.

Blazor data annotations validation package

The Microsoft.AspNetCore.Components.DataAnnotations.Validation is a package that fills validation experience gaps using the DataAnnotationsValidator component. The package is currently *experimental*.

> ⚠ **Warning**
>
> The Microsoft.AspNetCore.Components.DataAnnotations.Validation package has a latest version of *release candidate* at NuGet.org. Continue to use the

experimental release candidate package at this time. Experimental features are provided for the purpose of exploring feature viability and may not ship in a stable version. Watch the Announcements GitHub repository, the dotnet/aspnetcore GitHub repository, or this topic section for further updates.

Nested models, collection types, and complex types

Blazor provides support for validating form input using data annotations with the built-in DataAnnotationsValidator. However, the DataAnnotationsValidator only validates top-level properties of the model bound to the form that aren't collection- or complex-type properties.

To validate the bound model's entire object graph, including collection- and complex-type properties, use the `ObjectGraphDataAnnotationsValidator` provided by the *experimental* Microsoft.AspNetCore.Components.DataAnnotations.Validation package:

razor

```
<EditForm ...>
    <ObjectGraphDataAnnotationsValidator />
    ...
</EditForm>
```

Annotate model properties with `[ValidateComplexType]`. In the following model classes, the `ShipDescription` class contains additional data annotations to validate when the model is bound to the form:

`Starship.cs`:

C#

```
using System;
using System.ComponentModel.DataAnnotations;

public class Starship
{
    ...

    [ValidateComplexType]
    public ShipDescription ShipDescription { get; set; } = new();

    ...
}
```

`ShipDescription.cs`:

C#

```
using System;
using System.ComponentModel.DataAnnotations;

public class ShipDescription
{
    [Required]
    [StringLength(40, ErrorMessage = "Description too long (40 char).")]
    public string? ShortDescription { get; set; }

    [Required]
    [StringLength(240, ErrorMessage = "Description too long (240 char).")]
    public string? LongDescription { get; set; }
}
```

Enable the submit button based on form validation

To enable and disable the submit button based on form validation, the following example:

- Uses a shortened version of the earlier `Starfleet Starship Database` form (`Starship3` component) of the Example form section of the *Input components* article that only accepts a value for the ship's Id. The other `Starship` properties receive valid default values when an instance of the `Starship` type is created.
- Uses the form's EditContext to assign the model when the component is initialized.
- Validates the form in the context's OnFieldChanged callback to enable and disable the submit button.
- Implements IDisposable and unsubscribes the event handler in the `Dispose` method. For more information, see ASP.NET Core Razor component lifecycle.

> **Note**
>
> When assigning to the EditForm.EditContext, don't also assign an EditForm.Model to the EditForm.

`Starship14.razor`:

razor

```
@page "/starship-14"
@implements IDisposable
@inject ILogger<Starship14> Logger

<EditForm EditContext="editContext" OnValidSubmit="Submit"
FormName="Starship14">
    <DataAnnotationsValidator />
    <ValidationSummary />
    <div>
        <label>
            Identifier:
            <InputText @bind-Value="Model!.Id" />
        </label>
    </div>
    <div>
        <button type="submit" disabled="@formInvalid">Submit</button>
    </div>
</EditForm>

@code {
    private bool formInvalid = false;
    private EditContext? editContext;

    [SupplyParameterFromForm]
    private Starship? Model { get; set; }

    protected override void OnInitialized()
    {
        Model ??=
            new()
                {
                    Id = "NCC-1701",
                    Classification = "Exploration",
                    MaximumAccommodation = 150,
                    IsValidatedDesign = true,
                    ProductionDate = new DateTime(2245, 4, 11)
                };
        editContext = new(Model);
        editContext.OnFieldChanged += HandleFieldChanged;
    }

    private void HandleFieldChanged(object? sender, FieldChangedEventArgs e)
    {
        if (editContext is not null)
        {
            formInvalid = !editContext.Validate();
            StateHasChanged();
        }
    }

    private void Submit() => Logger.LogInformation("Submit: Processing
form");

    public void Dispose()
```

```
    {
        if (editContext is not null)
        {
            editContext.OnFieldChanged -= HandleFieldChanged;
        }
    }
}
```

If a form isn't preloaded with valid values and you wish to disable the `Submit` button on form load, set `formInvalid` to `true`.

A side effect of the preceding approach is that a validation summary (ValidationSummary component) is populated with invalid fields after the user interacts with any one field. Address this scenario in either of the following ways:

- Don't use a ValidationSummary component on the form.
- Make the ValidationSummary component visible when the submit button is selected (for example, in a `Submit` method).

razor

```
<EditForm ... EditContext="editContext" OnValidSubmit="Submit" ...>
    <DataAnnotationsValidator />
    <ValidationSummary style="@displaySummary" />

    ...

    <button type="submit" disabled="@formInvalid">Submit</button>
</EditForm>

@code {
    private string displaySummary = "display:none";

    ...

    private void Submit()
    {
        displaySummary = "display:block";
    }
}
```

Troubleshoot ASP.NET Core Blazor forms

This article provides troubleshooting guidance for Blazor forms.

Large form payloads and the SignalR message size limit

This section only applies to Blazor Web Apps, Blazor Server apps, and hosted Blazor WebAssembly solutions that implement SignalR.

If form processing fails because the component's form payload has exceeded the maximum incoming SignalR message size permitted for hub methods, the form can adopt streaming JS interop without increasing the message size limit. For more information on the size limit and the error thrown, see ASP.NET Core Blazor SignalR guidance.

In the following example a text area (`<textarea>`) is used with streaming JS interop to move up to 50,000 bytes of data to the server.

Add a JavaScript (JS) `getText` function to the app:

```
window.getText = (elem) => {
  const textValue = elem.value;
  const utf8Encoder = new TextEncoder();
  const encodedTextValue = utf8Encoder.encode(textValue);
  return encodedTextValue;
};
```

For information on where to place JS in a Blazor app, see JavaScript location in ASP.NET Core Blazor apps.

Due to security considerations, zero-length streams aren't permitted for streaming JS Interop. Therefore, the following `StreamFormData` component traps a JSException and returns an empty string if the text area is blank when the form is submitted.

`StreamFormData.razor`:

```
@page "/stream-form-data"
@inject IJSRuntime JS
@inject ILogger<StreamFormData> Logger

<h1>Stream form data with JS interop</h1>

<EditForm FormName="StreamFormData" Model="this" OnSubmit="Submit">
    <div>
        <label>
            &lt;textarea&gt; value streamed for assignment to
            <code>TextAreaValue (&lt;= 50,000 characters)</code>:
            <textarea @ref="largeTextArea" />
        </label>
    </div>
    <div>
        <button type="submit">Submit</button>
    </div>
</EditForm>

<div>
    Length: @TextAreaValue?.Length
</div>

@code {
    private ElementReference largeTextArea;

    public string? TextAreaValue { get; set; }

    protected override void OnInitialized() =>
        TextAreaValue ??= string.Empty;

    private async Task Submit()
    {
        TextAreaValue = await GetTextAsync();

        Logger.LogInformation("TextAreaValue length: {Length}",
            TextAreaValue.Length);
    }

    public async Task<string> GetTextAsync()
    {
        try
        {
            var streamRef =
                await JS.InvokeAsync<IJSStreamReference>("getText",
largeTextArea);
            var stream = await streamRef.OpenReadStreamAsync(maxAllowedSize:
```

```
50_000);
            var streamReader = new StreamReader(stream);

            return await streamReader.ReadToEndAsync();
        }
        catch (JSException jsException)
        {
            if (jsException.InnerException is
                    ArgumentOutOfRangeException outOfRangeException &&
                outOfRangeException.ActualValue is not null &&
                outOfRangeException.ActualValue is long actualLength &&
                actualLength == 0)
            {
                return string.Empty;
            }

            throw;
        }
    }
}
```

EditForm parameter error

> InvalidOperationException: EditForm requires a Model parameter, or an EditContext parameter, but not both.

Confirm that the EditForm assigns a Model **or** an EditContext. Don't use both for the same form.

When assigning to Model, confirm that the model type is instantiated.

Connection disconnected

> Error: Connection disconnected with error 'Error: Server returned an error on close: Connection closed with an error.'.

> System.IO.InvalidDataException: The maximum message size of 32768B was exceeded. The message size can be configured in AddHubOptions.

ASP.NET Core Blazor file uploads

Article • 10/04/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article explains how to upload files in Blazor with the InputFile component.

File uploads

> **⚠ Warning**
>
> Always follow security best practices when permitting users to upload files. For more information, see Upload files in ASP.NET Core.

Use the InputFile component to read browser file data into .NET code. The InputFile component renders an HTML `<input>` element of type `file` for single file uploads. Add the `multiple` attribute to permit the user to upload multiple files at once.

File selection isn't cumulative when using an InputFile component or its underlying HTML <input type="file">, so you can't add files to an existing file selection. The component always replaces the user's initial file selection, so file references from prior selections aren't available.

The following InputFile component executes the `LoadFiles` method when the OnChange (change) event occurs. An InputFileChangeEventArgs provides access to the selected file list and details about each file:

razor

```
<InputFile OnChange="LoadFiles" multiple />

@code {
    private void LoadFiles(InputFileChangeEventArgs e)
    {
        ...
```

```
    }
}
```

Rendered HTML:

HTML

```
<input multiple="" type="file" _bl_2="">
```

> **Note**
>
> In the preceding example, the `<input>` element's `_bl_2` attribute is used for Blazor's internal processing.

To read data from a user-selected file, call IBrowserFile.OpenReadStream on the file and read from the returned stream. For more information, see the File streams section.

OpenReadStream enforces a maximum size in bytes of its Stream. Reading one file or multiple files larger than 500 KB results in an exception. This limit prevents developers from accidentally reading large files into memory. The `maxAllowedSize` parameter of OpenReadStream can be used to specify a larger size if required.

If you need access to a Stream that represents the file's bytes, use IBrowserFile.OpenReadStream. Avoid reading the incoming file stream directly into memory all at once. For example, don't copy all of the file's bytes into a MemoryStream or read the entire stream into a byte array all at once. These approaches can result in degraded app performance and potential Denial of Service (DoS) risk, especially for server-side components. Instead, consider adopting either of the following approaches:

- Copy the stream directly to a file on disk without reading it into memory. Note that Blazor apps executing code on the server aren't able to access the client's file system directly.
- Upload files from the client directly to an external service. For more information, see the Upload files to an external service section.

In the following examples, `browserFile` represents the uploaded file and implements IBrowserFile. Working implementations for IBrowserFile are shown in the file upload components later in this article.

✔ The following approach is **recommended** because the file's Stream is provided directly to the consumer, a FileStream that creates the file at the provided path:

```
```

C#

```
await using FileStream fs = new(path, FileMode.Create);
await browserFile.OpenReadStream().CopyToAsync(fs);
```

✔ The following approach is **recommended** for Microsoft Azure Blob Storage because the file's Stream is provided directly to UploadBlobAsync:

C#

```
await blobContainerClient.UploadBlobAsync(
    trustedFileName, browserFile.OpenReadStream());
```

✘ The following approach is **NOT recommended** because the file's Stream content is read into a String in memory (`reader`):

C#

```
var reader =
    await new StreamReader(browserFile.OpenReadStream()).ReadToEndAsync();
```

✘ The following approach is **NOT recommended** for Microsoft Azure Blob Storage because the file's Stream content is copied into a MemoryStream in memory (`memoryStream`) before calling UploadBlobAsync:

C#

```
var memoryStream = new MemoryStream();
await browserFile.OpenReadStream().CopyToAsync(memoryStream);
await blobContainerClient.UploadBlobAsync(
    trustedFileName, memoryStream));
```

A component that receives an image file can call the BrowserFileExtensions.RequestImageFileAsync convenience method on the file to resize the image data within the browser's JavaScript runtime before the image is streamed into the app. Use cases for calling RequestImageFileAsync are most appropriate for Blazor WebAssembly apps.

File size read and upload limits

Server-side or client-side, there's no file read or upload size limit specifically for the InputFile component. However, client-side Blazor reads the file's bytes into a single JavaScript array buffer when marshalling the data from JavaScript to C#, which is limited

to 2 GB or to the device's available memory. Large file uploads (> 250 MB) may fail for client-side uploads using the InputFile component. For more information, see the following discussions:

- The Blazor InputFile Component should handle chunking when the file is uploaded (dotnet/runtime #84685)
- Request Streaming upload via http handler (dotnet/runtime #36634)

For large client-side file uploads that fail when attempting to use the InputFile component, we recommend chunking large files with a custom component using multiple HTTP range requests instead of using the InputFile component.

Work is currently scheduled for .NET 9 (late 2024) to address the client-side file size upload limitation.

Examples

The following examples demonstrate multiple file upload in a component. InputFileChangeEventArgs.GetMultipleFiles allows reading multiple files. Specify the maximum number of files to prevent a malicious user from uploading a larger number of files than the app expects. InputFileChangeEventArgs.File allows reading the first and only file if the file upload doesn't support multiple files.

InputFileChangeEventArgs is in the Microsoft.AspNetCore.Components.Forms namespace, which is typically one of the namespaces in the app's `_Imports.razor` file. When the namespace is present in the `_Imports.razor` file, it provides API member access to the app's components.

Namespaces in the `_Imports.razor` file aren't applied to C# files (`.cs`). C# files require an explicit using directive at the top of the class file:

razor

```
using Microsoft.AspNetCore.Components.Forms;
```

For testing file upload components, you can create test files of any size with PowerShell:

PowerShell

```
$out = new-object byte[] {SIZE}; (new-object Random).NextBytes($out);
[IO.File]::WriteAllBytes('{PATH}', $out)
```

In the preceding command:

- The `{SIZE}` placeholder is the size of the file in bytes (for example, `2097152` for a 2 MB file).
- The `{PATH}` placeholder is the path and file with file extension (for example, `D:/test_files/testfile2MB.txt`).

Server-side file upload example

To use the following code, create a `Development/unsafe_uploads` folder at the root of the app running in the `Development` environment.

Because the example uses the app's environment as part of the path where files are saved, additional folders are required if other environments are used in testing and production. For example, create a `Staging/unsafe_uploads` folder for the `Staging` environment. Create a `Production/unsafe_uploads` folder for the `Production` environment.

> ⚠ **Warning**
>
> The example saves files without scanning their contents, and the guidance in this article doesn't take into account additional security best practices for uploaded files. On staging and production systems, disable execute permission on the upload folder and scan files with an anti-virus/anti-malware scanner API immediately after upload. For more information, see Upload files in ASP.NET Core.

`FileUpload1.razor`:

razor

```
@page "/file-upload-1"
@using System
@using System.IO
@using Microsoft.AspNetCore.Hosting
@inject ILogger<FileUpload1> Logger
@inject IWebHostEnvironment Environment

<PageTitle>File Upload 1</PageTitle>

<h1>File Upload Example 1</h1>

<p>
    <label>
        Max file size:
        <input type="number" @bind="maxFileSize" />
    </label>
</p>
```

```
<p>
    <label>
        Max allowed files:
        <input type="number" @bind="maxAllowedFiles" />
    </label>
</p>

<p>
    <label>
        Upload up to @maxAllowedFiles of up to @maxFileSize bytes:
        <InputFile OnChange="LoadFiles" multiple />
    </label>
</p>

@if (isLoading)
{
    <p>Uploading...</p>
}
else
{
    <ul>
        @foreach (var file in loadedFiles)
        {
            <li>
                <ul>
                    <li>Name: @file.Name</li>
                    <li>Last modified: @file.LastModified.ToString()</li>
                    <li>Size (bytes): @file.Size</li>
                    <li>Content type: @file.ContentType</li>
                </ul>
            </li>
        }
    </ul>
}

@code {
    private List<IBrowserFile> loadedFiles = new();
    private long maxFileSize = 1024 * 15;
    private int maxAllowedFiles = 3;
    private bool isLoading;

    private async Task LoadFiles(InputFileChangeEventArgs e)
    {
        isLoading = true;
        loadedFiles.Clear();

        foreach (var file in e.GetMultipleFiles(maxAllowedFiles))
        {
            try
            {
                var trustedFileName = Path.GetRandomFileName();
                var path = Path.Combine(Environment.ContentRootPath,
                    Environment.EnvironmentName, "unsafe_uploads",
                    trustedFileName);
```

```
                await using FileStream fs = new(path, FileMode.Create);
                await file.OpenReadStream(maxFileSize).CopyToAsync(fs);

                loadedFiles.Add(file);

                Logger.LogInformation(
                    "Unsafe Filename: {UnsafeFilename} File saved:
{Filename}",
                    file.Name, trustedFileName);
            }
            catch (Exception ex)
            {
                Logger.LogError("File: {Filename} Error: {Error}",
                    file.Name, ex.Message);
            }
        }

        isLoading = false;
    }
}
```

Client-side file upload example

The following example processes file bytes and doesn't send files to a destination outside of the app. For an example of a Razor component that sends a file to a server or service, see the following sections:

- Upload files to a server with client-side rendering (CSR)
- Upload files to an external service

The component assumes that the Interactive WebAssembly render mode (`InteractiveWebAssembly`) is inherited from a parent component or applied globally to the app.

razor

```
@page "/file-upload-1"
@inject ILogger<FileUpload1> Logger

<PageTitle>File Upload 1</PageTitle>

<h1>File Upload Example 1</h1>

<p>
    <label>
        Max file size:
        <input type="number" @bind="maxFileSize" />
    </label>
</p>
```

```
<p>
    <label>
        Max allowed files:
        <input type="number" @bind="maxAllowedFiles" />
    </label>
</p>

<p>
    <label>
        Upload up to @maxAllowedFiles of up to @maxFileSize bytes:
        <InputFile OnChange="LoadFiles" multiple />
    </label>
</p>

@if (isLoading)
{
    <p>Uploading...</p>
}
else
{
    <ul>
        @foreach (var file in loadedFiles)
        {
            <li>
                <ul>
                    <li>Name: @file.Name</li>
                    <li>Last modified: @file.LastModified.ToString()</li>
                    <li>Size (bytes): @file.Size</li>
                    <li>Content type: @file.ContentType</li>
                </ul>
            </li>
        }
    </ul>
}

@code {
    private List<IBrowserFile> loadedFiles = new();
    private long maxFileSize = 1024 * 15;
    private int maxAllowedFiles = 3;
    private bool isLoading;

    private void LoadFiles(InputFileChangeEventArgs e)
    {
        isLoading = true;
        loadedFiles.Clear();

        foreach (var file in e.GetMultipleFiles(maxAllowedFiles))
        {
            try
            {
                loadedFiles.Add(file);
            }
            catch (Exception ex)
            {
```

```
                Logger.LogError("File: {FileName} Error: {Error}",
                    file.Name, ex.Message);
            }
        }

        isLoading = false;
    }
}
```

IBrowserFile returns metadata exposed by the browser as properties. Use this metadata for preliminary validation.

- Name
- Size
- LastModified
- ContentType

Never trust the values of the preceding properties, especially the Name property for display in the UI. Treat all user-supplied data as a significant security risk to the app, server, and network. For more information, see Upload files in ASP.NET Core.

Upload files to a server with server-side rendering

This section applies to Interactive Server components in Blazor Web Apps or Blazor Server apps.

The following example demonstrates uploading files from a server-side app to a backend web API controller in a separate app, possibly on a separate server.

In the server-side app's `Program` file, add IHttpClientFactory and related services that allow the app to create HttpClient instances:

C#

```
builder.Services.AddHttpClient();
```

For more information, see Make HTTP requests using IHttpClientFactory in ASP.NET Core.

For the examples in this section:

- The web API runs at the URL: `https://localhost:5001`
- The server-side app runs at the URL: `https://localhost:5003`

For testing, the preceding URLs are configured in the projects' `Properties/launchSettings.json` files.

The following `UploadResult` class maintains the result of an uploaded file. When a file fails to upload on the server, an error code is returned in `ErrorCode` for display to the user. A safe file name is generated on the server for each file and returned to the client in `StoredFileName` for display. Files are keyed between the client and server using the unsafe/untrusted file name in `FileName`.

`UploadResult.cs`:

C#

```
public class UploadResult
{
    public bool Uploaded { get; set; }
    public string? FileName { get; set; }
    public string? StoredFileName { get; set; }
    public int ErrorCode { get; set; }
}
```

A security best practice for production apps is to avoid sending error messages to clients that might reveal sensitive information about an app, server, or network. Providing detailed error messages can aid a malicious user in devising attacks on an app, server, or network. The example code in this section only sends back an error code number (`int`) for display by the component client-side if a server-side error occurs. If a user requires assistance with a file upload, they provide the error code to support personnel for support ticket resolution without ever knowing the exact cause of the error.

The following `LazyBrowserFileStream` class defines a custom stream type that lazily calls OpenReadStream just before the first bytes of the stream are requested. The stream isn't transmitted from the browser to the server until reading the stream begins in .NET.

`LazyBrowserFileStream.cs`:

C#

```
using Microsoft.AspNetCore.Components.Forms;
using System.Diagnostics.CodeAnalysis;

namespace BlazorSample;

internal sealed class LazyBrowserFileStream(IBrowserFile file, int
maxAllowedSize)
    : Stream
```

```
{
    private readonly IBrowserFile file = file;
    private readonly int maxAllowedSize = maxAllowedSize;
    private Stream? underlyingStream;
    private bool isDisposed;

    public override bool CanRead => true;

    public override bool CanSeek => false;

    public override bool CanWrite => false;

    public override long Length => file.Size;

    public override long Position
    {
        get => underlyingStream?.Position ?? 0;
        set => throw new NotSupportedException();
    }

    public override void Flush() => underlyingStream?.Flush();

    public override Task<int> ReadAsync(byte[] buffer, int offset, int
count,
        CancellationToken cancellationToken)
    {
        EnsureStreamIsOpen();

        return underlyingStream.ReadAsync(buffer, offset, count,
cancellationToken);
    }

    public override ValueTask<int> ReadAsync(Memory<byte> buffer,
        CancellationToken cancellationToken = default)
    {
        EnsureStreamIsOpen();
        return underlyingStream.ReadAsync(buffer, cancellationToken);
    }

    [MemberNotNull(nameof(underlyingStream))]
    private void EnsureStreamIsOpen() =>
        underlyingStream ??= file.OpenReadStream(maxAllowedSize);

    protected override void Dispose(bool disposing)
    {
        if (isDisposed)
        {
            return;
        }

        underlyingStream?.Dispose();
        isDisposed = true;

        base.Dispose(disposing);
    }
```

```
    public override int Read(byte[] buffer, int offset, int count)
        => throw new NotSupportedException();

    public override long Seek(long offset, SeekOrigin origin)
        => throw new NotSupportedException();

    public override void SetLength(long value)
        => throw new NotSupportedException();

    public override void Write(byte[] buffer, int offset, int count)
        => throw new NotSupportedException();
}
```

The following `FileUpload2` component:

- Permits users to upload files from the client.
- Displays the untrusted/unsafe file name provided by the client in the UI. The untrusted/unsafe file name is automatically HTML-encoded by Razor for safe display in the UI.

> ⚠ **Warning**
>
> **Don't trust file names supplied by clients** for:
>
> - Saving the file to a file system or service.
> - Display in UIs that don't encode file names automatically or via developer code.
>
> For more information on security considerations when uploading files to a server, see Upload files in ASP.NET Core.

`FileUpload2.razor`:

razor

```
@page "/file-upload-2"
@using System.Net.Http.Headers
@using System.Text.Json
@inject IHttpClientFactory ClientFactory
@inject ILogger<FileUpload2> Logger

<PageTitle>File Upload 2</PageTitle>

<h1>File Upload Example 2</h1>

<p>
    This example requires a backend server API to function. For more
```

            var client = ClientFactory.CreateClient();

            var response =
                await client.PostAsync("https://localhost:5001/Filesave",
                content);

            if (response.IsSuccessStatusCode)
            {
                var options = new JsonSerializerOptions
```

```
                {
                    PropertyNameCaseInsensitive = true,
                };

                using var responseStream =
                    await response.Content.ReadAsStreamAsync();

                var newUploadResults = await JsonSerializer
                    .DeserializeAsync<IList<UploadResult>>(responseStream,
options);

                if (newUploadResults is not null)
                {
                    uploadResults =
uploadResults.Concat(newUploadResults).ToList();
                }
            }
        }

        shouldRender = true;
    }

    private static bool FileUpload(IList<UploadResult> uploadResults,
        string? fileName, ILogger<FileUpload2> logger, out UploadResult
result)
    {
        result = uploadResults.SingleOrDefault(f => f.FileName == fileName)
?? new();

        if (!result.Uploaded)
        {
            logger.LogInformation("{FileName} not uploaded (Err: 5)",
fileName);
            result.ErrorCode = 5;
        }

        return result.Uploaded;
    }

    private class File
    {
        public string? Name { get; set; }
    }
}
```

If the component limits file uploads to a single file at a time or if the component only adopts interactive client-side rendering (CSR, `InteractiveWebAssembly`), the component can avoid the use of the `LazyBrowserFileStream` and use a Stream. The following demonstrates the changes for the `FileUpload2` component:

diff

```
- var stream = new LazyBrowserFileStream(file, maxFileSize);
- var fileContent = new StreamContent(stream);
+ var fileContent = new StreamContent(file.OpenReadStream(maxFileSize));
```

Remove the `LazyBrowserFileStream` class (`LazyBrowserFileStream.cs`), as it isn't used.

The following controller in the web API project saves uploaded files from the client.

> **ⓘ Important**
>
> The controller in this section is intended for use in a separate web API project from the Blazor app. The web API should mitigate Cross-Site Request Forgery (XSRF/CSRF) attacks if file upload users are authenticated.

To use the following code, create a `Development/unsafe_uploads` folder at the root of the web API project for the app running in the `Development` environment.

Because the example uses the app's environment as part of the path where files are saved, additional folders are required if other environments are used in testing and production. For example, create a `Staging/unsafe_uploads` folder for the `Staging` environment. Create a `Production/unsafe_uploads` folder for the `Production` environment.

> **⚠ Warning**
>
> The example saves files without scanning their contents, and the guidance in this article doesn't take into account additional security best practices for uploaded files. On staging and production systems, disable execute permission on the upload folder and scan files with an anti-virus/anti-malware scanner API immediately after upload. For more information, see Upload files in ASP.NET Core.

`Controllers/FilesaveController.cs`:

C#

```
using System.Net;
using Microsoft.AspNetCore.Mvc;

[ApiController]
[Route("[controller]")]
public class FilesaveController(
    IHostEnvironment env, ILogger<FilesaveController> logger)
    : ControllerBase
```

```
{
    [HttpPost]
    public async Task<ActionResult<IList<UploadResult>>> PostFile(
        [FromForm] IEnumerable<IFormFile> files)
    {
        var maxAllowedFiles = 3;
        long maxFileSize = 1024 * 15;
        var filesProcessed = 0;
        var resourcePath = new Uri($"{Request.Scheme}://{Request.Host}/");
        List<UploadResult> uploadResults = [];

        foreach (var file in files)
        {
            var uploadResult = new UploadResult();
            string trustedFileNameForFileStorage;
            var untrustedFileName = file.FileName;
            uploadResult.FileName = untrustedFileName;
            var trustedFileNameForDisplay =
                WebUtility.HtmlEncode(untrustedFileName);

            if (filesProcessed < maxAllowedFiles)
            {
                if (file.Length == 0)
                {
                    logger.LogInformation("{FileName} length is 0 (Err: 1)",
                        trustedFileNameForDisplay);
                    uploadResult.ErrorCode = 1;
                }
                else if (file.Length > maxFileSize)
                {
                    logger.LogInformation("{FileName} of {Length} bytes is "
+
                        "larger than the limit of {Limit} bytes (Err: 2)",
                        trustedFileNameForDisplay, file.Length,
maxFileSize);
                    uploadResult.ErrorCode = 2;
                }
                else
                {
                    try
                    {
                        trustedFileNameForFileStorage =
Path.GetRandomFileName();
                        var path = Path.Combine(env.ContentRootPath,
                            env.EnvironmentName, "unsafe_uploads",
                            trustedFileNameForFileStorage);

                        await using FileStream fs = new(path,
FileMode.Create);
                        await file.CopyToAsync(fs);

                        logger.LogInformation("{FileName} saved at {Path}",
                            trustedFileNameForDisplay, path);
                        uploadResult.Uploaded = true;
                        uploadResult.StoredFileName =
```

```
trustedFileNameForFileStorage;
                    }
                    catch (IOException ex)
                    {
                        logger.LogError("{FileName} error on upload (Err:
3): {Message}",
                            trustedFileNameForDisplay, ex.Message);
                        uploadResult.ErrorCode = 3;
                    }
                }

                filesProcessed++;
            }
            else
            {
                logger.LogInformation("{FileName} not uploaded because the "
+
                    "request exceeded the allowed {Count} of files (Err:
4)",
                    trustedFileNameForDisplay, maxAllowedFiles);
                uploadResult.ErrorCode = 4;
            }

            uploadResults.Add(uploadResult);
        }

        return new CreatedResult(resourcePath, uploadResults);
    }
}
```

In the preceding code, GetRandomFileName is called to generate a secure file name. Never trust the file name provided by the browser, as a cyberattacker may choose an existing file name that overwrites an existing file or send a path that attempts to write outside of the app.

The server app must register controller services and map controller endpoints. For more information, see Routing to controller actions in ASP.NET Core.

Upload files to a server with client-side rendering (CSR)

This section applies to client-side rendered (CSR) components in Blazor Web Apps or Blazor WebAssembly apps.

The following example demonstrates uploading files to a backend web API controller in a separate app, possibly on a separate server, from a component in a Blazor Web App that adopts CSR or a component in a Blazor WebAssembly app.

The following `UploadResult` class maintains the result of an uploaded file. When a file fails to upload on the server, an error code is returned in `ErrorCode` for display to the user. A safe file name is generated on the server for each file and returned to the client in `StoredFileName` for display. Files are keyed between the client and server using the unsafe/untrusted file name in `FileName`.

`UploadResult.cs`:

C#

```
public class UploadResult
{
    public bool Uploaded { get; set; }
    public string? FileName { get; set; }
    public string? StoredFileName { get; set; }
    public int ErrorCode { get; set; }
}
```

> **Note**
>
> The preceding `UploadResult` class can be shared between client- and server-based projects. When client and server projects share the class, add an import to each project's `_Imports.razor` file for the shared project. For example:
>
> razor
>
> ```
> @using BlazorSample.Shared
> ```

The following `FileUpload2` component:

- Permits users to upload files from the client.
- Displays the untrusted/unsafe file name provided by the client in the UI. The untrusted/unsafe file name is automatically HTML-encoded by Razor for safe display in the UI.

A security best practice for production apps is to avoid sending error messages to clients that might reveal sensitive information about an app, server, or network. Providing detailed error messages can aid a malicious user in devising attacks on an app, server, or network. The example code in this section only sends back an error code number (`int`) for display by the component client-side if a server-side error occurs. If a user requires assistance with a file upload, they provide the error code to support

personnel for support ticket resolution without ever knowing the exact cause of the error.

> ⚠ **Warning**
>
> **Don't trust file names supplied by clients** for:
>
> - Saving the file to a file system or service.
> - Display in UIs that don't encode file names automatically or via developer code.
>
> For more information on security considerations when uploading files to a server, see Upload files in ASP.NET Core.

In the Blazor Web App main project, add IHttpClientFactory and related services in the project's `Program` file:

```
C#

builder.Services.AddHttpClient();
```

The `HttpClient` services must be added to the main project because the client-side component is prerendered on the server. If you disable prerendering for the following component, you aren't required to provide the `HttpClient` services in the main app and don't need to add the preceding line to the main project.

For more information on adding `HttpClient` services to an ASP.NET Core app, see Make HTTP requests using IHttpClientFactory in ASP.NET Core.

The client project (`.Client`) of a Blazor Web App must also register an HttpClient for HTTP POST requests to a backend web API controller. Confirm or add the following to the client project's `Program` file:

```
C#

builder.Services.AddScoped(sp =>
    new HttpClient { BaseAddress = new
Uri(builder.HostEnvironment.BaseAddress) });
```

The preceding example sets the base address with `builder.HostEnvironment.BaseAddress` (IWebAssemblyHostEnvironment.BaseAddress), which gets the base address for the app and is typically derived from the `<base>` tag's

`href` value in the host page. If you're calling an external web API, set the URI to the web API's base address.

Specify the Interactive WebAssembly render mode attribute at the top of the following component in a Blazor Web App:

razor

```
@rendermode InteractiveWebAssembly
```

`FileUpload2.razor`:

razor

```
@page "/file-upload-2"
@using System.Linq
@using System.Net.Http.Headers
@inject HttpClient Http
@inject ILogger<FileUpload2> Logger

<PageTitle>File Upload 2</PageTitle>

<h1>File Upload Example 2</h1>

<p>
    <label>
        Upload up to @maxAllowedFiles files:
        <InputFile OnChange="OnInputFileChange" multiple />
    </label>
</p>

@if (files.Count > 0)
{
    <div class="card">
        <div class="card-body">
            <ul>
                @foreach (var file in files)
                {
                    <li>
                        File: @file.Name
                        <br>
                        @if (FileUpload(uploadResults, file.Name, Logger,
                           out var result))
                        {
                            <span>
                                Stored File Name: @result.StoredFileName
                            </span>
                        }
                        else
                        {
                            <span>
```

```
                                There was an error uploading the file
                                (Error: @result.ErrorCode).
                            </span>
                        }
                    </li>
                }
            </ul>
        </div>
    </div>
}

@code {
    private List<File> files = new();
    private List<UploadResult> uploadResults = new();
    private int maxAllowedFiles = 3;
    private bool shouldRender;

    protected override bool ShouldRender() => shouldRender;

    private async Task OnInputFileChange(InputFileChangeEventArgs e)
    {
        shouldRender = false;
        long maxFileSize = 1024 * 15;
        var upload = false;

        using var content = new MultipartFormDataContent();

        foreach (var file in e.GetMultipleFiles(maxAllowedFiles))
        {
            if (uploadResults.SingleOrDefault(
                f => f.FileName == file.Name) is null)
            {
                try
                {
                    files.Add(new() { Name = file.Name });

StreamContent(file.OpenReadStream(maxFileSize));

                    fileContent.Headers.ContentType =
                        new MediaTypeHeaderValue(file.ContentType);

                    content.Add(
                        content: fileContent,
                        name: "\"files\"",
                        fileName: file.Name);

                    upload = true;
                }
                catch (Exception ex)
                {
                    Logger.LogInformation(
                        "{FileName} not uploaded (Err: 6): {Message}",
                        file.Name, ex.Message);
```

```
                    uploadResults.Add(
                        new()
                        {
                            FileName = file.Name,
                            ErrorCode = 6,
                            Uploaded = false
                        });
                }
            }
        }

        if (upload)
        {
            var response = await Http.PostAsync("/Filesave", content);

            var newUploadResults = await response.Content
                .ReadFromJsonAsync<IList<UploadResult>>();

            if (newUploadResults is not null)
            {
                uploadResults =
uploadResults.Concat(newUploadResults).ToList();
            }
        }

        shouldRender = true;
    }

    private static bool FileUpload(IList<UploadResult> uploadResults,
        string? fileName, ILogger<FileUpload2> logger, out UploadResult
result)
    {
        result = uploadResults.SingleOrDefault(f => f.FileName == fileName)
?? new();

        if (!result.Uploaded)
        {
            logger.LogInformation("{FileName} not uploaded (Err: 5)",
fileName);
            result.ErrorCode = 5;
        }

        return result.Uploaded;
    }

    private class File
    {
        public string? Name { get; set; }
    }
}
```

The following controller in the server-side project saves uploaded files from the client.

To use the following code, create a `Development/unsafe_uploads` folder at the root of the server-side project for the app running in the `Development` environment.

Because the example uses the app's environment as part of the path where files are saved, additional folders are required if other environments are used in testing and production. For example, create a `Staging/unsafe_uploads` folder for the `Staging` environment. Create a `Production/unsafe_uploads` folder for the `Production` environment.

> ⚠ **Warning**
>
> The example saves files without scanning their contents, and the guidance in this article doesn't take into account additional security best practices for uploaded files. On staging and production systems, disable execute permission on the upload folder and scan files with an anti-virus/anti-malware scanner API immediately after upload. For more information, see Upload files in ASP.NET Core.

In the following example, update the shared project's namespace to match the shared project if a shared project is supplying the `UploadResult` class.

`Controllers/FilesaveController.cs`:

C#

```
using System;
using System.Collections.Generic;
using System.IO;
using System.Net;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Http;
using Microsoft.AspNetCore.Mvc;
using Microsoft.Extensions.Logging;
using BlazorSample.Shared;

[ApiController]
[Route("[controller]")]
public class FilesaveController(
    IHostEnvironment env, ILogger<FilesaveController> logger)
    : ControllerBase
{
    [HttpPost]
    public async Task<ActionResult<IList<UploadResult>>> PostFile(
        [FromForm] IEnumerable<IFormFile> files)
    {
        var maxAllowedFiles = 3;
        long maxFileSize = 1024 * 15;
        var filesProcessed = 0;
```

```
        var resourcePath = new Uri($"{Request.Scheme}://{Request.Host}/");
        List<UploadResult> uploadResults = [];

        foreach (var file in files)
        {
            var uploadResult = new UploadResult();
            string trustedFileNameForFileStorage;
            var untrustedFileName = file.FileName;
            uploadResult.FileName = untrustedFileName;
            var trustedFileNameForDisplay =
                WebUtility.HtmlEncode(untrustedFileName);

            if (filesProcessed < maxAllowedFiles)
            {
                if (file.Length == 0)
                {
                    logger.LogInformation("{FileName} length is 0 (Err: 1)",
                        trustedFileNameForDisplay);
                    uploadResult.ErrorCode = 1;
                }
                else if (file.Length > maxFileSize)
                {
                    logger.LogInformation("{FileName} of {Length} bytes is "
+
                        "larger than the limit of {Limit} bytes (Err: 2)",
                        trustedFileNameForDisplay, file.Length,
maxFileSize);
                    uploadResult.ErrorCode = 2;
                }
                else
                {
                    try
                    {
                        trustedFileNameForFileStorage =
Path.GetRandomFileName();
                        var path = Path.Combine(env.ContentRootPath,
                            env.EnvironmentName, "unsafe_uploads",
                            trustedFileNameForFileStorage);

                        await using FileStream fs = new(path,
FileMode.Create);
                        await file.CopyToAsync(fs);

                        logger.LogInformation("{FileName} saved at {Path}",
                            trustedFileNameForDisplay, path);
                        uploadResult.Uploaded = true;
                        uploadResult.StoredFileName =
trustedFileNameForFileStorage;
                    }
                    catch (IOException ex)
                    {
                        logger.LogError("{FileName} error on upload (Err:
3): {Message}",
                            trustedFileNameForDisplay, ex.Message);
                        uploadResult.ErrorCode = 3;
```

```
                    }
                }

                filesProcessed++;
            }
            else
            {
                logger.LogInformation("{FileName} not uploaded because the "
+
                    "request exceeded the allowed {Count} of files (Err:
4)",
                    trustedFileNameForDisplay, maxAllowedFiles);
                uploadResult.ErrorCode = 4;
            }

            uploadResults.Add(uploadResult);
        }

        return new CreatedResult(resourcePath, uploadResults);
    }
}
```

In the preceding code, GetRandomFileName is called to generate a secure file name. Never trust the file name provided by the browser, as a cyberattacker may choose an existing file name that overwrites an existing file or send a path that attempts to write outside of the app.

The server app must register controller services and map controller endpoints. For more information, see Routing to controller actions in ASP.NET Core.

Cancel a file upload

A file upload component can detect when a user has cancelled an upload by using a CancellationToken when calling into the IBrowserFile.OpenReadStream or StreamReader.ReadAsync.

Create a CancellationTokenSource for the `InputFile` component. At the start of the `OnInputFileChange` method, check if a previous upload is in progress.

If a file upload is in progress:

- Call Cancel on the previous upload.
- Create a new CancellationTokenSource for the next upload and pass the CancellationTokenSource.Token to OpenReadStream or ReadAsync.

Upload files server-side with progress

The following example demonstrates how to upload files in a server-side app with upload progress displayed to the user.

To use the following example in a test app:

- **Create a folder to save uploaded files for the `Development` environment: `Development/unsafe_uploads`.**
- Configure the maximum file size (`maxFileSize`, 15 KB in the following example) and maximum number of allowed files (`maxAllowedFiles`, 3 in the following example).
- Set the buffer to a different value (10 KB in the following example), if desired, for increased granularity in progress reporting. We don't recommended using a buffer larger than 30 KB due to performance and security concerns.

> ⚠ **Warning**
>
> The example saves files without scanning their contents, and the guidance in this article doesn't take into account additional security best practices for uploaded files. On staging and production systems, disable execute permission on the upload folder and scan files with an anti-virus/anti-malware scanner API immediately after upload. For more information, see Upload files in ASP.NET Core.

`FileUpload3.razor`:

razor

```razor
@page "/file-upload-3"
@inject ILogger<FileUpload3> Logger
@inject IWebHostEnvironment Environment

<PageTitle>File Upload 3</PageTitle>

<h1>File Upload Example 3</h1>

<p>
    <label>
        Max file size:
        <input type="number" @bind="maxFileSize" />
    </label>
</p>

<p>
    <label>
        Max allowed files:
        <input type="number" @bind="maxAllowedFiles" />
    </label>
</p>
```

```
<p>
    <label>
        Upload up to @maxAllowedFiles of up to @maxFileSize bytes:
        <InputFile OnChange="LoadFiles" multiple />
    </label>
</p>

@if (isLoading)
{
    <p>Progress: @string.Format("{0:P0}", progressPercent)</p>
}
else
{
    <ul>
        @foreach (var file in loadedFiles)
        {
            <li>
                <ul>
                    <li>Name: @file.Name</li>
                    <li>Last modified: @file.LastModified.ToString()</li>
                    <li>Size (bytes): @file.Size</li>
                    <li>Content type: @file.ContentType</li>
                </ul>
            </li>
        }
    </ul>
}

@code {
    private List<IBrowserFile> loadedFiles = new();
    private long maxFileSize = 1024 * 15;
    private int maxAllowedFiles = 3;
    private bool isLoading;
    private decimal progressPercent;

    private async Task LoadFiles(InputFileChangeEventArgs e)
    {
        isLoading = true;
        loadedFiles.Clear();
        progressPercent = 0;

        foreach (var file in e.GetMultipleFiles(maxAllowedFiles))
        {
            try
            {
                var trustedFileName = Path.GetRandomFileName();
                var path = Path.Combine(Environment.ContentRootPath,
                    Environment.EnvironmentName, "unsafe_uploads",
trustedFileName);

                await using FileStream writeStream = new(path,
FileMode.Create);
                using var readStream = file.OpenReadStream(maxFileSize);
                var bytesRead = 0;
                var totalRead = 0;
```

```
                var buffer = new byte[1024 * 10];

                while ((bytesRead = await readStream.ReadAsync(buffer)) !=
0)
                {
                    totalRead += bytesRead;
                    await writeStream.WriteAsync(buffer, 0, bytesRead);
                    progressPercent = Decimal.Divide(totalRead, file.Size);
                    StateHasChanged();
                }

                loadedFiles.Add(file);

                Logger.LogInformation(
                    "Unsafe Filename: {UnsafeFilename} File saved:
{Filename}",
                    file.Name, trustedFileName);
            }
            catch (Exception ex)
            {
                Logger.LogError("File: {FileName} Error: {Error}",
                    file.Name, ex.Message);
            }
        }

        isLoading = false;
    }
}
```

For more information, see the following API resources:

- FileStream: Provides a Stream for a file, supporting both synchronous and asynchronous read and write operations.
- FileStream.ReadAsync: The preceding `FileUpload3` component reads the stream asynchronously with ReadAsync. Reading a stream synchronously with Read isn't supported in Razor components.

File streams

With server interactivity, file data is streamed over the SignalR connection into .NET code on the server as the file is read.

For a WebAssembly-rendered component, file data is streamed directly into the .NET code within the browser.

Upload image preview

For an image preview of uploading images, start by adding an `InputFile` component with a component reference and an `OnChange` handler:

razor

```razor
<InputFile @ref="inputFile" OnChange="ShowPreview" />
```

Add an image element with an element reference, which serves as the placeholder for the image preview:

razor

```razor
<img @ref="previewImageElem" />
```

Add the associated references:

razor

```razor
@code {
    private InputFile? inputFile;
    private ElementReference previewImageElem;
}
```

In JavaScript, add a function called with an HTML input and img element that performs the following:

- Extracts the selected file.
- Creates an object URL with createObjectURL.
- Sets an event listener to revoke the object URL with revokeObjectURL after the image is loaded, so memory isn't leaked.
- Sets the `img` element's source to display the image.

JavaScript

```javascript
window.previewImage = (inputElem, imgElem) => {
  const url = URL.createObjectURL(inputElem.files[0]);
  imgElem.addEventListener('load', () => URL.revokeObjectURL(url), { once:
true });
  imgElem.src = url;
}
```

Finally, use an injected IJSRuntime to add the `OnChange` handler that calls the JavaScript function:

razor

```
@inject IJSRuntime JS

...

@code {
    ...

    private async Task ShowPreview() => await JS.InvokeVoidAsync(
        "previewImage", inputFile!.Element, previewImageElem);
}
```

The preceding example is for uploading a single image. The approach can be expanded to support `multiple` images.

The following `FileUpload4` component shows the complete example.

`FileUpload4.razor`:

razor

```
@page "/file-upload-4"
@inject IJSRuntime JS

<h1>File Upload Example</h1>

<InputFile @ref="inputFile" OnChange="ShowPreview" />

<img style="max-width:200px;max-height:200px" @ref="previewImageElem" />

@code {
    private InputFile? inputFile;
    private ElementReference previewImageElem;

    private async Task ShowPreview() => await JS.InvokeVoidAsync(
        "previewImage", inputFile!.Element, previewImageElem);
}
```

Upload files to an external service

Instead of an app handling file upload bytes and the app's server receiving uploaded files, clients can directly upload files to an external service. The app can safely process the files from the external service on demand. This approach hardens the app and its server against malicious attacks and potential performance problems.

Consider an approach that uses Azure Files, Azure Blob Storage, or a third-party service with the following potential benefits:

- Upload files from the client directly to an external service with a JavaScript client library or REST API. For example, Azure offers the following client libraries and APIs:
  - Azure Storage File Share client library
  - Azure Files REST API
  - Azure Storage Blob client library for JavaScript
  - Blob service REST API
- Authorize user uploads with a user-delegated shared-access signature (SAS) token generated by the app (server-side) for each client file upload. For example, Azure offers the following SAS features:
  - Azure Storage File Share client library for JavaScript: with SAS Token
  - Azure Storage Blob client library for JavaScript: with SAS Token
- Provide automatic redundancy and file share backup.
- Limit uploads with quotas. Note that Azure Blob Storage's quotas are set at the account level, not the container level. However, Azure Files quotas are at the file share level and might provide better control over upload limits. For more information, see the Azure documents linked earlier in this list.
- Secure files with server-side encryption (SSE).

For more information on Azure Blob Storage and Azure Files, see the Azure Storage documentation.

Server-side SignalR message size limit

File uploads may fail even before they start, when Blazor retrieves data about the files that exceeds the maximum SignalR message size.

SignalR defines a message size limit that applies to every message Blazor receives, and the InputFile component streams files to the server in messages that respect the configured limit. However, the first message, which indicates the set of files to upload, is sent as a unique single message. The size of the first message may exceed the SignalR message size limit. The issue isn't related to the size of the files, it's related to the number of files.

The logged error is similar to the following:

> Error: Connection disconnected with error 'Error: Server returned an error on close: Connection closed with an error.'. e.log @ blazor.server.js:1

When uploading files, reaching the message size limit on the first message is rare. If the limit is reached, the app can configure HubOptions.MaximumReceiveMessageSize with a larger value.

For more information on SignalR configuration and how to set MaximumReceiveMessageSize, see ASP.NET Core Blazor SignalR guidance.

Maximum parallel invocations per client hub setting

Blazor relies on MaximumParallelInvocationsPerClient set to 1, which is the default value.

Increasing the value leads to a high probability that `CopyTo` operations throw `System.InvalidOperationException: 'Reading is not allowed after reader was completed.'`. For more information, see MaximumParallelInvocationsPerClient > 1 breaks file upload in Blazor Server mode (dotnet/aspnetcore #53951).

Troubleshoot

The line that calls IBrowserFile.OpenReadStream throws a System.TimeoutException:

> System.TimeoutException: Did not receive any data in the allotted time.

Possible causes:

- Using the Autofac Inversion of Control (IoC) container instead of the built-in ASP.NET Core dependency injection container. To resolve the issue, set DisableImplicitFromServicesParameters to `true` in the server-side circuit handler hub options. For more information, see FileUpload: Did not receive any data in the allotted time (dotnet/aspnetcore #38842).
- Not reading the stream to completion. This isn't a framework issue. Trap the exception and investigate it further in your local environment/network.
- Using server-side rendering and calling OpenReadStream on multiple files before reading them to completion. To resolve the issue, use the `LazyBrowserFileStream` class and approach described in the Upload files to a server with server-side rendering section of this article.

ASP.NET Core Blazor file downloads

Article • 11/06/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article explains how to download files in Blazor apps.

File downloads

This article covers approaches for the following scenarios, where a file shouldn't be opened by a browser but downloaded and saved on the client:

- Stream file content to a raw binary data buffer on the client: Typically, this approach is used for relatively small files (< 250 MB).
- Download a file via a URL without streaming: Usually, this approach is used for relatively large files (> 250 MB).

When downloading files from a different origin than the app, Cross-Origin Resource Sharing (CORS) considerations apply. For more information, see the Cross-Origin Resource Sharing (CORS) section.

Security considerations

Use caution when providing users with the ability to download files from a server. Cyberattackers may execute Denial of Service (DoS) attacks, API exploitation attacks, or attempt to compromise networks and servers in other ways.

Security steps that reduce the likelihood of a successful attack are:

- Download files from a dedicated file download area on the server, preferably from a non-system drive. Using a dedicated location makes it easier to impose security restrictions on downloadable files. Disable execute permissions on the file download area.

- Client-side security checks are easy to circumvent by malicious users. Always perform client-side security checks on the server, too.
- Don't receive files from users or other untrusted sources and then make the files available for immediate download without performing security checks on the files. For more information, see Upload files in ASP.NET Core.

Download from a stream

This section applies to files that are typically up to 250 MB in size.

The recommended approach for downloading relatively small files (< 250 MB) is to stream file content to a raw binary data buffer on the client with JavaScript (JS) interop. This approach is effective for components that adopt an interactive render mode but not components that adopt static server-side rendering (static SSR).

> ⚠ **Warning**
>
> The approach in this section reads the file's content into a JS ArrayBuffer. This approach loads the entire file into the client's memory, which can impair performance. To download relatively large files (>= 250 MB), we recommend following the guidance in the Download from a URL section.

The following `downloadFileFromStream` JS function:

- Reads the provided stream into an ArrayBuffer.
- Creates a Blob to wrap the `ArrayBuffer`.
- Creates an object URL to serve as the file's download address.
- Creates an HTMLAnchorElement (`<a>` element).
- Assigns the file's name (`fileName`) and URL (`url`) for the download.
- Triggers the download by firing a click event on the anchor element.
- Removes the anchor element.
- Revokes the object URL (`url`) by calling URL.revokeObjectURL. **This is an important step to ensure memory isn't leaked on the client.**

HTML

```
<script>
  window.downloadFileFromStream = async (fileName, contentStreamReference)
=> {
    const arrayBuffer = await contentStreamReference.arrayBuffer();
    const blob = new Blob([arrayBuffer]);
    const url = URL.createObjectURL(blob);
    const anchorElement = document.createElement('a');
```

```
    anchorElement.href = url;
    anchorElement.download = fileName ?? '';
    anchorElement.click();
    anchorElement.remove();
    URL.revokeObjectURL(url);
  }
</script>
```

> **Note**
>
> For general guidance on JS location and our recommendations for production apps, see JavaScript location in ASP.NET Core Blazor apps.

The following component:

- Uses native byte-streaming interop to ensure efficient transfer of the file to the client.
- Has a method named `GetFileStream` to retrieve a Stream for the file that's downloaded to clients. Alternative approaches include retrieving a file from storage or generating a file dynamically in C# code. For this demonstration, the app creates a 50 KB file of random data from a new byte array (`new byte[]`). The bytes are wrapped with a MemoryStream to serve as the example's dynamically-generated binary file.
- The `DownloadFileFromStream` method:
  - Retrieves the Stream from `GetFileStream`.
  - Specifies a file name when file is saved on the user's machine. The following example names the file `quote.txt`.
  - Wraps the Stream in a DotNetStreamReference, which allows streaming the file data to the client.
  - Invokes the `downloadFileFromStream` JS function to accept the data on the client.

`FileDownload1.razor`:

razor

```
@page "/file-download-1"
@using System.IO
@inject IJSRuntime JS

<PageTitle>File Download 1</PageTitle>

<h1>File Download Example 1</h1>

<button @onclick="DownloadFileFromStream">
    Download File From Stream
```

```
</button>

@code {
    private Stream GetFileStream()
    {
        var randomBinaryData = new byte[50 * 1024];
        var fileStream = new MemoryStream(randomBinaryData);

        return fileStream;
    }

    private async Task DownloadFileFromStream()
    {
        var fileStream = GetFileStream();
        var fileName = "log.bin";

        using var streamRef = new DotNetStreamReference(stream: fileStream);

        await JS.InvokeVoidAsync("downloadFileFromStream", fileName,
streamRef);
    }
}
```

For a component in a server-side app that must return a Stream for a physical file, the component can call File.OpenRead, as the following example demonstrates:

C#

```
private Stream GetFileStream() => File.OpenRead(@"{PATH}");
```

In the preceding example, the `{PATH}` placeholder is the path to the file. The `@` prefix indicates that the string is a *verbatim string literal*, which permits the use of backslashes (`\`) in a Windows OS path and embedded double-quotes (`""`) for a single quote in the path. Alternatively, avoid the string literal (`@`) and use either of the following approaches:

- Use escaped backslashes (`\\`) and quotes (`\"`).
- Use forward slashes (`/`) in the path, which are supported across platforms in ASP.NET Core apps, and escaped quotes (`\"`).

Download from a URL

This section applies to files that are relatively large, typically 250 MB or larger.

The recommended approach for downloading relatively large files (>= 250 MB) with interactively-rendered components or files of any size for statically-rendered

components is to use JS to trigger an anchor element with the file's name and URL.

The example in this section uses a download file named `quote.txt`, which is placed in a folder named `files` in the app's web root (`wwwroot` folder). The use of the `files` folder is only for demonstration purposes. You can organize downloadable files in any folder layout within the web root (`wwwroot` folder) that you prefer, including serving the files directly from the `wwwroot` folder.

`wwwroot/files/quote.txt`:

text

```
When victory is ours, we'll wipe every trace of the Thals and their city
from the face of this land. We will avenge the deaths of all Kaleds who've
fallen in the cause of right and justice and build a peace which will be a
monument to their sacrifice. Our battle cry will be "Total extermination of
the Thals!"

- General Ravon (Guy Siner, http://guysiner.com/)
  Dr. Who: Genesis of the Daleks (https://www.bbc.co.uk/programmes/p00vd5g2)
  Copyright 1975 BBC (https://www.bbc.co.uk/)
```

The following `triggerFileDownload` JS function:

- Creates an HTMLAnchorElement (`<a>` element).
- Assigns the file's name (`fileName`) and URL (`url`) for the download.
- Triggers the download by firing a click event on the anchor element.
- Removes the anchor element.

HTML

```
<script>
  window.triggerFileDownload = (fileName, url) => {
    const anchorElement = document.createElement('a');
    anchorElement.href = url;
    anchorElement.download = fileName ?? '';
    anchorElement.click();
    anchorElement.remove();
  }
</script>
```

> **Note**
>
> For general guidance on JS location and our recommendations for production apps, see JavaScript location in ASP.NET Core Blazor apps.

The following example component downloads the file from the same origin that the app uses. If the file download is attempted from a different origin, configure Cross-Origin Resource Sharing (CORS). For more information, see the Cross-Origin Resource Sharing (CORS) section.

`FileDownload2.razor`:

razor

```razor
@page "/file-download-2"
@inject IJSRuntime JS

<PageTitle>File Download 2</PageTitle>

<h1>File Download Example 2</h1>

<button @onclick="DownloadFileFromURL">
    Download File From URL
</button>

@code {
    private async Task DownloadFileFromURL()
    {
        var fileName = "quote.txt";
        var fileURL = "/files/quote.txt";
        await JS.InvokeVoidAsync("triggerFileDownload", fileName, fileURL);
    }
}
```

For interactive components, the button in the preceding example calls the `DownloadFileFromURL` handler to invoke the JavaScript (JS) function `triggerFileDownload`.

If the component adopts static server-side rendering (static SSR), add an event handler for the button (addEventListener (MDN documentation)) to call `triggerFileDownload` following the guidance in ASP.NET Core Blazor JavaScript with static server-side rendering (static SSR).

Cross-Origin Resource Sharing (CORS)

Without taking further steps to enable Cross-Origin Resource Sharing (CORS) for files that don't have the same origin as the app, downloading files won't pass CORS checks made by the browser.

For more information on CORS with ASP.NET Core apps and other Microsoft products and services that host files for download, see the following resources:

- Enable Cross-Origin Requests (CORS) in ASP.NET Core
- Using Azure CDN with CORS (Azure documentation)
- Cross-Origin Resource Sharing (CORS) support for Azure Storage (REST documentation)
- Core Cloud Services - Set up CORS for your website and storage assets (Learn module)
- IIS CORS module Configuration Reference (IIS documentation)

ASP.NET Core Blazor JavaScript interoperability (JS interop)

Article • 09/18/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

A Blazor app can invoke JavaScript (JS) functions from .NET methods and .NET methods from JS functions. These scenarios are called *JavaScript interoperability* (*JS interop*).

Further JS interop guidance is provided in the following articles:

- Call JavaScript functions from .NET methods in ASP.NET Core Blazor
- Call .NET methods from JavaScript functions in ASP.NET Core Blazor

> **Note**
>
> JavaScript `[JSImport]`/`[JSExport]` interop API is available for client-side components in ASP.NET Core in .NET 7 or later.
>
> For more information, see JavaScript JSImport/JSExport interop with ASP.NET Core Blazor.

Compression for interactive server components with untrusted data

With compression, which is enabled by default, avoid creating secure (authenticated/authorized) interactive server-side components that render data from untrusted sources. Untrusted sources include route parameters, query strings, data from JS interop, and any other source of data that a third-party user can control (databases, external services). For more information, see ASP.NET Core Blazor SignalR guidance and Threat mitigation guidance for ASP.NET Core Blazor interactive server-side rendering.

JavaScript interop abstractions and features package

The @microsoft/dotnet-js-interop package (npmjs.com) (Microsoft.JSInterop NuGet package) provides abstractions and features for interop between .NET and JavaScript (JS) code. Reference source is available in the dotnet/aspnetcore GitHub repository (/src/JSInterop folder). For more information, see the GitHub repository's `README.md` file.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

- TypeScript
- Tutorial: Create an ASP.NET Core app with TypeScript in Visual Studio
- Manage npm packages in Visual Studio

Interaction with the DOM

Only mutate the DOM with JavaScript (JS) when the object doesn't interact with Blazor. Blazor maintains representations of the DOM and interacts directly with DOM objects. If an element rendered by Blazor is modified externally using JS directly or via JS Interop, the DOM may no longer match Blazor's internal representation, which can result in undefined behavior. Undefined behavior may merely interfere with the presentation of elements or their functions but may also introduce security risks to the app or server.

This guidance not only applies to your own JS interop code but also to any JS libraries that the app uses, including anything provided by a third-party framework, such as Bootstrap JS and jQuery.

In a few documentation examples, JS interop is used to mutate an element *purely for demonstration purposes* as part of an example. In those cases, a warning appears in the text.

For more information, see Call JavaScript functions from .NET methods in ASP.NET Core Blazor.

JavaScript class with a field of type function

A JavaScript class with a field of type function isn't supported by Blazor JS interop. Use Javascript functions in classes.

❌ `GreetingHelpers.sayHello` in the following class as a field of type function isn't discovered by Blazor's JS interop and can't be executed from C# code:

JavaScript

```
export class GreetingHelpers {
  sayHello = function() {
    ...
  }
}
```

✔ `GreetingHelpers.sayHello` in the following class as a function is supported:

JavaScript

```
export class GreetingHelpers {
  sayHello() {
    ...
  }
}
```

Arrow functions are also supported:

JavaScript

```
export class GreetingHelpers {
  sayHello = () => {
    ...
  }
}
```

Avoid inline event handlers

A JavaScript function can be invoked directly from an inline event handler. In the following example, `alertUser` is a JavaScript function called when the button is selected by the user:

HTML

```
<button onclick="alertUser">Click Me!</button>
```

However, the use of inline event handlers is a *poor design choice* for calling JavaScript functions:

- Mixing HTML markup and JavaScript code often leads to unmaintainable code.
- Inline event handler execution may be blocked by a Content Security Policy (CSP) (MDN documentation).

We recommend avoiding inline event handlers in favor of approaches that assign handlers in JavaScript with addEventListener, as the following example demonstrates:

`AlertUser.razor.js`:

JavaScript

```
export function alertUser() {
  alert('The button was selected!');
}

export function addHandlers() {
  const btn = document.getElementById("btn");
  btn.addEventListener("click", alertUser);
}
```

`AlertUser.razor`:

razor

```
@page "/alert-user"
@implements IAsyncDisposable
@inject IJSRuntime JS

<h1>Alert User</h1>

<p>
    <button id="btn">Click Me!</button>
</p>

@code {
    private IJSObjectReference? module;

    protected async override Task OnAfterRenderAsync(bool firstRender)
    {
        if (firstRender)
        {
            module = await JS.InvokeAsync<IJSObjectReference>("import",
```

```
                "./Components/Pages/AlertUser.razor.js");

            await module.InvokeVoidAsync("addHandlers");
        }
    }

    async ValueTask IAsyncDisposable.DisposeAsync()
    {
        if (module is not null)
        {
            await module.DisposeAsync();
        }
    }
}
```

For more information, see the following resources:

- JavaScript location in ASP.NET Core Blazor apps
- Introduction to events (MDN documentation)

Asynchronous JavaScript calls

JS interop calls are asynchronous, regardless of whether the called code is synchronous or asynchronous. Calls are asynchronous to ensure that components are compatible across server-side and client-side rendering models. When adopting server-side rendering, JS interop calls must be asynchronous because they're sent over a network connection. For apps that exclusively adopt client-side rendering, synchronous JS interop calls are supported.

For more information, see the following articles:

- Call JavaScript functions from .NET methods in ASP.NET Core Blazor
- Call .NET methods from JavaScript functions in ASP.NET Core Blazor

Object serialization

Blazor uses System.Text.Json for serialization with the following requirements and default behaviors:

- Types must have a default constructor, get/set accessors must be public, and fields are never serialized.
- Global default serialization isn't customizable to avoid breaking existing component libraries, impacts on performance and security, and reductions in reliability.
- Serializing .NET member names results in lowercase JSON key names.

- JSON is deserialized as JsonElement C# instances, which permit mixed casing. Internal casting for assignment to C# model properties works as expected in spite of any case differences between JSON key names and C# property names.
- Complex framework types, such as KeyValuePair, might be trimmed away by the IL Trimmer on publish and not present for JS interop. We recommend creating custom types for types that the IL Trimmer trims away.
- Blazor always relies on reflection for JSON serialization, including when using C# source generation. Setting `JsonSerializerIsReflectionEnabledByDefault` to `false` in the app's project file results in an error when serialization is attempted.

JsonConverter API is available for custom serialization. Properties can be annotated with a [JsonConverter] attribute to override default serialization for an existing data type.

For more information, see the following resources in the .NET documentation:

- JSON serialization and deserialization (marshalling and unmarshalling) in .NET
- How to customize property names and values with System.Text.Json
- How to write custom converters for JSON serialization (marshalling) in .NET

Blazor supports optimized byte array JS interop that avoids encoding/decoding byte arrays into Base64. The app can apply custom serialization and pass the resulting bytes. For more information, see Call JavaScript functions from .NET methods in ASP.NET Core Blazor.

DOM cleanup tasks during component disposal

Don't execute JS interop code for DOM cleanup tasks during component disposal. Instead, use the MutationObserver pattern in JavaScript (JS) on the client for the following reasons:

- The component may have been removed from the DOM by the time your cleanup code executes in `Dispose{Async}`.
- During server-side rendering, the Blazor renderer may have been disposed by the framework by the time your cleanup code executes in `Dispose{Async}`.

The MutationObserver pattern allows you to run a function when an element is removed from the DOM.

In the following example, the `DOMCleanup` component:

- Contains a `<div>` with an `id` of `cleanupDiv`. The `<div>` element is removed from the DOM along with the rest of the component's DOM markup when the component is removed from the DOM.

- Loads the `DOMCleanup` JS class from the `DOMCleanup.razor.js` file and calls its `createObserver` function to set up the `MutationObserver` callback. These tasks are accomplished in the OnAfterRenderAsync lifecycle method.

`DOMCleanup.razor`:

razor

```razor
@page "/dom-cleanup"
@implements IAsyncDisposable
@inject IJSRuntime JS

<h1>DOM Cleanup Example</h1>

<div id="cleanupDiv"></div>

@code {
    private IJSObjectReference? module;

    protected override async Task OnAfterRenderAsync(bool firstRender)
    {
        if (firstRender)
        {
            module = await JS.InvokeAsync<IJSObjectReference>(
                "import", "./Components/Pages/DOMCleanup.razor.js");

            await module.InvokeVoidAsync("DOMCleanup.createObserver");
        }
    }

    async ValueTask IAsyncDisposable.DisposeAsync()
    {
        if (module is not null)
        {
            await module.DisposeAsync();
        }
    }
}
```

In the following example, the `MutationObserver` callback is executed each time a DOM change occurs. Execute your cleanup code when the `if` statement confirms that the target element (`cleanupDiv`) was removed (`if (targetRemoved) { ... }`). It's important to disconnect and delete the `MutationObserver` to avoid a memory leak after your cleanup code executes.

`DOMCleanup.razor.js` placed side-by-side with the preceding `DOMCleanup` component:

JavaScript

```
export class DOMCleanup {
  static observer;

  static createObserver() {
    const target = document.querySelector('#cleanupDiv');

    this.observer = new MutationObserver(function (mutations) {
      const targetRemoved = mutations.some(function (mutation) {
        const nodes = Array.from(mutation.removedNodes);
        return nodes.indexOf(target) !== -1;
      });

      if (targetRemoved) {
        // Cleanup resources here
        // ...

        // Disconnect and delete MutationObserver
        this.observer && this.observer.disconnect();
        delete this.observer;
      }
    });

    this.observer.observe(target.parentNode, { childList: true });
  }
}

window.DOMCleanup = DOMCleanup;
```

JavaScript interop calls without a circuit

This section only applies to server-side apps.

JavaScript (JS) interop calls can't be issued after a SignalR circuit is disconnected. Without a circuit during component disposal or at any other time that a circuit doesn't exist, the following method calls fail and log a message that the circuit is disconnected as a JSDisconnectedException:

- JS interop method calls
  - IJSRuntime.InvokeAsync
  - JSRuntimeExtensions.InvokeAsync
  - JSRuntimeExtensions.InvokeVoidAsync
- `Dispose`/`DisposeAsync` calls on any IJSObjectReference.

In order to avoid logging JSDisconnectedException or to log custom information, catch the exception in a try-catch statement.

For the following component disposal example:

- The component implements IAsyncDisposable.
- `objInstance` is an IJSObjectReference.
- JSDisconnectedException is caught and not logged.
- Optionally, you can log custom information in the `catch` statement at whatever log level you prefer. The following example doesn't log custom information because it assumes the developer doesn't care about when or where circuits are disconnected during component disposal.

C#

```
async ValueTask IAsyncDisposable.DisposeAsync()
{
    try
    {
        if (objInstance is not null)
        {
            await objInstance.DisposeAsync();
        }
    }
    catch (JSDisconnectedException)
    {
    }
}
```

If you must clean up your own JS objects or execute other JS code on the client after a circuit is lost, use the MutationObserver pattern in JS on the client. The MutationObserver pattern allows you to run a function when an element is removed from the DOM.

For more information, see the following articles:

- Handle errors in ASP.NET Core Blazor apps: The *JavaScript interop* section discusses error handling in JS interop scenarios.
- ASP.NET Core Razor component lifecycle: The *Component disposal with* `IDisposable` *and* `IAsyncDisposable` section describes how to implement disposal patterns in Razor components.

Cached JavaScript files

JavaScript (JS) files and other static assets aren't generally cached on clients during development in the Development environment. During development, static asset requests include the Cache-Control header with a value of no-cache or max-age with a value of zero (`0`).

During production in the Production environment, JS files are usually cached by clients.

To disable client-side caching in browsers, developers usually adopt one of the following approaches:

- Disable caching when the browser's developer tools console is open. Guidance can be found in the developer tools documentation of each browser maintainer:
  - Chrome DevTools
  - Microsoft Edge Developer Tools overview
- Perform a manual browser refresh of any webpage of the Blazor app to reload JS files from the server. ASP.NET Core's HTTP Caching Middleware always honors a valid no-cache Cache-Control header sent by a client.

For more information, see:

- ASP.NET Core Blazor environments
- Response caching in ASP.NET Core

Size limits on JavaScript interop calls

This section only applies to interactive components in server-side apps. For client-side components, the framework doesn't impose a limit on the size of JavaScript (JS) interop inputs and outputs.

For interactive components in server-side apps, JS interop calls passing data from the client to the server are limited in size by the maximum incoming SignalR message size permitted for hub methods, which is enforced by HubOptions.MaximumReceiveMessageSize (default: 32 KB). JS to .NET SignalR messages larger than MaximumReceiveMessageSize throw an error. The framework doesn't impose a limit on the size of a SignalR message from the hub to a client. For more information on the size limit, error messages, and guidance on dealing with message size limits, see ASP.NET Core Blazor SignalR guidance.

Determine where the app is running

If it's relevant for the app to know where code is running for JS interop calls, use OperatingSystem.IsBrowser to determine if the component is executing in the context of browser on WebAssembly.

JavaScript location in ASP.NET Core Blazor apps

Article • 10/03/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

Load JavaScript (JS) code using any of the following approaches:

- Load a script in <head> markup (*Not generally recommended*)
- Load a script in <body> markup
- Load a script from an external JavaScript file (.js) collocated with a component
- Load a script from an external JavaScript file (.js)
- Inject a script before or after Blazor starts

> **Warning**
>
> Only place a `<script>` tag in a component file (`.razor`) if the component is guaranteed to adopt static server-side rendering (static SSR) because the `<script>` tag can't be updated dynamically.

> **Note**
>
> Documentation examples usually place scripts in a `<script>` tag or load global scripts from external files. These approaches pollute the client with global functions. For production apps, we recommend placing JS into separate JS modules that can be imported when needed. For more information, see the JavaScript isolation in JavaScript modules section.

Load a script in `<head>` markup

The approach in this section isn't generally recommended.

Place the JavaScript (JS) tags (`<script>...</script>`) in the <head> element markup:

HTML

```
<head>
    ...

    <script>
      window.jsMethod = (methodParameter) => {
        ...
      };
    </script>
</head>
```

Loading JS from the `<head>` isn't the best approach for the following reasons:

- JS interop may fail if the script depends on Blazor. We recommend loading scripts using one of the other approaches, not via the `<head>` markup.
- The page may become interactive slower due to the time it takes to parse the JS in the script.

Load a script in `<body>` markup

Place the JavaScript tags (`<script>...</script>`) inside the closing </body> element after the Blazor script reference:

HTML

```
<body>
    ...

    <script src="{BLAZOR SCRIPT}"></script>
    <script>
      window.jsMethod = (methodParameter) => {
        ...
      };
    </script>
</body>
```

In the preceding example, the `{BLAZOR SCRIPT}` placeholder is the Blazor script path and file name. For the location of the script, see ASP.NET Core Blazor project structure.

Load a script from an external JavaScript file (`.js`) collocated with a component

Collocation of JavaScript (JS) files for Razor components is a convenient way to organize scripts in an app.

Razor components of Blazor apps collocate JS files using the `.razor.js` extension and are publicly addressable using the path to the file in the project:

`{PATH}/{COMPONENT}.razor.js`

- The `{PATH}` placeholder is the path to the component.
- The `{COMPONENT}` placeholder is the component.

When the app is published, the framework automatically moves the script to the web root. Scripts are moved to `bin/Release/{TARGET FRAMEWORK MONIKER}/publish/wwwroot/{PATH}/{COMPONENT}.razor.js`, where the placeholders are:

- `{TARGET FRAMEWORK MONIKER}` is the Target Framework Moniker (TFM).
- `{PATH}` is the path to the component.
- `{COMPONENT}` is the component name.

No change is required to the script's relative URL, as Blazor takes care of placing the JS file in published static assets for you.

This section and the following examples are primarily focused on explaining JS file collocation. The first example demonstrates a collocated JS file with an ordinary JS function. The second example demonstrates the use of a module to load a function, which is the recommended approach for most production apps. Calling JS from .NET is fully covered in Call JavaScript functions from .NET methods in ASP.NET Core Blazor, where there are further explanations of the Blazor JS API with additional examples. Component disposal, which is present in the second example, is covered in ASP.NET Core Razor component lifecycle.

The following `JsCollocation1` component loads a script via a HeadContent component and calls a JS function with IJSRuntime.InvokeAsync. The `{PATH}` placeholder is the path to the component.

> **ⓘ Important**
>
> If you use the following code for a demonstration in a test app, change the `{PATH}` placeholder to the path of the component (example: `Components/Pages` in .NET 8 or later or `Pages` in .NET 7 or earlier). In a Blazor Web App (.NET 8 or later), the component requires an interactive render mode applied either globally to the app or to the component definition.

Add the following script after the Blazor script (location of the Blazor start script):

HTML

```
<script src="{PATH}/JsCollocation1.razor.js"></script>
```

`JsCollocation1` component (`{PATH}/JsCollocation1.razor`):

razor

```
@page "/js-collocation-1"
@inject IJSRuntime JS

<PageTitle>JS Collocation 1</PageTitle>

<h1>JS Collocation Example 1</h1>

<button @onclick="ShowPrompt">Call showPrompt1</button>

@if (!string.IsNullOrEmpty(result))
{
    <p>
        Hello @result!
    </p>
}

@code {
    private string? result;

    public async void ShowPrompt()
    {
        result = await JS.InvokeAsync<string>(
            "showPrompt1", "What's your name?");
        StateHasChanged();
    }
}
```

The collocated JS file is placed next to the `JsCollocation1` component file with the file name `JsCollocation1.razor.js`. In the `JsCollocation1` component, the script is referenced at the path of the collocated file. In the following example, the `showPrompt1` function accepts the user's name from a Window prompt() and returns it to the `JsCollocation1` component for display.

`{PATH}/JsCollocation1.razor.js`:

JavaScript

```
function showPrompt1(message) {
  return prompt(message, 'Type your name here');
```

```
}
```

The preceding approach isn't recommended for general use in production apps because the approach pollutes the client with global functions. A better approach for production apps is to use JS modules. The same general principles apply to loading a JS module from a collocated JS file, as the next example demonstrates.

The following `JsCollocation2` component's `OnAfterRenderAsync` method loads a JS module into `module`, which is an IJSObjectReference of the component class. `module` is used to call the `showPrompt2` function. The `{PATH}` placeholder is the path to the component.

> **ⓘ Important**
>
> If you use the following code for a demonstration in a test app, change the `{PATH}` placeholder to the path of the component. In a Blazor Web App (.NET 8 or later), the component requires an interactive render mode applied either globally to the app or to the component definition.

`JsCollocation2` component (`{PATH}/JsCollocation2.razor`):

razor

```razor
@page "/js-collocation-2"
@implements IAsyncDisposable
@inject IJSRuntime JS

<PageTitle>JS Collocation 2</PageTitle>

<h1>JS Collocation Example 2</h1>

<button @onclick="ShowPrompt">Call showPrompt2</button>

@if (!string.IsNullOrEmpty(result))
{
    <p>
        Hello @result!
    </p>
}

@code {
    private IJSObjectReference? module;
    private string? result;

    protected async override Task OnAfterRenderAsync(bool firstRender)
    {
        if (firstRender)
```

```
        {
            /*
                Change the {PATH} placeholder in the next line to the path
of
                the collocated JS file in the app. Examples:

                ./Components/Pages/JsCollocation2.razor.js (.NET 8 or later)
                ./Pages/JsCollocation2.razor.js (.NET 7 or earlier)
            */
            module = await JS.InvokeAsync<IJSObjectReference>("import",
                "./{PATH}/JsCollocation2.razor.js");
        }
    }

    public async void ShowPrompt()
    {
        if (module is not null)
        {
            result = await module.InvokeAsync<string>(
                "showPrompt2", "What's your name?");
            StateHasChanged();
        }
    }

    async ValueTask IAsyncDisposable.DisposeAsync()
    {
        if (module is not null)
        {
            await module.DisposeAsync();
        }
    }
}
```

`{PATH}/JsCollocation2.razor.js`:

JavaScript

```
export function showPrompt2(message) {
  return prompt(message, 'Type your name here');
}
```

Use of scripts and modules for collocated JS in a Razor class library (RCL) is only supported for Blazor's JS interop mechanism based on the IJSRuntime interface. If you're implementing JavaScript [JSImport]/[JSExport] interop, see JavaScript JSImport/JSExport interop with ASP.NET Core Blazor.

For scripts or modules provided by a Razor class library (RCL) using IJSRuntime-based JS interop, the following path is used:

`./_content/{PACKAGE ID}/{PATH}/{COMPONENT}.{EXTENSION}.js`

- The path segment for the current directory (`./`) is required in order to create the correct static asset path to the JS file.
- The `{PACKAGE ID}` placeholder is the RCL's package identifier (or library name for a class library referenced by the app).
- The `{PATH}` placeholder is the path to the component. If a Razor component is located at the root of the RCL, the path segment isn't included.
- The `{COMPONENT}` placeholder is the component name.
- The `{EXTENSION}` placeholder matches the extension of component, either `razor` or `cshtml`.

In the following Blazor app example:

- The RCL's package identifier is `AppJS`.
- A module's scripts are loaded for the `JsCollocation3` component (`JsCollocation3.razor`).
- The `JsCollocation3` component is in the `Components/Pages` folder of the RCL.

C#

```
module = await JS.InvokeAsync<IJSObjectReference>("import",
    "./_content/AppJS/Components/Pages/JsCollocation3.razor.js");
```

For more information on RCLs, see Consume ASP.NET Core Razor components from a Razor class library (RCL).

Load a script from an external JavaScript file (`.js`)

Place the JavaScript (JS) tags (`<script>...</script>`) with a script source (`src`) path inside the closing </body> element after the Blazor script reference:

HTML

```
<body>
    ...

    <script src="{BLAZOR SCRIPT}"></script>
    <script src="{SCRIPT PATH AND FILE NAME (.js)}"></script>
</body>
```

For the placeholders in the preceding example:

- The `{BLAZOR SCRIPT}` placeholder is the Blazor script path and file name. For the location of the script, see ASP.NET Core Blazor project structure.

- The `{SCRIPT PATH AND FILE NAME (.js)}` placeholder is the path and script file name under `wwwroot`.

In the following example of the preceding `<script>` tag, the `scripts.js` file is in the `wwwroot/js` folder of the app:

HTML

```
<script src="js/scripts.js"></script>
```

You can also serve scripts directly from the `wwwroot` folder if you prefer not to keep all of your scripts in a separate folder under `wwwroot`:

HTML

```
<script src="scripts.js"></script>
```

When the external JS file is supplied by a Razor class library, specify the JS file using its stable static web asset path: `_content/{PACKAGE ID}/{SCRIPT PATH AND FILE NAME (.js)}`:

- The `{PACKAGE ID}` placeholder is the library's package ID. The package ID defaults to the project's assembly name if `<PackageId>` isn't specified in the project file.
- The `{SCRIPT PATH AND FILE NAME (.js)}` placeholder is the path and file name under `wwwroot`.

HTML

```
<body>
    ...

    <script src="{BLAZOR SCRIPT}"></script>
    <script src="_content/{PACKAGE ID}/{SCRIPT PATH AND FILE NAME (.js)}">
</script>
</body>
```

In the following example of the preceding `<script>` tag:

- The Razor class library has an assembly name of `ComponentLibrary`, and a `<PackageId>` isn't specified in the library's project file.
- The `scripts.js` file is in the class library's `wwwroot` folder.

HTML

```
<script src="_content/ComponentLibrary/scripts.js"></script>
```

For more information, see Consume ASP.NET Core Razor components from a Razor class library (RCL).

Inject a script before or after Blazor starts

To ensure scripts load before or after Blazor starts, use a JavaScript initializer. For more information and examples, see ASP.NET Core Blazor startup.

JavaScript isolation in JavaScript modules

Blazor enables JavaScript (JS) isolation in standard JS modules (ECMAScript specification).

JS isolation provides the following benefits:

- Imported JS no longer pollutes the global namespace.
- Consumers of a library and components aren't required to import the related JS.

For more information, see Call JavaScript functions from .NET methods in ASP.NET Core Blazor.

Dynamic import with the import() operator is supported with ASP.NET Core and Blazor:

JavaScript

```
if ({CONDITION}) import("/additionalModule.js");
```

In the preceding example, the `{CONDITION}` placeholder represents a conditional check to determine if the module should be loaded.

For browser compatibility, see Can I use: JavaScript modules: dynamic import.

Call JavaScript functions from .NET methods in ASP.NET Core Blazor

Article • 10/18/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article explains how to invoke JavaScript (JS) functions from .NET.

For information on how to call .NET methods from JS, see Call .NET methods from JavaScript functions in ASP.NET Core Blazor.

Invoke JS functions

IJSRuntime is registered by the Blazor framework. To call into JS from .NET, inject the IJSRuntime abstraction and call one of the following methods:

- IJSRuntime.InvokeAsync
- JSRuntimeExtensions.InvokeAsync
- JSRuntimeExtensions.InvokeVoidAsync

For the preceding .NET methods that invoke JS functions:

- The function identifier (`String`) is relative to the global scope (`window`). To call `window.someScope.someFunction`, the identifier is `someScope.someFunction`. There's no need to register the function before it's called.
- Pass any number of JSON-serializable arguments in `Object[]` to a JS function.
- The cancellation token (`CancellationToken`) propagates a notification that operations should be canceled.
- `TimeSpan` represents a time limit for a JS operation.
- The `TValue` return type must also be JSON serializable. `TValue` should match the .NET type that best maps to the JSON type returned.
- A JS Promise is returned for `InvokeAsync` methods. `InvokeAsync` unwraps the Promise and returns the value awaited by the Promise.

For Blazor apps with prerendering enabled, which is the default for server-side apps, calling into JS isn't possible during prerendering. For more information, see the Prerendering section.

The following example is based on TextDecoder, a JS-based decoder. The example demonstrates how to invoke a JS function from a C# method that offloads a requirement from developer code to an existing JS API. The JS function accepts a byte array from a C# method, decodes the array, and returns the text to the component for display.

HTML

```
<script>
  window.convertArray = (win1251Array) => {
    var win1251decoder = new TextDecoder('windows-1251');
    var bytes = new Uint8Array(win1251Array);
    var decodedArray = win1251decoder.decode(bytes);
    return decodedArray;
  };
</script>
```

> **Note**
>
> For general guidance on JS location and our recommendations for production apps, see JavaScript location in ASP.NET Core Blazor apps.

The following component:

- Invokes the `convertArray` JS function with InvokeAsync when selecting a button (**`Convert Array`**).
- After the JS function is called, the passed array is converted into a string. The string is returned to the component for display (`text`).

`CallJs1.razor`:

razor

```
@page "/call-js-1"
@inject IJSRuntime JS

<PageTitle>Call JS 1</PageTitle>

<h1>Call JS Example 1</h1>

<p>
    <button @onclick="ConvertArray">Convert Array</button>
```

```
</p>

<p>
    @text
</p>

<p>
    Quote ©2005 <a href="https://www.uphe.com">Universal Pictures</a>:
    <a href="https://www.uphe.com/movies/serenity-2005">Serenity</a><br>
    <a href="https://www.imdb.com/name/nm0472710/">David Krumholtz on
IMDB</a>
</p>

@code {
    private MarkupString text;

    private uint[] quoteArray =
        new uint[]
        {
            60, 101, 109, 62, 67, 97, 110, 39, 116, 32, 115, 116, 111, 112,
32,
            116, 104, 101, 32, 115, 105, 103, 110, 97, 108, 44, 32, 77, 97,
            108, 46, 60, 47, 101, 109, 62, 32, 45, 32, 77, 114, 46, 32, 85,
110,
            105, 118, 101, 114, 115, 101, 10, 10,
        };

    private async Task ConvertArray() =>
        text = new(await JS.InvokeAsync<string>("convertArray",
quoteArray));
}
```

JavaScript API restricted to user gestures

This section applies to server-side components.

Some browser JavaScript (JS) APIs can only be executed in the context of a user gesture, such as using the Fullscreen API (MDN documentation). These APIs can't be called through the JS interop mechanism in server-side components because UI event handling is performed asynchronously and generally no longer in the context of the user gesture. The app must handle the UI event completely in JavaScript, so use `onclick` instead of Blazor's `@onclick` directive attribute.

Invoke JavaScript functions without reading a returned value (`InvokeVoidAsync`)

Use InvokeVoidAsync when:

- .NET isn't required to read the result of a JavaScript (JS) call.
- JS functions return void(0)/void 0 or undefined.

Provide a `displayTickerAlert1` JS function. The function is called with InvokeVoidAsync and doesn't return a value:

HTML

```
<script>
  window.displayTickerAlert1 = (symbol, price) => {
    alert(`${symbol}: $${price}!`);
  };
</script>
```

> **Note**
>
> For general guidance on JS location and our recommendations for production apps, see JavaScript location in ASP.NET Core Blazor apps.

Component (`.razor`) example (`InvokeVoidAsync`)

`TickerChanged` calls the `handleTickerChanged1` method in the following component.

`CallJs2.razor`:

razor

```
@page "/call-js-2"
@inject IJSRuntime JS

<PageTitle>Call JS 2</PageTitle>

<h1>Call JS Example 2</h1>

<p>
    <button @onclick="SetStock">Set Stock</button>
</p>

@if (stockSymbol is not null)
{
    <p>@stockSymbol price: @price.ToString("c")</p>
}

@code {
    private string? stockSymbol;
    private decimal price;
```

```
    private async Task SetStock()
    {
        stockSymbol =
            $"{(char)('A' + Random.Shared.Next(0, 26))}" +
            $"{(char)('A' + Random.Shared.Next(0, 26))}";
        price = Random.Shared.Next(1, 101);
        await JS.InvokeVoidAsync("displayTickerAlert1", stockSymbol, price);
    }
}
```

Class (`.cs`) example (`InvokeVoidAsync`)

`JsInteropClasses1.cs`:

C#

```
using Microsoft.JSInterop;

namespace BlazorSample;

public class JsInteropClasses1(IJSRuntime js) : IDisposable
{
    private readonly IJSRuntime js = js;

    public async ValueTask TickerChanged(string symbol, decimal price) =>
        await js.InvokeVoidAsync("displayTickerAlert1", symbol, price);

    // Calling SuppressFinalize(this) prevents derived types that introduce
    // a finalizer from needing to re-implement IDisposable.
    public void Dispose() => GC.SuppressFinalize(this);
}
```

`TickerChanged` calls the `handleTickerChanged1` method in the following component.

`CallJs3.razor`:

razor

```
@page "/call-js-3"
@implements IDisposable
@inject IJSRuntime JS

<PageTitle>Call JS 3</PageTitle>

<h1>Call JS Example 3</h1>

<p>
    <button @onclick="SetStock">Set Stock</button>
</p>
```

```
@if (stockSymbol is not null)
{
    <p>@stockSymbol price: @price.ToString("c")</p>
}

@code {
    private string? stockSymbol;
    private decimal price;
    private JsInteropClasses1? jsClass;

    protected override void OnInitialized() => jsClass = new(JS);

    private async Task SetStock()
    {
        if (jsClass is not null)
        {
            stockSymbol =
                $"{(char)('A' + Random.Shared.Next(0, 26))}" +
                $"{(char)('A' + Random.Shared.Next(0, 26))}";
            price = Random.Shared.Next(1, 101);
            await jsClass.TickerChanged(stockSymbol, price);
        }
    }

    public void Dispose() => jsClass?.Dispose();
}
```

Invoke JavaScript functions and read a returned value (`InvokeAsync`)

Use InvokeAsync when .NET should read the result of a JavaScript (JS) call.

Provide a `displayTickerAlert2` JS function. The following example returns a string for display by the caller:

HTML

```
<script>
  window.displayTickerAlert2 = (symbol, price) => {
    if (price < 20) {
      alert(`${symbol}: $${price}!`);
      return "User alerted in the browser.";
    } else {
      return "User NOT alerted.";
    }
  };
</script>
```

> ⓘ Note
>
> For general guidance on JS location and our recommendations for production apps, see JavaScript location in ASP.NET Core Blazor apps.

Component (`.razor`) example (`InvokeAsync`)

`TickerChanged` calls the `handleTickerChanged2` method and displays the returned string in the following component.

`CallJs4.razor`:

razor

```
@page "/call-js-4"
@inject IJSRuntime JS

<PageTitle>Call JS 4</PageTitle>

<h1>Call JS Example 4</h1>

<p>
    <button @onclick="SetStock">Set Stock</button>
</p>

@if (stockSymbol is not null)
{
    <p>@stockSymbol price: @price.ToString("c")</p>
}

@if (result is not null)
{
    <p>@result</p>
}

@code {
    private string? stockSymbol;
    private decimal price;
    private string? result;

    private async Task SetStock()
    {
        stockSymbol =
            $"{(char)('A' + Random.Shared.Next(0, 26))}" +
            $"{(char)('A' + Random.Shared.Next(0, 26))}";
        price = Random.Shared.Next(1, 101);
        var interopResult =
            await JS.InvokeAsync<string>("displayTickerAlert2", stockSymbol,
price);
```

```
        result = $"Result of TickerChanged call for {stockSymbol} at " +
            $"{price.ToString("c")}: {interopResult}";
    }
}
```

Class (`.cs`) example (`InvokeAsync`)

`JsInteropClasses2.cs`:

C#

```
using Microsoft.JSInterop;

namespace BlazorSample;

public class JsInteropClasses2(IJSRuntime js) : IDisposable
{
    private readonly IJSRuntime js = js;

    public async ValueTask<string> TickerChanged(string symbol, decimal
price) =>
        await js.InvokeAsync<string>("displayTickerAlert2", symbol, price);

    // Calling SuppressFinalize(this) prevents derived types that introduce
    // a finalizer from needing to re-implement IDisposable.
    public void Dispose() => GC.SuppressFinalize(this);
}
```

`TickerChanged` calls the `handleTickerChanged2` method and displays the returned string in the following component.

`CallJs5.razor`:

razor

```
@page "/call-js-5"
@implements IDisposable
@inject IJSRuntime JS

<PageTitle>Call JS 5</PageTitle>

<h1>Call JS Example 5</h1>

<p>
    <button @onclick="SetStock">Set Stock</button>
</p>

@if (stockSymbol is not null)
{
```

```
    <p>@stockSymbol price: @price.ToString("c")</p>
}

@if (result is not null)
{
    <p>@result</p>
}

@code {
    private string? stockSymbol;
    private decimal price;
    private JsInteropClasses2? jsClass;
    private string? result;

    protected override void OnInitialized() => jsClass = new(JS);

    private async Task SetStock()
    {
        if (jsClass is not null)
        {
            stockSymbol =
                $"{(char)('A' + Random.Shared.Next(0, 26))}" +
                $"{(char)('A' + Random.Shared.Next(0, 26))}";
            price = Random.Shared.Next(1, 101);
            var interopResult = await jsClass.TickerChanged(stockSymbol,
price);
            result = $"Result of TickerChanged call for {stockSymbol} at " +
                $"{price.ToString("c")}: {interopResult}";
        }
    }

    public void Dispose() => jsClass?.Dispose();
}
```

Dynamic content generation scenarios

For dynamic content generation with BuildRenderTree, use the `[Inject]` attribute:

razor

```
[Inject]
IJSRuntime JS { get; set; }
```

Prerendering

This section applies to server-side apps that prerender Razor components. Prerendering is covered in Prerender ASP.NET Core Razor components.

> **Note**
>
> Internal navigation for **interactive routing** in Blazor Web Apps doesn't involve requesting new page content from the server. Therefore, prerendering doesn't occur for internal page requests. If the app adopts interactive routing, perform a full page reload for component examples that demonstrate prerendering behavior. For more information, see **Prerender ASP.NET Core Razor components**.

During prerendering, calling into JavaScript (JS) isn't possible. The following example demonstrates how to use JS interop as part of a component's initialization logic in a way that's compatible with prerendering.

The following `scrollElementIntoView` function:

- Scrolls to the passed element with scrollIntoView.
- Returns the element's `top` property value from the getBoundingClientRect method.

JavaScript

```
window.scrollElementIntoView = (element) => {
  element.scrollIntoView();
  return element.getBoundingClientRect().top;
}
```

Where IJSRuntime.InvokeAsync calls the JS function in component code, the ElementReference is only used in OnAfterRenderAsync and not in any earlier lifecycle method because there's no HTML DOM element until after the component is rendered.

StateHasChanged (reference source) is called to enqueue rerendering of the component with the new state obtained from the JS interop call (for more information, see ASP.NET Core Razor component rendering). An infinite loop isn't created because StateHasChanged is only called when `scrollPosition` is `null`.

`PrerenderedInterop.razor`:

razor

```
@page "/prerendered-interop"
@using Microsoft.AspNetCore.Components
@using Microsoft.JSInterop
@inject IJSRuntime JS

<PageTitle>Prerendered Interop</PageTitle>
```

```razor
<h1>Prerendered Interop Example</h1>

<div @ref="divElement" style="margin-top:2000px">
    Set value via JS interop call: <strong>@scrollPosition</strong>
</div>

@code {
    private ElementReference divElement;
    private double? scrollPosition;

    protected override async Task OnAfterRenderAsync(bool firstRender)
    {
        if (firstRender && scrollPosition is null)
        {
            scrollPosition = await JS.InvokeAsync<double>(
                "scrollElementIntoView", divElement);

            StateHasChanged();
        }
    }
}
```

The preceding example pollutes the client with a global function. For a better approach in production apps, see JavaScript isolation in JavaScript modules.

Synchronous JS interop in client-side components

This section only applies to client-side components.

JS interop calls are asynchronous, regardless of whether the called code is synchronous or asynchronous. Calls are asynchronous to ensure that components are compatible across server-side and client-side render modes. On the server, all JS interop calls must be asynchronous because they're sent over a network connection.

If you know for certain that your component only runs on WebAssembly, you can choose to make synchronous JS interop calls. This has slightly less overhead than making asynchronous calls and can result in fewer render cycles because there's no intermediate state while awaiting results.

To make a synchronous call from .NET to JavaScript in a client-side component, cast IJSRuntime to IJSInProcessRuntime to make the JS interop call:

razor

```razor
@inject IJSRuntime JS
```

```
...

@code {
    protected override void HandleSomeEvent()
    {
        var jsInProcess = (IJSInProcessRuntime)JS;
        var value = jsInProcess.Invoke<string>
("javascriptFunctionIdentifier");
    }
}
```

When working with IJSObjectReference in ASP.NET Core 5.0 or later client-side components, you can use IJSInProcessObjectReference synchronously instead. IJSInProcessObjectReference implements IAsyncDisposable/IDisposable and should be disposed for garbage collection to prevent a memory leak, as the following example demonstrates:

razor

```
@inject IJSRuntime JS
@implements IAsyncDisposable

...

@code {
    ...
    private IJSInProcessObjectReference? module;

    protected override async Task OnAfterRenderAsync(bool firstRender)
    {
        if (firstRender)
        {
            module = await JS.InvokeAsync<IJSInProcessObjectReference>
("import",
            "./scripts.js");
        }
    }

    ...

    async ValueTask IAsyncDisposable.DisposeAsync()
    {
        if (module is not null)
        {
            await module.DisposeAsync();
        }
    }
}
```

JavaScript location

Load JavaScript (JS) code using any of approaches described by the article on JavaScript location:

- Load a script in <head> markup (*Not generally recommended*)
- Load a script in <body> markup
- Load a script from an external JavaScript file (.js) collocated with a component
- Load a script from an external JavaScript file (.js)
- Inject a script before or after Blazor starts

For information on isolating scripts in JS modules, see the JavaScript isolation in JavaScript modules section.

> ⚠ **Warning**
>
> Only place a `<script>` tag in a component file (`.razor`) if the component is guaranteed to adopt static server-side rendering (static SSR) because the `<script>` tag can't be updated dynamically.

JavaScript isolation in JavaScript modules

Blazor enables JavaScript (JS) isolation in standard JavaScript modules (ECMAScript specification). JavaScript module loading works the same way in Blazor as it does for other types of web apps, and you're free to customize how modules are defined in your app. For a guide on how to use JavaScript modules, see MDN Web Docs: JavaScript modules.

JS isolation provides the following benefits:

- Imported JS no longer pollutes the global namespace.
- Consumers of a library and components aren't required to import the related JS.

Dynamic import with the import() operator is supported with ASP.NET Core and Blazor:

JavaScript

```
if ({CONDITION}) import("/additionalModule.js");
```

In the preceding example, the `{CONDITION}` placeholder represents a conditional check to determine if the module should be loaded.

For browser compatibility, see Can I use: JavaScript modules: dynamic import.

For example, the following JS module exports a JS function for showing a browser window prompt. Place the following JS code in an external JS file.

`wwwroot/scripts.js`:

JavaScript

```
export function showPrompt(message) {
  return prompt(message, 'Type anything here');
}
```

Add the preceding JS module to an app or class library as a static web asset in the `wwwroot` folder and then import the module into the .NET code by calling InvokeAsync on the IJSRuntime instance.

IJSRuntime imports the module as an IJSObjectReference, which represents a reference to a JS object from .NET code. Use the IJSObjectReference to invoke exported JS functions from the module.

`CallJs6.razor`:

razor

```
@page "/call-js-6"
@implements IAsyncDisposable
@inject IJSRuntime JS

<PageTitle>Call JS 6</PageTitle>

<h1>Call JS Example 6</h1>

<p>
    <button @onclick="TriggerPrompt">Trigger browser window prompt</button>
</p>

<p>
    @result
</p>

@code {
    private IJSObjectReference? module;
    private string? result;

    protected override async Task OnAfterRenderAsync(bool firstRender)
    {
        if (firstRender)
        {
            module = await JS.InvokeAsync<IJSObjectReference>("import",
```

```
                "./scripts.js");
        }
    }

    private async Task TriggerPrompt() => result = await Prompt("Provide
text");

    public async ValueTask<string?> Prompt(string message) =>
        module is not null ?
            await module.InvokeAsync<string>("showPrompt", message) : null;

    async ValueTask IAsyncDisposable.DisposeAsync()
    {
        if (module is not null)
        {
            await module.DisposeAsync();
        }
    }
}
```

In the preceding example:

- By convention, the `import` identifier is a special identifier used specifically for importing a JS module.
- Specify the module's external JS file using its stable static web asset path: `./{SCRIPT PATH AND FILE NAME (.js)}`, where:
  - The path segment for the current directory (`./`) is required in order to create the correct static asset path to the JS file.
  - The `{SCRIPT PATH AND FILE NAME (.js)}` placeholder is the path and file name under `wwwroot`.
- Disposes the IJSObjectReference for garbage collection in IAsyncDisposable.DisposeAsync.

Dynamically importing a module requires a network request, so it can only be achieved asynchronously by calling InvokeAsync.

`IJSInProcessObjectReference` represents a reference to a JS object whose functions can be invoked synchronously in client-side components. For more information, see the Synchronous JS interop in client-side components section.

> ⓘ **Note**
>
> When the external JS file is supplied by a Razor class library, specify the module's JS file using its stable static web asset path: `./_content/{PACKAGE ID}/{SCRIPT PATH AND FILE NAME (.js)}`:

- The path segment for the current directory (`./`) is required in order to create the correct static asset path to the JS file.
- The `{PACKAGE ID}` placeholder is the library's package ID. The package ID defaults to the project's assembly name if `<PackageId>` isn't specified in the project file. In the following example, the library's assembly name is `ComponentLibrary` and the library's project file doesn't specify `<PackageId>`.
- The `{SCRIPT PATH AND FILE NAME (.js)}` placeholder is the path and file name under `wwwroot`. In the following example, the external JS file (`script.js`) is placed in the class library's `wwwroot` folder.
- `module` is a private nullable IJSObjectReference of the component class (`private IJSObjectReference? module;`).

C#

```
module = await js.InvokeAsync<IJSObjectReference>(
    "import", "./_content/ComponentLibrary/scripts.js");
```

For more information, see Consume ASP.NET Core Razor components from a Razor class library (RCL).

Throughout the Blazor documentation, examples use the `.js` file extension for module files, not the newer .mjs file extension (RFC 9239). Our documentation continues to use the `.js` file extension for the same reasons the Mozilla Foundation's documentation continues to use the `.js` file extension. For more information, see Aside — .mjs versus .js (MDN documentation).

Capture references to elements

Some JavaScript (JS) interop scenarios require references to HTML elements. For example, a UI library may require an element reference for initialization, or you might need to call command-like APIs on an element, such as `click` or `play`.

Capture references to HTML elements in a component using the following approach:

- Add an `@ref` attribute to the HTML element.
- Define a field of type ElementReference whose name matches the value of the `@ref` attribute.

The following example shows capturing a reference to the `username` `<input>` element:

razor

```razor
<input @ref="username" ... />

@code {
    private ElementReference username;
}
```

> ⚠ **Warning**
>
> Only use an element reference to mutate the contents of an empty element that doesn't interact with Blazor. This scenario is useful when a third-party API supplies content to the element. Because Blazor doesn't interact with the element, there's no possibility of a conflict between Blazor's representation of the element and the DOM.
>
> In the following example, it's *dangerous* to mutate the contents of the unordered list (`ul`) using `MyList` via JS interop because Blazor interacts with the DOM to populate this element's list items (`<li>`) from the `Todos` object:
>
> razor
>
> ```razor
> <ul @ref="MyList">
>     @foreach (var item in Todos)
>     {
>         <li>@item.Text</li>
>     }
> </ul>
> ```
>
> Using the `MyList` element reference to merely read DOM content or trigger an event is supported.
>
> If JS interop *mutates the contents* of element `MyList` and Blazor attempts to apply diffs to the element, the diffs won't match the DOM. Modifying the contents of the list via JS interop with the `MyList` element reference is ***not supported***.
>
> For more information, see ASP.NET Core Blazor JavaScript interoperability (JS interop).

An ElementReference is passed through to JS code via JS interop. The JS code receives an HTMLElement instance, which it can use with normal DOM APIs. For example, the following code defines a .NET extension method (`TriggerClickEvent`) that enables sending a mouse click to an element.

The JS function `clickElement` creates a click event on the passed HTML element (`element`):

JavaScript

```
window.interopFunctions = {
  clickElement : function (element) {
    element.click();
  }
}
```

To call a JS function that doesn't return a value, use JSRuntimeExtensions.InvokeVoidAsync. The following code triggers a client-side click event by calling the preceding JS function with the captured ElementReference:

razor

```
@inject IJSRuntime JS

<button @ref="exampleButton">Example Button</button>

<button @onclick="TriggerClick">
    Trigger click event on <code>Example Button</code>
</button>

@code {
    private ElementReference exampleButton;

    public async Task TriggerClick()
    {
        await JS.InvokeVoidAsync(
            "interopFunctions.clickElement", exampleButton);
    }
}
```

To use an extension method, create a static extension method that receives the IJSRuntime instance:

C#

```
public static async Task TriggerClickEvent(this ElementReference elementRef,
    IJSRuntime js)
{
    await js.InvokeVoidAsync("interopFunctions.clickElement", elementRef);
}
```

The `clickElement` method is called directly on the object. The following example assumes that the `TriggerClickEvent` method is available from the `JsInteropClasses`

namespace:

```razor
@inject IJSRuntime JS
@using JsInteropClasses

<button @ref="exampleButton">Example Button</button>

<button @onclick="TriggerClick">
    Trigger click event on <code>Example Button</code>
</button>

@code {
    private ElementReference exampleButton;

    public async Task TriggerClick()
    {
        await exampleButton.TriggerClickEvent(JS);
    }
}
```

> **ⓘ Important**
>
> The `exampleButton` variable is only populated after the component is rendered. If an unpopulated **ElementReference** is passed to JS code, the JS code receives a value of `null`. To manipulate element references after the component has finished rendering, use the **OnAfterRenderAsync or OnAfterRender component lifecycle methods**.

When working with generic types and returning a value, use ValueTask<TResult>:

```C#
public static ValueTask<T> GenericMethod<T>(
        this ElementReference elementRef, IJSRuntime js) =>
    js.InvokeAsync<T>("{JAVASCRIPT FUNCTION}", elementRef);
```

The `{JAVASCRIPT FUNCTION}` placeholder is the JS function identifier.

`GenericMethod` is called directly on the object with a type. The following example assumes that the `GenericMethod` is available from the `JsInteropClasses` namespace:

```razor
```

```
@inject IJSRuntime JS
@using JsInteropClasses

<input @ref="username" />

<button @onclick="OnClickMethod">Do something generic</button>

<p>
    returnValue: @returnValue
</p>

@code {
    private ElementReference username;
    private string? returnValue;

    private async Task OnClickMethod()
    {
        returnValue = await username.GenericMethod<string>(JS);
    }
}
```

Reference elements across components

An ElementReference can't be passed between components because:

- The instance is only guaranteed to exist after the component is rendered, which is during or after a component's OnAfterRender/OnAfterRenderAsync method executes.
- An ElementReference is a struct, which can't be passed as a component parameter.

For a parent component to make an element reference available to other components, the parent component can:

- Allow child components to register callbacks.
- Invoke the registered callbacks during the OnAfterRender event with the passed element reference. Indirectly, this approach allows child components to interact with the parent's element reference.

HTML

```
<style>
    .red { color: red }
</style>
```

HTML

```
<script>
  function setElementClass(element, className) {
    var myElement = element;
    myElement.classList.add(className);
  }
</script>
```

> **Note**
>
> For general guidance on JS location and our recommendations for production apps, see JavaScript location in ASP.NET Core Blazor apps.

`CallJs7.razor` (parent component):

razor

```
@page "/call-js-7"

<PageTitle>Call JS 7</PageTitle>

<h1>Call JS Example 7</h1>

<h2 @ref="title">Hello, world!</h2>

Welcome to your new app.

<SurveyPrompt Parent="this" Title="How is Blazor working for you?" />
```

`CallJs7.razor.cs`:

C#

```
using Microsoft.AspNetCore.Components;

namespace BlazorSample.Pages;

public partial class CallJs7 :
    ComponentBase, IObservable<ElementReference>, IDisposable
{
    private bool disposing;
    private readonly List<IObserver<ElementReference>> subscriptions = [];
    private ElementReference title;

    protected override void OnAfterRender(bool firstRender)
    {
        base.OnAfterRender(firstRender);

        foreach (var subscription in subscriptions)
```

```
            {
                subscription.OnNext(title);
            }
        }

        public void Dispose()
        {
            disposing = true;

            foreach (var subscription in subscriptions)
            {
                try
                {
                    subscription.OnCompleted();
                }
                catch (Exception)
                {
                }
            }

            subscriptions.Clear();

            // The following prevents derived types that introduce a
            // finalizer from needing to re-implement IDisposable.
            GC.SuppressFinalize(this);
        }

        public IDisposable Subscribe(IObserver<ElementReference> observer)
        {
            if (disposing)
            {
                throw new InvalidOperationException("Parent being disposed");
            }

            subscriptions.Add(observer);

            return new Subscription(observer, this);
        }

        private class Subscription(IObserver<ElementReference> observer,
            CallJs7 self) : IDisposable
        {
            public IObserver<ElementReference> Observer { get; } = observer;
            public CallJs7 Self { get; } = self;

            public void Dispose() => Self.subscriptions.Remove(Observer);
        }
    }
```

In the preceding example, the namespace of the app is `BlazorSample`. If testing the code locally, update the namespace.

`SurveyPrompt.razor` (child component):

razor

```razor
<div class="alert alert-secondary mt-4">
    <span class="oi oi-pencil me-2" aria-hidden="true"></span>
    <strong>@Title</strong>

    <span class="text-nowrap">
        Please take our
        <a target="_blank" class="font-weight-bold link-dark"
href="https://go.microsoft.com/fwlink/?linkid=2186158">brief survey</a>
    </span>
    and tell us what you think.
</div>

@code {
    // Demonstrates how a parent component can supply parameters
    [Parameter]
    public string? Title { get; set; }
}
```

`SurveyPrompt.razor.cs`:

C#

```
using Microsoft.AspNetCore.Components;
using Microsoft.JSInterop;

namespace BlazorSample.Components;

public partial class SurveyPrompt :
    ComponentBase, IObserver<ElementReference>, IDisposable
{
    private IDisposable? subscription = null;

    [Parameter]
    public IObservable<ElementReference>? Parent { get; set; }

    [Inject]
    public IJSRuntime? JS {get; set;}

    protected override void OnParametersSet()
    {
        base.OnParametersSet();

        subscription?.Dispose();
        subscription = Parent?.Subscribe(this);
    }

    public void OnCompleted() => subscription = null;

    public void OnError(Exception error) => subscription = null;

    public void OnNext(ElementReference value) =>
```

```
        _ = (JS?.InvokeAsync<object>("setElementClass", [value, "red"]));

    public void Dispose()
    {
        subscription?.Dispose();

        // The following prevents derived types that introduce a
        // finalizer from needing to re-implement IDisposable.
        GC.SuppressFinalize(this);
    }
}
```

In the preceding example, the namespace of the app is `BlazorSample` with shared components in the `Shared` folder. If testing the code locally, update the namespace.

Harden JavaScript interop calls

This section only applies to Interactive Server components, but client-side components may also set JS interop timeouts if conditions warrant it.

In server-side apps with server interactivity, JavaScript (JS) interop may fail due to networking errors and should be treated as unreliable. Blazor apps use a one minute timeout for JS interop calls. If an app can tolerate a more aggressive timeout, set the timeout using one of the following approaches.

Set a global timeout in the `Program.cs` with CircuitOptions.JSInteropDefaultCallTimeout:

C#

```
builder.Services.AddRazorComponents()
    .AddInteractiveServerComponents(options =>
        options.JSInteropDefaultCallTimeout = {TIMEOUT});
```

The `{TIMEOUT}` placeholder is a TimeSpan (for example, `TimeSpan.FromSeconds(80)`).

Set a per-invocation timeout in component code. The specified timeout overrides the global timeout set by JSInteropDefaultCallTimeout:

C#

```
var result = await JS.InvokeAsync<string>("{ID}", {TIMEOUT}, new[] { "Arg1"
});
```

In the preceding example:

- The `{TIMEOUT}` placeholder is a TimeSpan (for example, `TimeSpan.FromSeconds(80)`).
- The `{ID}` placeholder is the identifier for the function to invoke. For example, the value `someScope.someFunction` invokes the function `window.someScope.someFunction`.

Although a common cause of JS interop failures are network failures with server-side components, per-invocation timeouts can be set for JS interop calls for client-side components. Although no SignalR circuit exists for a client-side component, JS interop calls might fail for other reasons that apply.

For more information on resource exhaustion, see Threat mitigation guidance for ASP.NET Core Blazor interactive server-side rendering.

Avoid circular object references

Objects that contain circular references can't be serialized on the client for either:

- .NET method calls.
- JavaScript method calls from C# when the return type has circular references.

JavaScript libraries that render UI

Sometimes you may wish to use JavaScript (JS) libraries that produce visible user interface elements within the browser DOM. At first glance, this might seem difficult because Blazor's diffing system relies on having control over the tree of DOM elements and runs into errors if some external code mutates the DOM tree and invalidates its mechanism for applying diffs. This isn't a Blazor-specific limitation. The same challenge occurs with any diff-based UI framework.

Fortunately, it's straightforward to embed externally-generated UI within a Razor component UI reliably. The recommended technique is to have the component's code (`.razor` file) produce an empty element. As far as Blazor's diffing system is concerned, the element is always empty, so the renderer does not recurse into the element and instead leaves its contents alone. This makes it safe to populate the element with arbitrary externally-managed content.

The following example demonstrates the concept. Within the `if` statement when `firstRender` is `true`, interact with `unmanagedElement` outside of Blazor using JS interop. For example, call an external JS library to populate the element. Blazor leaves the element's contents alone until this component is removed. When the component is removed, the component's entire DOM subtree is also removed.

razor

```razor
<h1>Hello! This is a Razor component rendered at @DateTime.Now</h1>

<div @ref="unmanagedElement"></div>

@code {
    private ElementReference unmanagedElement;

    protected override async Task OnAfterRenderAsync(bool firstRender)
    {
        if (firstRender)
        {
            ...
        }
    }
}
```

Consider the following example that renders an interactive map using open-source Mapbox APIs.

The following JS module is placed into the app or made available from a Razor class library.

> **Note**
>
> To create the Mapbox map, obtain an access token from Mapbox Sign in and provide it where the `{ACCESS TOKEN}` appears in the following code.

`wwwroot/mapComponent.js`:

JavaScript

```javascript
import 'https://api.mapbox.com/mapbox-gl-js/v1.12.0/mapbox-gl.js';

mapboxgl.accessToken = '{ACCESS TOKEN}';

export function addMapToElement(element) {
  return new mapboxgl.Map({
    container: element,
    style: 'mapbox://styles/mapbox/streets-v11',
    center: [-74.5, 40],
    zoom: 9
  });
}

export function setMapCenter(map, latitude, longitude) {
```

```
  map.setCenter([longitude, latitude]);
}
```

To produce correct styling, add the following stylesheet tag to the host HTML page.

Add the following `<link>` element to the `<head>` element markup (location of <head> content):

HTML

```
<link href="https://api.mapbox.com/mapbox-gl-js/v1.12.0/mapbox-gl.css"
    rel="stylesheet" />
```

`CallJs8.razor`:

razor

```
@page "/call-js-8"
@implements IAsyncDisposable
@inject IJSRuntime JS

<PageTitle>Call JS 8</PageTitle>

<HeadContent>
    <link href="https://api.mapbox.com/mapbox-gl-js/v1.12.0/mapbox-gl.css"
        rel="stylesheet" />
</HeadContent>

<h1>Call JS Example 8</h1>

<div @ref="mapElement" style='width:400px;height:300px'></div>

<button @onclick="() => ShowAsync(51.454514, -2.587910)">Show Bristol,
UK</button>
<button @onclick="() => ShowAsync(35.6762, 139.6503)">Show Tokyo,
Japan</button>

@code
{
    private ElementReference mapElement;
    private IJSObjectReference? mapModule;
    private IJSObjectReference? mapInstance;

    protected override async Task OnAfterRenderAsync(bool firstRender)
    {
        if (firstRender)
        {
            mapModule = await JS.InvokeAsync<IJSObjectReference>(
                "import", "./mapComponent.js");
            mapInstance = await mapModule.InvokeAsync<IJSObjectReference>(
                "addMapToElement", mapElement);
```

```
        }
    }

    private async Task ShowAsync(double latitude, double longitude)
    {
        if (mapModule is not null && mapInstance is not null)
        {
            await mapModule.InvokeVoidAsync("setMapCenter", mapInstance,
                latitude, longitude);
        }
    }

    async ValueTask IAsyncDisposable.DisposeAsync()
    {
        if (mapInstance is not null)
        {
            await mapInstance.DisposeAsync();
        }

        if (mapModule is not null)
        {
            await mapModule.DisposeAsync();
        }
    }
}
```

The preceding example produces an interactive map UI. The user:

- Can drag to scroll or zoom.
- Select buttons to jump to predefined locations.

In the preceding example:

- The `<div>` with `@ref="mapElement"` is left empty as far as Blazor is concerned. The `mapbox-gl.js` script can safely populate the element and modify its contents. Use this technique with any JS library that renders UI. You can embed components from a third-party JS SPA framework inside Razor components, as long as they don't try to reach out and modify other parts of the page. It is **not** safe for external JS code to modify elements that Blazor does not regard as empty.
- When using this approach, bear in mind the rules about how Blazor retains or destroys DOM elements. The component safely handles button click events and updates the existing map instance because DOM elements are retained where possible. If you were rendering a list of map elements from inside a `@foreach` loop, you want to use `@key` to ensure the preservation of component instances. Otherwise, changes in the list data could cause component instances to retain the state of previous instances in an undesirable manner. For more information, see how to use the @key directive attribute to preserve the relationship among elements, components, and model objects.
- The example encapsulates JS logic and dependencies within a JavaScript module and loads the module dynamically using the `import` identifier. For more information, see JavaScript isolation in JavaScript modules.

Byte array support

Blazor supports optimized byte array JavaScript (JS) interop that avoids encoding/decoding byte arrays into Base64. The following example uses JS interop to pass a byte array to JavaScript.

Provide a `receiveByteArray` JS function. The function is called with InvokeVoidAsync and doesn't return a value:

HTML

```
<script>
  window.receiveByteArray = (bytes) => {
    let utf8decoder = new TextDecoder();
    let str = utf8decoder.decode(bytes);
    return str;
  };
</script>
```

> ⓘ Note
>
> For general guidance on JS location and our recommendations for production apps, see JavaScript location in ASP.NET Core Blazor apps.

`CallJs9.razor`:

razor

```
@page "/call-js-9"
@inject IJSRuntime JS

<h1>Call JS Example 9</h1>

<p>
    <button @onclick="SendByteArray">Send Bytes</button>
</p>

<p>
    @result
</p>

<p>
    Quote &copy;2005 <a href="https://www.uphe.com">Universal Pictures</a>:
    <a href="https://www.uphe.com/movies/serenity-2005">Serenity</a><br>
    <a href="https://www.imdb.com/name/nm0821612/">Jewel Staite on IMDB</a>
</p>

@code {
```

```
    private string? result;

    private async Task SendByteArray()
    {
        var bytes = new byte[] { 0x45, 0x76, 0x65, 0x72, 0x79, 0x74, 0x68,
0x69,
            0x6e, 0x67, 0x27, 0x73, 0x20, 0x73, 0x68, 0x69, 0x6e, 0x79,
0x2c,
            0x20, 0x43, 0x61, 0x70, 0x74, 0x69, 0x61, 0x6e, 0x2e, 0x20,
0x4e,
            0x6f, 0x74, 0x20, 0x74, 0x6f, 0x20, 0x66, 0x72, 0x65, 0x74, 0x2e
};

        result = await JS.InvokeAsync<string>("receiveByteArray", bytes);
    }
}
```

Stream from .NET to JavaScript

Blazor supports streaming data directly from .NET to JavaScript (JS). Streams are created using a DotNetStreamReference.

DotNetStreamReference represents a .NET stream and uses the following parameters:

- `stream`: The stream sent to JS.
- `leaveOpen`: Determines if the stream is left open after transmission. If a value isn't provided, `leaveOpen` defaults to `false`.

In JS, use an array buffer or a readable stream to receive the data:

- Using an ArrayBuffer:

  JavaScript

  ```
  async function streamToJavaScript(streamRef) {
    const data = await streamRef.arrayBuffer();
  }
  ```

- Using a ReadableStream:

  JavaScript

  ```
  async function streamToJavaScript(streamRef) {
    const stream = await streamRef.stream();
  }
  ```

In C# code:

C#

```
var streamRef = new DotNetStreamReference(stream: {STREAM}, leaveOpen:
false);
await JS.InvokeVoidAsync("streamToJavaScript", streamRef);
```

In the preceding example:

- The `{STREAM}` placeholder represents the Stream sent to JS.
- `JS` is an injected IJSRuntime instance.

Disposing a DotNetStreamReference instance is usually unnecessary. When `leaveOpen` is set to its default value of `false`, the underlying Stream is automatically disposed after transmission to JS.

If `leaveOpen` is `true`, then disposing a DotNetStreamReference doesn't dispose its underlying Stream. The app's code determines when to dispose the underlying Stream. When deciding how to dispose the underlying Stream, consider the following:

- Disposing a Stream while it's being transmitted to JS is considered an application error and may cause an unhandled exception to occur.
- Stream transmission begins as soon as the DotNetStreamReference is passed as an argument to a JS interop call, regardless of whether the stream is actually used in JS logic.

Given these characteristics, we recommend disposing the underlying Stream only after it's fully consumed by JS (the promise returned by `arrayBuffer` or `stream` resolves). It follows that a DotNetStreamReference should only be passed to JS if it's unconditionally going to be consumed by JS logic.

Call .NET methods from JavaScript functions in ASP.NET Core Blazor covers the reverse operation, streaming from JavaScript to .NET.

ASP.NET Core Blazor file downloads covers how to download a file in Blazor.

Catch JavaScript exceptions

To catch JS exceptions, wrap the JS interop in a try-catch block and catch a JSException.

In the following example, the `nonFunction` JS function doesn't exist. When the function isn't found, the JSException is trapped with a Message that indicates the following error:

> `Could not find 'nonFunction' ('nonFunction' was undefined).`

`CallJs11.razor`:

razor

```razor
@page "/call-js-11"
@inject IJSRuntime JS

<PageTitle>Call JS 11</PageTitle>

<h1>Call JS Example 11</h1>

<p>
    <button @onclick="CatchUndefinedJSFunction">Catch Exception</button>
</p>

<p>
    @result
</p>

<p>
    @errorMessage
</p>

@code {
    private string? errorMessage;
    private string? result;

    private async Task CatchUndefinedJSFunction()
    {
        try
        {
            result = await JS.InvokeAsync<string>("nonFunction");
        }
        catch (JSException e)
        {
            errorMessage = $"Error Message: {e.Message}";
        }
    }
}
```

Abort a long-running JavaScript function

Use a JS AbortController with a CancellationTokenSource in the component to abort a long-running JavaScript function from C# code.

The following JS `Helpers` class contains a simulated long-running function, `longRunningFn`, to count continuously until the AbortController.signal indicates that AbortController.abort has been called. The `sleep` function is for demonstration purposes to simulate slow execution of the long-running function and wouldn't be

present in production code. When a component calls `stopFn`, the `longRunningFn` is signalled to abort via the `while` loop conditional check on AbortSignal.aborted.

HTML

```
<script>
  class Helpers {
    static #controller = new AbortController();

    static async #sleep(ms) {
      return new Promise(resolve => setTimeout(resolve, ms));
    }

    static async longRunningFn() {
      var i = 0;
      while (!this.#controller.signal.aborted) {
        i++;
        console.log(`longRunningFn: ${i}`);
        await this.#sleep(1000);
      }
    }

    static stopFn() {
      this.#controller.abort();
      console.log('longRunningFn aborted!');
    }
  }

  window.Helpers = Helpers;
</script>
```

> **Note**
>
> For general guidance on JS location and our recommendations for production apps, see JavaScript location in ASP.NET Core Blazor apps.

The following component:

- Invokes the JS function `longRunningFn` when the **`Start Task`** button is selected. A CancellationTokenSource is used to manage the execution of the long-running function. CancellationToken.Register sets a JS interop call delegate to execute the JS function `stopFn` when the CancellationTokenSource.Token is cancelled.
- When the **`Cancel Task`** button is selected, the CancellationTokenSource.Token is cancelled with a call to Cancel.
- The CancellationTokenSource is disposed in the `Dispose` method.

`CallJs12.razor`:

razor

```razor
@page "/call-js-12"
@inject IJSRuntime JS

<h1>Cancel long-running JS interop</h1>

<p>
    <button @onclick="StartTask">Start Task</button>
    <button @onclick="CancelTask">Cancel Task</button>
</p>

@code {
    private CancellationTokenSource? cts;

    private async Task StartTask()
    {
        cts = new CancellationTokenSource();
        cts.Token.Register(() => JS.InvokeVoidAsync("Helpers.stopFn"));

        await JS.InvokeVoidAsync("Helpers.longRunningFn");
    }

    private void CancelTask()
    {
        cts?.Cancel();
    }

    public void Dispose()
    {
        cts?.Cancel();
        cts?.Dispose();
    }
}
```

A browser's developer tools console indicates the execution of the long-running JS function after the `Start Task` button is selected and when the function is aborted after the `Cancel Task` button is selected:

Console

```
longRunningFn: 1
longRunningFn: 2
longRunningFn: 3
longRunningFn aborted!
```

JavaScript `[JSImport]`/`[JSExport]` interop

This section applies to client-side components.

As an alternative to interacting with JavaScript (JS) in client-side components using Blazor's JS interop mechanism based on the IJSRuntime interface, a JS `[JSImport]`/`[JSExport]` interop API is available to apps targeting .NET 7 or later.

For more information, see JavaScript JSImport/JSExport interop with ASP.NET Core Blazor.

Unmarshalled JavaScript interop

This section applies to client-side components.

Unmarshalled interop using the IJSUnmarshalledRuntime interface is obsolete and should be replaced with JavaScript `[JSImport]`/`[JSExport]` interop.

For more information, see JavaScript JSImport/JSExport interop with ASP.NET Core Blazor.

Disposal of JavaScript interop object references

Examples throughout the JavaScript (JS) interop articles demonstrate typical object disposal patterns:

- When calling JS from .NET, as described in this article, dispose any created IJSObjectReference/IJSInProcessObjectReference/`JSObjectReference` either from .NET or from JS to avoid leaking JS memory.
- When calling .NET from JS, as described in Call .NET methods from JavaScript functions in ASP.NET Core Blazor, dispose of a created DotNetObjectReference either from .NET or from JS to avoid leaking .NET memory.

JS interop object references are implemented as a map keyed by an identifier on the side of the JS interop call that creates the reference. When object disposal is initiated from either the .NET or JS side, Blazor removes the entry from the map, and the object can be garbage collected as long as no other strong reference to the object is present.

At a minimum, always dispose objects created on the .NET side to avoid leaking .NET managed memory.

DOM cleanup tasks during component disposal

For more information, see ASP.NET Core Blazor JavaScript interoperability (JS interop).

JavaScript interop calls without a circuit

For more information, see ASP.NET Core Blazor JavaScript interoperability (JS interop).

Call .NET methods from JavaScript functions in ASP.NET Core Blazor

Article • 10/25/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article explains how to invoke .NET methods from JavaScript (JS).

For information on how to call JS functions from .NET, see Call JavaScript functions from .NET methods in ASP.NET Core Blazor.

Invoke a static .NET method

To invoke a static .NET method from JavaScript (JS), use the JS functions:

- `DotNet.invokeMethodAsync` (*recommended*): Asynchronous for both server-side and client-side components.
- `DotNet.invokeMethod`: Synchronous for client-side components only.

Pass in the name of the assembly containing the method, the identifier of the static .NET method, and any arguments.

In the following example:

- The `{ASSEMBLY NAME}` placeholder is the app's assembly name.
- The `{.NET METHOD ID}` placeholder is the .NET method identifier.
- The `{ARGUMENTS}` placeholder are optional, comma-separated arguments to pass to the method, each of which must be JSON-serializable.

JavaScript

```
DotNet.invokeMethodAsync('{ASSEMBLY NAME}', '{.NET METHOD ID}',
{ARGUMENTS});
```

`DotNet.invokeMethodAsync` returns a JS Promise representing the result of the operation. `DotNet.invokeMethod` (client-side components) returns the result of the operation.

> **Important**
>
> For server-side components, we recommend the asynchronous function (`invokeMethodAsync`) over the synchronous version (`invokeMethod`).

The .NET method must be public, static, and have the [JSInvokable] attribute.

In the following example:

- The `{<T>}` placeholder indicates the return type, which is only required for methods that return a value.
- The `{.NET METHOD ID}` placeholder is the method identifier.

razor

```
@code {
    [JSInvokable]
    public static Task{<T>} {.NET METHOD ID}()
    {
        ...
    }
}
```

> **Note**
>
> Calling open generic methods isn't supported with static .NET methods but is supported with instance methods. For more information, see the Call .NET generic class methods section.

In the following component, the `ReturnArrayAsync` C# method returns an `int` array. The [JSInvokable] attribute is applied to the method, which makes the method invokable by JS.

`CallDotnet1.razor`:

razor

```
@page "/call-dotnet-1"
@implements IAsyncDisposable
```

```razor
@inject IJSRuntime JS

<PageTitle>Call .NET 1</PageTitle>

<h1>Call .NET Example 1</h1>

<p>
    <button id="btn">Trigger .NET static method</button>
</p>

<p>
    See the result in the developer tools console.
</p>

@code {
    private IJSObjectReference? module;

    protected override async Task OnAfterRenderAsync(bool firstRender)
    {
        if (firstRender)
        {
            module = await JS.InvokeAsync<IJSObjectReference>("import",
                "./Components/Pages/CallDotnet1.razor.js");

            await module.InvokeVoidAsync("addHandlers");
        }
    }

    [JSInvokable]
    public static Task<int[]> ReturnArrayAsync() =>
        Task.FromResult(new int[] { 11, 12, 13 });

    async ValueTask IAsyncDisposable.DisposeAsync()
    {
        if (module is not null)
        {
            await module.DisposeAsync();
        }
    }
}
```

`CallDotnet1.razor.js`:

JavaScript

```javascript
export function returnArrayAsync() {
  DotNet.invokeMethodAsync('BlazorSample', 'ReturnArrayAsync')
    .then(data => {
      console.log(data);
    });
}

export function addHandlers() {
```

```
  const btn = document.getElementById("btn");
  btn.addEventListener("click", returnArrayAsync);
}
```

The `addHandlers` JS function adds a click event to the button. The `returnArrayAsync` JS function is assigned as the handler.

The `returnArrayAsync` JS function calls the `ReturnArrayAsync` .NET method of the component, which logs the result to the browser's web developer tools console. `BlazorSample` is the app's assembly name.

> **Note**
>
> For general guidance on JS location and our recommendations for production apps, see JavaScript location in ASP.NET Core Blazor apps.

When the **`Trigger .NET static method`** button is selected, the browser's developer tools console output displays the array data. The format of the output differs slightly among browsers. The following output shows the format used by Microsoft Edge:

Console

```
Array(3) [ 11, 12, 13 ]
```

Pass data to a .NET method when calling the `invokeMethodAsync` function by passing the data as arguments.

To demonstrate passing data to .NET, pass a starting position to the `ReturnArrayAsync` method where the method is invoked in JS:

JavaScript

```
export function returnArrayAsync() {
  DotNet.invokeMethodAsync('BlazorSample', 'ReturnArrayAsync', 14)
    .then(data => {
      console.log(data);
    });
}
```

The component's invokable `ReturnArrayAsync` method receives the starting position and constructs the array from it. The array is returned for logging to the console:

C#

```
[JSInvokable]
public static Task<int[]> ReturnArrayAsync(int startPosition) =>
    Task.FromResult(Enumerable.Range(startPosition, 3).ToArray());
```

After the app is recompiled and the browser is refreshed, the following output appears in the browser's console when the button is selected:

Console

```
Array(3) [ 14, 15, 16 ]
```

The .NET method identifier for the JS call is the .NET method name, but you can specify a different identifier using the [JSInvokable] attribute constructor. In the following example, `DifferentMethodName` is the assigned method identifier for the `ReturnArrayAsync` method:

C#

```
[JSInvokable("DifferentMethodName")]
```

In the call to `DotNet.invokeMethodAsync` (server-side or client-side components) or `DotNet.invokeMethod` (client-side components only), call `DifferentMethodName` to execute the `ReturnArrayAsync` .NET method:

- `DotNet.invokeMethodAsync('BlazorSample', 'DifferentMethodName');`
- `DotNet.invokeMethod('BlazorSample', 'DifferentMethodName');` (client-side components only)

> **Note**
>
> The `ReturnArrayAsync` method example in this section returns the result of a Task without the use of explicit C# async and await keywords. Coding methods with async and await is typical of methods that use the await keyword to return the value of asynchronous operations.
>
> `ReturnArrayAsync` method composed with async and await keywords:
>
> C#
>
> ```
> [JSInvokable]
> public static async Task<int[]> ReturnArrayAsync() =>
>     await Task.FromResult(new int[] { 11, 12, 13 });
> ```

For more information, see Asynchronous programming with async and await in the C# guide.

Create JavaScript object and data references to pass to .NET

Call `DotNet.createJSObjectReference(jsObject)` to construct a JS object reference so that it can be passed to .NET, where `jsObject` is the JS Object used to create the JS object reference. The following example passes a reference to the non-serializable `window` object to .NET, which receives it in the `ReceiveWindowObject` C# method as an IJSObjectReference:

JavaScript

```
DotNet.invokeMethodAsync('{ASSEMBLY NAME}', 'ReceiveWindowObject',
  DotNet.createJSObjectReference(window));
```

C#

```
[JSInvokable]
public static void ReceiveWindowObject(IJSObjectReference objRef)
{
    ...
}
```

In the preceding example, the `{ASSEMBLY NAME}` placeholder is the app's namespace.

> **Note**
>
> The preceding example doesn't require disposal of the `JSObjectReference`, as a reference to the `window` object isn't held in JS.

Maintaining a reference to a `JSObjectReference` requires disposing of it to avoid leaking JS memory on the client. The following example refactors the preceding code to capture a reference to the `JSObjectReference`, followed by a call to `DotNet.disposeJSObjectReference()` to dispose of the reference:

JavaScript

```
var jsObjectReference = DotNet.createJSObjectReference(window);
```

```
DotNet.invokeMethodAsync('{ASSEMBLY NAME}', 'ReceiveWindowObject',
jsObjectReference);

DotNet.disposeJSObjectReference(jsObjectReference);
```

In the preceding example, the `{ASSEMBLY NAME}` placeholder is the app's namespace.

Call `DotNet.createJSStreamReference(streamReference)` to construct a JS stream reference so that it can be passed to .NET, where `streamReference` is an ArrayBuffer, Blob, or any typed array, such as Uint8Array or Float32Array, used to create the JS stream reference.

Invoke an instance .NET method

To invoke an instance .NET method from JavaScript (JS):

- Pass the .NET instance by reference to JS by wrapping the instance in a DotNetObjectReference and calling Create on it.
- Invoke a .NET instance method from JS using `invokeMethodAsync` (*recommended*) or `invokeMethod` (client-side components only) from the passed DotNetObjectReference. Pass the identifier of the instance .NET method and any arguments. The .NET instance can also be passed as an argument when invoking other .NET methods from JS.

  In the following example:
  - `dotNetHelper` is a DotNetObjectReference.
  - The `{.NET METHOD ID}` placeholder is the .NET method identifier.
  - The `{ARGUMENTS}` placeholder are optional, comma-separated arguments to pass to the method, each of which must be JSON-serializable.

  JavaScript

  ```
  dotNetHelper.invokeMethodAsync('{.NET METHOD ID}', {ARGUMENTS});
  ```

  > **Note**
  >
  > `invokeMethodAsync` and `invokeMethod` don't accept an assembly name parameter when invoking an instance method.

`invokeMethodAsync` returns a JS Promise representing the result of the operation.
`invokeMethod` (client-side components only) returns the result of the operation.

> **Important**
>
> For server-side components, we recommend the asynchronous function (`invokeMethodAsync`) over the synchronous version (`invokeMethod`).

- Dispose of the DotNetObjectReference.

The following sections of this article demonstrate various approaches for invoking an instance .NET method:

- Pass a DotNetObjectReference to an individual JavaScript function
- Pass a DotNetObjectReference to a class with multiple JavaScript functions
- Call .NET generic class methods
- Class instance examples
- Component instance .NET method helper class

Avoid trimming JavaScript-invokable .NET methods

This section applies to client-side apps with ahead-of-time (AOT) compilation and runtime relinking enabled.

Several of the examples in the following sections are based on a class instance approach, where the JavaScript-invokable .NET method marked with the [JSInvokable] attribute is a member of a class that isn't a Razor component. When such .NET methods are located in a Razor component, they're protected from runtime relinking/trimming. In order to protect the .NET methods from trimming outside of Razor components, implement the methods with the DynamicDependency attribute on the class's constructor, as the following example demonstrates:

C#

```
using System.Diagnostics.CodeAnalysis;
using Microsoft.JSInterop;

public class ExampleClass {

    [DynamicDependency(nameof(ExampleJSInvokableMethod))]
    public ExampleClass()
    {
```

```
    }

    [JSInvokable]
    public string ExampleJSInvokableMethod()
    {
        ...
    }
}
```

For more information, see Prepare .NET libraries for trimming: DynamicDependency.

Pass a `DotNetObjectReference` to an individual JavaScript function

The example in this section demonstrates how to pass a DotNetObjectReference to an individual JavaScript (JS) function.

The following `sayHello1` JS function receives a DotNetObjectReference and calls `invokeMethodAsync` to call the `GetHelloMessage` .NET method of a component:

HTML

```
<script>
  window.sayHello1 = (dotNetHelper) => {
    return dotNetHelper.invokeMethodAsync('GetHelloMessage');
  };
</script>
```

> **Note**
>
> For general guidance on JS location and our recommendations for production apps, see JavaScript location in ASP.NET Core Blazor apps.

In the preceding example, the variable name `dotNetHelper` is arbitrary and can be changed to any preferred name.

For the following component:

- The component has a JS-invokable .NET method named `GetHelloMessage`.
- When the **`Trigger .NET instance method`** button is selected, the JS function `sayHello1` is called with the DotNetObjectReference.
- `sayHello1`:
  - Calls `GetHelloMessage` and receives the message result.

    - Returns the message result to the calling `TriggerDotNetInstanceMethod` method.
- The returned message from `sayHello1` in `result` is displayed to the user.
- To avoid a memory leak and allow garbage collection, the .NET object reference created by DotNetObjectReference is disposed in the `Dispose` method.

`CallDotnet2.razor`:

razor

```razor
@page "/call-dotnet-2"
@implements IDisposable
@inject IJSRuntime JS

<PageTitle>Call .NET 2</PageTitle>

<h1>Call .NET Example 2</h1>

<p>
    <label>
        Name: <input @bind="name" />
    </label>
</p>

<p>
    <button @onclick="TriggerDotNetInstanceMethod">
        Trigger .NET instance method
    </button>
</p>

<p>
    @result
</p>

@code {
    private string? name;
    private string? result;
    private DotNetObjectReference<CallDotnet2>? objRef;

    protected override void OnInitialized() =>
        objRef = DotNetObjectReference.Create(this);

    public async Task TriggerDotNetInstanceMethod() =>
        result = await JS.InvokeAsync<string>("sayHello1", objRef);

    [JSInvokable]
    public string GetHelloMessage() => $"Hello, {name}!";

    public void Dispose() => objRef?.Dispose();
}
```

In the preceding example, the variable name `dotNetHelper` is arbitrary and can be changed to any preferred name.

Use the following guidance to pass arguments to an instance method:

Add parameters to the .NET method invocation. In the following example, a name is passed to the method. Add additional parameters to the list as needed.

HTML

```
<script>
  window.sayHello2 = (dotNetHelper, name) => {
    return dotNetHelper.invokeMethodAsync('GetHelloMessage', name);
  };
</script>
```

In the preceding example, the variable name `dotNetHelper` is arbitrary and can be changed to any preferred name.

Provide the parameter list to the .NET method.

`CallDotnet3.razor`:

razor

```
@page "/call-dotnet-3"
@implements IDisposable
@inject IJSRuntime JS

<PageTitle>Call .NET 3</PageTitle>

<h1>Call .NET Example 3</h1>

<p>
    <label>
        Name: <input @bind="name" />
    </label>
</p>

<p>
    <button @onclick="TriggerDotNetInstanceMethod">
        Trigger .NET instance method
    </button>
</p>

<p>
    @result
</p>

@code {
```

```
    private string? name;
    private string? result;
    private DotNetObjectReference<CallDotnet3>? objRef;

    protected override void OnInitialized() =>
        objRef = DotNetObjectReference.Create(this);

    public async Task TriggerDotNetInstanceMethod() =>
        result = await JS.InvokeAsync<string>("sayHello2", objRef, name);

    [JSInvokable]
    public string GetHelloMessage(string passedName) => $"Hello,
{passedName}!";

    public void Dispose() => objRef?.Dispose();
}
```

In the preceding example, the variable name `dotNetHelper` is arbitrary and can be changed to any preferred name.

Pass a `DotNetObjectReference` to a class with multiple JavaScript functions

The example in this section demonstrates how to pass a DotNetObjectReference to a JavaScript (JS) class with multiple functions.

Create and pass a DotNetObjectReference from the OnAfterRenderAsync lifecycle method to a JS class for multiple functions to use. Make sure that the .NET code disposes of the DotNetObjectReference, as the following example shows.

In the following component, the `Trigger JS function` buttons call JS functions by setting the JS `onclick` property, not Blazor's `@onclick` directive attribute.

`CallDotNetExampleOneHelper.razor`:

razor

```
@page "/call-dotnet-example-one-helper"
@implements IAsyncDisposable
@inject IJSRuntime JS

<PageTitle>Call .NET Example</PageTitle>

<h1>Pass <code>DotNetObjectReference</code> to a JavaScript class</h1>

<p>
    <label>
        Message: <input @bind="name" />
```

```
    </label>
</p>

<p>
    <button id="sayHelloBtn">
        Trigger JS function <code>sayHello</code>
    </button>
</p>

<p>
    <button id="welcomeVisitorBtn">
        Trigger JS function <code>welcomeVisitor</code>
    </button>
</p>

@code {
    private IJSObjectReference? module;
    private string? name;
    private DotNetObjectReference<CallDotNetExampleOneHelper>? dotNetHelper;

    protected override async Task OnAfterRenderAsync(bool firstRender)
    {
        if (firstRender)
        {
            module = await JS.InvokeAsync<IJSObjectReference>("import",
                "./Components/Pages/CallDotNetExampleOneHelper.razor.js");

            dotNetHelper = DotNetObjectReference.Create(this);
            await module.InvokeVoidAsync("GreetingHelpers.setDotNetHelper",
                dotNetHelper);

            await module.InvokeVoidAsync("addHandlers");
        }
    }

    [JSInvokable]
    public string GetHelloMessage() => $"Hello, {name}!";

    [JSInvokable]
    public string GetWelcomeMessage() => $"Welcome, {name}!";

    async ValueTask IAsyncDisposable.DisposeAsync()
    {
        if (module is not null)
        {
            await module.DisposeAsync();
        }

        dotNetHelper?.Dispose();
    }
}
```

In the preceding example:

- `JS` is an injected IJSRuntime instance. IJSRuntime is registered by the Blazor framework.
- The variable name `dotNetHelper` is arbitrary and can be changed to any preferred name.
- The component must explicitly dispose of the DotNetObjectReference to permit garbage collection and prevent a memory leak.

`CallDotNetExampleOneHelper.razor.js`:

JavaScript

```
export class GreetingHelpers {
  static dotNetHelper;

  static setDotNetHelper(value) {
    GreetingHelpers.dotNetHelper = value;
  }

  static async sayHello() {
    const msg =
      await
GreetingHelpers.dotNetHelper.invokeMethodAsync('GetHelloMessage');
    alert(`Message from .NET: "${msg}"`);
  }

  static async welcomeVisitor() {
    const msg =
      await
GreetingHelpers.dotNetHelper.invokeMethodAsync('GetWelcomeMessage');
    alert(`Message from .NET: "${msg}"`);
  }
}

export function addHandlers() {
  const sayHelloBtn = document.getElementById("sayHelloBtn");
  sayHelloBtn.addEventListener("click", GreetingHelpers.sayHello);

  const welcomeVisitorBtn = document.getElementById("welcomeVisitorBtn");
  welcomeVisitorBtn.addEventListener("click",
GreetingHelpers.welcomeVisitor);
}
```

In the preceding example, the variable name `dotNetHelper` is arbitrary and can be changed to any preferred name.

> **Note**

For general guidance on JS location and our recommendations for production apps, see JavaScript location in ASP.NET Core Blazor apps.

Call .NET generic class methods

JavaScript (JS) functions can call .NET generic class methods, where a JS function calls a .NET method of a generic class.

In the following generic type class (`GenericType<TValue>`):

- The class has a single type parameter (`TValue`) with a single generic `Value` property.
- The class has two non-generic methods marked with the [JSInvokable] attribute, each with a generic type parameter named `newValue`:
  - `Update` synchronously updates the value of `Value` from `newValue`.
  - `UpdateAsync` asynchronously updates the value of `Value` from `newValue` after creating an awaitable task with Task.Yield that asynchronously yields back to the current context when awaited.
- Each of the class methods write the type of `TValue` and the value of `Value` to the console. Writing to the console is only for demonstration purposes. Production apps usually avoid writing to the console in favor of app *logging*. For more information, see ASP.NET Core Blazor logging and Logging in .NET Core and ASP.NET Core.

> **Note**
>
> *Open generic types and methods* don't specify types for type placeholders. Conversely, *closed generics* supply types for all type placeholders. The examples in this section demonstrate closed generics, but invoking JS interop *instance methods* with open generics ***is supported***. Use of open generics isn't supported for static .NET method invocations, which were described earlier in this article.

For more information, see the following articles:

- Generic classes and methods (C# documentation)
- Generic Classes (C# Programming Guide)
- Generics in .NET (.NET documentation)

`GenericType.cs`:

```
C#
```

```
using Microsoft.JSInterop;

public class GenericType<TValue>
{
    public TValue? Value { get; set; }

    [JSInvokable]
    public void Update(TValue newValue)
    {
        Value = newValue;

        Console.WriteLine($"Update: GenericType<{typeof(TValue)}>:
{Value}");
    }

    [JSInvokable]
    public async void UpdateAsync(TValue newValue)
    {
        await Task.Yield();
        Value = newValue;

        Console.WriteLine($"UpdateAsync: GenericType<{typeof(TValue)}>:
{Value}");
    }
}
```

In the following `invokeMethodsAsync` function:

- The generic type class's `Update` and `UpdateAsync` methods are called with arguments representing strings and numbers.
- Client-side components support calling .NET methods synchronously with `invokeMethod`. `syncInterop` receives a boolean value indicating if the JS interop is occurring on the client. When `syncInterop` is `true`, `invokeMethod` is safely called. If the value of `syncInterop` is `false`, only the asynchronous function `invokeMethodAsync` is called because the JS interop is executing in a server-side component.
- For demonstration purposes, the DotNetObjectReference function call (`invokeMethod` or `invokeMethodAsync`), the .NET method called (`Update` or `UpdateAsync`), and the argument are written to the console. The arguments use a random number to permit matching the JS function call to the .NET method invocation (also written to the console on the .NET side). Production code usually doesn't write to the console, either on the client or the server. Production apps usually rely upon app *logging*. For more information, see ASP.NET Core Blazor logging and Logging in .NET Core and ASP.NET Core.

HTML

```
<script>
  const randomInt = () => Math.floor(Math.random() * 99999);

  window.invokeMethodsAsync = async (syncInterop, dotNetHelper1,
dotNetHelper2) => {
    var n = randomInt();
    console.log(`JS: invokeMethodAsync:Update('string ${n}')`);
    await dotNetHelper1.invokeMethodAsync('Update', `string ${n}`);

    n = randomInt();
    console.log(`JS: invokeMethodAsync:UpdateAsync('string ${n}')`);
    await dotNetHelper1.invokeMethodAsync('UpdateAsync', `string ${n}`);

    if (syncInterop) {
      n = randomInt();
      console.log(`JS: invokeMethod:Update('string ${n}')`);
      dotNetHelper1.invokeMethod('Update', `string ${n}`);
    }

    n = randomInt();
    console.log(`JS: invokeMethodAsync:Update(${n})`);
    await dotNetHelper2.invokeMethodAsync('Update', n);

    n = randomInt();
    console.log(`JS: invokeMethodAsync:UpdateAsync(${n})`);
    await dotNetHelper2.invokeMethodAsync('UpdateAsync', n);

    if (syncInterop) {
      n = randomInt();
      console.log(`JS: invokeMethod:Update(${n})`);
      dotNetHelper2.invokeMethod('Update', n);
    }
  };
</script>
```

> ⓘ Note
>
> For general guidance on JS location and our recommendations for production apps, see JavaScript location in ASP.NET Core Blazor apps.

In the following `GenericsExample` component:

- The JS function `invokeMethodsAsync` is called when the **`Invoke Interop`** button is selected.
- A pair of DotNetObjectReference types are created and passed to the JS function for instances of the `GenericType` as a `string` and an `int`.

`GenericsExample.razor`:

razor

```razor
@page "/generics-example"
@implements IDisposable
@inject IJSRuntime JS

<p>
    <button @onclick="InvokeInterop">Invoke Interop</button>
</p>

<ul>
    <li>genericType1: @genericType1?.Value</li>
    <li>genericType2: @genericType2?.Value</li>
</ul>

@code {
    private GenericType<string> genericType1 = new() { Value = "string 0" };
    private GenericType<int> genericType2 = new() { Value = 0 };
    private DotNetObjectReference<GenericType<string>>? objRef1;
    private DotNetObjectReference<GenericType<int>>? objRef2;

    protected override void OnInitialized()
    {
        objRef1 = DotNetObjectReference.Create(genericType1);
        objRef2 = DotNetObjectReference.Create(genericType2);
    }

    public async Task InvokeInterop()
    {
        var syncInterop = OperatingSystem.IsBrowser();

        await JS.InvokeVoidAsync(
            "invokeMethodsAsync", syncInterop, objRef1, objRef2);
    }

    public void Dispose()
    {
        objRef1?.Dispose();
        objRef2?.Dispose();
    }
}
```

In the preceding example, `JS` is an injected IJSRuntime instance. IJSRuntime is registered by the Blazor framework.

The following demonstrates typical output of the preceding example when the **`Invoke Interop`** button is selected in a client-side component:

> JS: invokeMethodAsync:Update('string 37802')
> .NET: Update: GenericType<System.String>: string 37802
> JS: invokeMethodAsync:UpdateAsync('string 53051')

> JS: invokeMethod:Update('string 26784')
> .NET: Update: GenericType<System.String>: string 26784
> JS: invokeMethodAsync:Update(14107)
> .NET: Update: GenericType<System.Int32>: 14107
> JS: invokeMethodAsync:UpdateAsync(48995)
> JS: invokeMethod:Update(12872)
> .NET: Update: GenericType<System.Int32>: 12872
> .NET: UpdateAsync: GenericType<System.String>: string 53051
> .NET: UpdateAsync: GenericType<System.Int32>: 48995

If the preceding example is implemented in a server-side component, the synchronous calls with `invokeMethod` are avoided. For server-side components, we recommend the asynchronous function (`invokeMethodAsync`) over the synchronous version (`invokeMethod`).

Typical output of a server-side component:

> JS: invokeMethodAsync:Update('string 34809')
> .NET: Update: GenericType<System.String>: string 34809
> JS: invokeMethodAsync:UpdateAsync('string 93059')
> JS: invokeMethodAsync:Update(41997)
> .NET: Update: GenericType<System.Int32>: 41997
> JS: invokeMethodAsync:UpdateAsync(24652)
> .NET: UpdateAsync: GenericType<System.String>: string 93059
> .NET: UpdateAsync: GenericType<System.Int32>: 24652

The preceding output examples demonstrate that asynchronous methods execute and complete in an *arbitrary order* depending on several factors, including thread scheduling and the speed of method execution. It isn't possible to reliably predict the order of completion for asynchronous method calls.

Class instance examples

The following `sayHello1` JS function:

- Calls the `GetHelloMessage` .NET method on the passed DotNetObjectReference.
- Returns the message from `GetHelloMessage` to the `sayHello1` caller.

```
HTML
```

```
<script>
  window.sayHello1 = (dotNetHelper) => {
    return dotNetHelper.invokeMethodAsync('GetHelloMessage');
  };
</script>
```

> **Note**
>
> For general guidance on JS location and our recommendations for production apps, see JavaScript location in ASP.NET Core Blazor apps.

In the preceding example, the variable name `dotNetHelper` is arbitrary and can be changed to any preferred name.

The following `HelloHelper` class has a JS-invokable .NET method named `GetHelloMessage`. When `HelloHelper` is created, the name in the `Name` property is used to return a message from `GetHelloMessage`.

`HelloHelper.cs`:

C#

```
using Microsoft.JSInterop;

namespace BlazorSample;

public class HelloHelper(string? name)
{
    public string? Name { get; set; } = name ?? "No Name";

    [JSInvokable]
    public string GetHelloMessage() => $"Hello, {Name}!";
}
```

The `CallHelloHelperGetHelloMessage` method in the following `JsInteropClasses3` class invokes the JS function `sayHello1` with a new instance of `HelloHelper`.

`JsInteropClasses3.cs`:

C#

```
using Microsoft.JSInterop;

namespace BlazorSample;
```

```
public class JsInteropClasses3(IJSRuntime js)
{
    private readonly IJSRuntime js = js;

    public async ValueTask<string> CallHelloHelperGetHelloMessage(string?
name)
    {
        using var objRef = DotNetObjectReference.Create(new
HelloHelper(name));
        return await js.InvokeAsync<string>("sayHello1", objRef);
    }
}
```

To avoid a memory leak and allow garbage collection, the .NET object reference created by DotNetObjectReference is disposed when the object reference goes out of scope with using var syntax.

When the **`Trigger .NET instance method`** button is selected in the following component, `JsInteropClasses3.CallHelloHelperGetHelloMessage` is called with the value of `name`.

`CallDotnet4.razor`:

razor

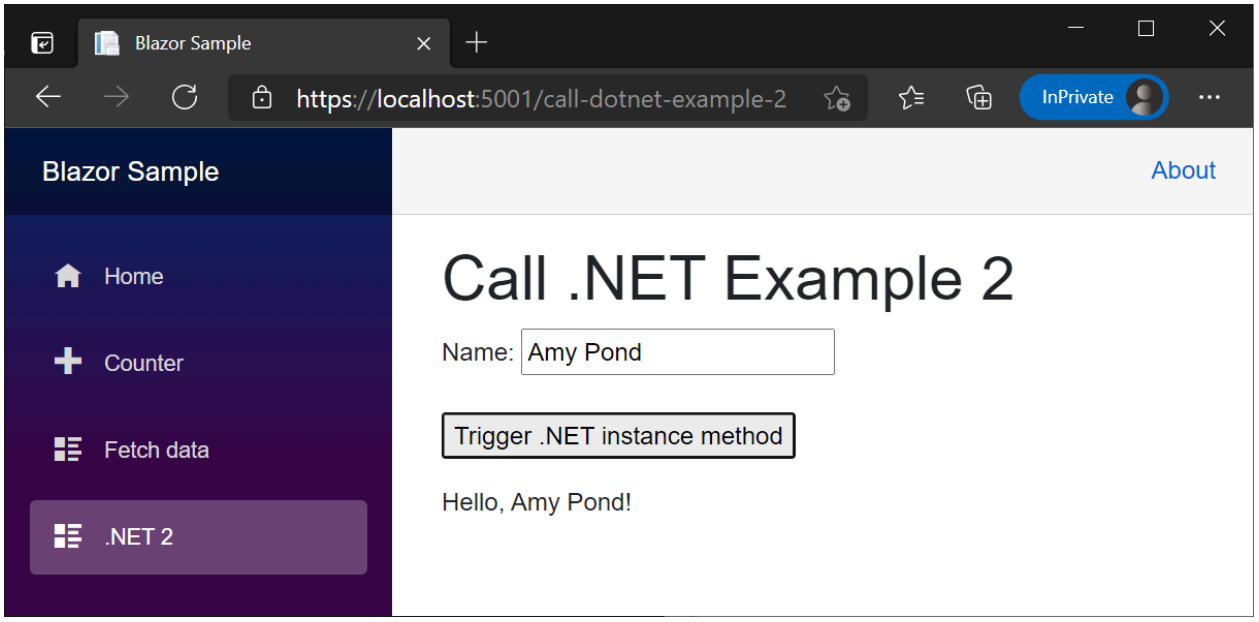
```
@page "/call-dotnet-4"
@inject IJSRuntime JS

<PageTitle>Call .NET 4</PageTitle>

<h1>Call .NET Example 4</h1>

<p>
    <label>
        Name: <input @bind="name" />
    </label>
</p>

<p>
    <button @onclick="TriggerDotNetInstanceMethod">
        Trigger .NET instance method
    </button>
</p>



<p>
    @result
</p>

@code {
    private string? name;
    private string? result;
    private JsInteropClasses3? jsInteropClasses;
```

```
    protected override void OnInitialized() =>
        jsInteropClasses = new JsInteropClasses3(JS);

    private async Task TriggerDotNetInstanceMethod()
    {
        if (jsInteropClasses is not null)
        {
            result = await
jsInteropClasses.CallHelloHelperGetHelloMessage(name);
        }
    }
}
```

The following image shows the rendered component with the name `Amy Pond` in the `Name` field. After the button is selected, `Hello, Amy Pond!` is displayed in the UI:

The preceding pattern shown in the `JsInteropClasses3` class can also be implemented entirely in a component.

`CallDotnet5.razor`:

razor

```
@page "/call-dotnet-5"
@inject IJSRuntime JS

<PageTitle>Call .NET 5</PageTitle>

<h1>Call .NET Example 5</h1>

<p>
    <label>
        Name: <input @bind="name" />
    </label>
```

```
</p>

<p>
    <button @onclick="TriggerDotNetInstanceMethod">
        Trigger .NET instance method
    </button>
</p>

<p>
    @result
</p>

@code {
    private string? name;
    private string? result;

    public async Task TriggerDotNetInstanceMethod()
    {
        using var objRef = DotNetObjectReference.Create(new
HelloHelper(name));
        result = await JS.InvokeAsync<string>("sayHello1", objRef);
    }
}
```

To avoid a memory leak and allow garbage collection, the .NET object reference created by DotNetObjectReference is disposed when the object reference goes out of scope with using var syntax.

The output displayed by the component is `Hello, Amy Pond!` when the name `Amy Pond` is provided in the `name` field.

In the preceding component, the .NET object reference is disposed. If a class or component doesn't dispose the DotNetObjectReference, dispose it from the client by calling `dispose` on the passed DotNetObjectReference:

JavaScript

```
window.{JS FUNCTION NAME} = (dotNetHelper) => {
  dotNetHelper.invokeMethodAsync('{.NET METHOD ID}');
  dotNetHelper.dispose();
}
```

In the preceding example:

- The `{JS FUNCTION NAME}` placeholder is the JS function's name.
- The variable name `dotNetHelper` is arbitrary and can be changed to any preferred name.
- The `{.NET METHOD ID}` placeholder is the .NET method identifier.

Component instance .NET method helper class

A helper class can invoke a .NET instance method as an Action. Helper classes are useful in scenarios where using static .NET methods aren't applicable:

- When several components of the same type are rendered on the same page.
- In server-side apps with multiple users concurrently using the same component.

In the following example:

- The component contains several `ListItem1` components.
- Each `ListItem1` component is composed of a message and a button.
- When a `ListItem1` component button is selected, that `ListItem1`'s `UpdateMessage` method changes the list item text and hides the button.

The following `MessageUpdateInvokeHelper` class maintains a JS-invokable .NET method, `UpdateMessageCaller`, to invoke the Action specified when the class is instantiated.

`MessageUpdateInvokeHelper.cs`:

C#

```
using Microsoft.JSInterop;

namespace BlazorSample;

public class MessageUpdateInvokeHelper(Action action)
{
    private readonly Action action = action;

    [JSInvokable]
    public void UpdateMessageCaller() => action.Invoke();
}
```

The following `updateMessageCaller` JS function invokes the `UpdateMessageCaller` .NET method.

HTML

```
<script>
  window.updateMessageCaller = (dotNetHelper) => {
    dotNetHelper.invokeMethodAsync('UpdateMessageCaller');
    dotNetHelper.dispose();
  }
</script>
```

> **Note**
>
> For general guidance on JS location and our recommendations for production apps, see JavaScript location in ASP.NET Core Blazor apps.

In the preceding example, the variable name `dotNetHelper` is arbitrary and can be changed to any preferred name.

The following `ListItem1` component is a shared component that can be used any number of times in a parent component and creates list items (`<li>...</li>`) for an HTML list (`<ul>...</ul>` or `<ol>...</ol>`). Each `ListItem1` component instance establishes an instance of `MessageUpdateInvokeHelper` with an Action set to its `UpdateMessage` method.

When a `ListItem1` component's **`InteropCall`** button is selected, `updateMessageCaller` is invoked with a created DotNetObjectReference for the `MessageUpdateInvokeHelper` instance. This permits the framework to call `UpdateMessageCaller` on that `ListItem1`'s `MessageUpdateInvokeHelper` instance. The passed DotNetObjectReference is disposed in JS (`dotNetHelper.dispose()`).

`ListItem1.razor`:

razor

```
@inject IJSRuntime JS

<li>
    @message
    <button @onclick="InteropCall"
style="display:@display">InteropCall</button>
</li>

@code {
    private string message = "Select one of these list item buttons.";
    private string display = "inline-block";
    private MessageUpdateInvokeHelper? messageUpdateInvokeHelper;

    protected override void OnInitialized()
    {
        messageUpdateInvokeHelper = new
MessageUpdateInvokeHelper(UpdateMessage);
    }

    protected async Task InteropCall()
    {
        if (messageUpdateInvokeHelper is not null)
        {
```

```
            await JS.InvokeVoidAsync("updateMessageCaller",
                DotNetObjectReference.Create(messageUpdateInvokeHelper));
        }
    }

    private void UpdateMessage()
    {
        message = "UpdateMessage Called!";
        display = "none";
        StateHasChanged();
    }
}
```

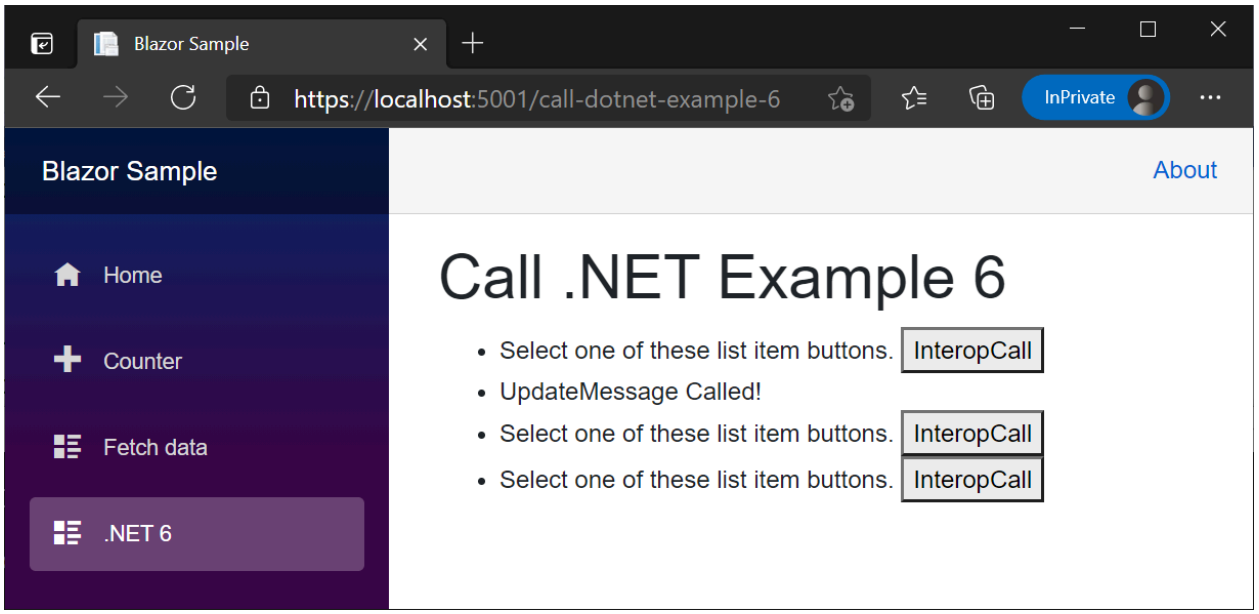
StateHasChanged is called to update the UI when `message` is set in `UpdateMessage`. If `StateHasChanged` isn't called, Blazor has no way of knowing that the UI should be updated when the Action is invoked.

The following parent component includes four list items, each an instance of the `ListItem1` component.

`CallDotnet6.razor`:

razor

```
@page "/call-dotnet-6"



<PageTitle>Call .NET 6</PageTitle>

<h1>Call .NET Example 6</h1>

<ul>
    <ListItem1 />
    <ListItem1 />
    <ListItem1 />
    <ListItem1 />
</ul>
```

The following image shows the rendered parent component after the second **`InteropCall`** button is selected:

- The second `ListItem1` component has displayed the `UpdateMessage Called!` message.
- The **`InteropCall`** button for the second `ListItem1` component isn't visible because the button's CSS `display` property is set to `none`.

Component instance .NET method called from `DotNetObjectReference` assigned to an element property

The assignment of a DotNetObjectReference to a property of an HTML element permits calling .NET methods on a component instance:

- An element reference is captured (ElementReference).
- In the component's OnAfterRender{Async} method, a JavaScript (JS) function is invoked with the element reference and the component instance as a DotNetObjectReference. The JS function attaches the DotNetObjectReference to the element in a property.
- When an element event is invoked in JS (for example, `onclick`), the element's attached DotNetObjectReference is used to call a .NET method.

Similar to the approach described in the Component instance .NET method helper class section, this approach is useful in scenarios where using static .NET methods aren't applicable:

- When several components of the same type are rendered on the same page.
- In server-side apps with multiple users concurrently using the same component.
- The .NET method is invoked from a JS event (for example, `onclick`), not from a Blazor event (for example, `@onclick`).

In the following example:

- The component contains several `ListItem2` components, which is a shared component.

- Each `ListItem2` component is composed of a list item message `<span>` and a second `<span>` with a `display` CSS property set to `inline-block` for display.
- When a `ListItem2` component list item is selected, that `ListItem2`'s `UpdateMessage` method changes the list item text in the first `<span>` and hides the second `<span>` by setting its `display` property to `none`.

The following `assignDotNetHelper` JS function assigns the DotNetObjectReference to an element in a property named `dotNetHelper`. The following `interopCall` JS function uses the DotNetObjectReference for the passed element to invoke a .NET method named `UpdateMessage`.

`ListItem2.razor.js`:

JavaScript

```
export function assignDotNetHelper(element, dotNetHelper) {
  element.dotNetHelper = dotNetHelper;
}

export async function interopCall(element) {
  await element.dotNetHelper.invokeMethodAsync('UpdateMessage');
}
```

> **Note**
>
> For general guidance on JS location and our recommendations for production apps, see JavaScript location in ASP.NET Core Blazor apps.

In the preceding example, the variable name `dotNetHelper` is arbitrary and can be changed to any preferred name.

The following `ListItem2` component is a shared component that can be used any number of times in a parent component and creates list items (`<li>...</li>`) for an HTML list (`<ul>...</ul>` or `<ol>...</ol>`).

Each `ListItem2` component instance invokes the `assignDotNetHelper` JS function in OnAfterRenderAsync with an element reference (the first `<span>` element of the list item) and the component instance as a DotNetObjectReference.

When a `ListItem2` component's message `<span>` is selected, `interopCall` is invoked passing the `<span>` element as a parameter (`this`), which invokes the `UpdateMessage` .NET method. In `UpdateMessage`, StateHasChanged is called to update the UI when

`message` is set and the `display` property of the second `<span>` is updated. If `StateHasChanged` isn't called, Blazor has no way of knowing that the UI should be updated when the method is invoked.

The DotNetObjectReference is disposed when the component is disposed.

`ListItem2.razor`:

razor

```
@inject IJSRuntime JS
@implements IAsyncDisposable

<li>
    <span style="font-weight:bold;color:@color" @ref="elementRef"
        @onclick="CallJSToInvokeDotnet">
        @message
    </span>
    <span style="display:@display">
        Not Updated Yet!
    </span>
</li>

@code {
    private IJSObjectReference? module;
    private DotNetObjectReference<ListItem2>? objRef;
    private ElementReference elementRef;
    private string display = "inline-block";
    private string message = "Select one of these list items.";
    private string color = "initial";

    protected override async Task OnAfterRenderAsync(bool firstRender)
    {
        if (firstRender)
        {
            module = await JS.InvokeAsync<IJSObjectReference>("import",
                "./Components/ListItem2.razor.js");

            objRef = DotNetObjectReference.Create(this);
            await module.InvokeVoidAsync("assignDotNetHelper", elementRef,
objRef);
        }
    }

    public async void CallJSToInvokeDotnet()
    {
        if (module is not null)
        {
            await module.InvokeVoidAsync("interopCall", elementRef);
        }
    }

    [JSInvokable]
```

```
    public void UpdateMessage()
    {
        message = "UpdateMessage Called!";
        display = "none";
        color = "MediumSeaGreen";
        StateHasChanged();
    }

    async ValueTask IAsyncDisposable.DisposeAsync()
    {
        if (module is not null)
        {
            await module.DisposeAsync();
        }

        objRef?.Dispose();
    }
}
```

The following parent component includes four list items, each an instance of the `ListItem2` component.

`CallDotnet7.razor`:

razor

```
@page "/call-dotnet-7"

<PageTitle>Call .NET 7</PageTitle>

<h1>Call .NET Example 7</h1>

<ul>
    <ListItem2 />
    <ListItem2 />
    <ListItem2 />
    <ListItem2 />
</ul>
```

Synchronous JS interop in client-side components

This section only applies to client-side components.

JS interop calls are asynchronous, regardless of whether the called code is synchronous or asynchronous. Calls are asynchronous to ensure that components are compatible

across server-side and client-side render modes. On the server, all JS interop calls must be asynchronous because they're sent over a network connection.

If you know for certain that your component only runs on WebAssembly, you can choose to make synchronous JS interop calls. This has slightly less overhead than making asynchronous calls and can result in fewer render cycles because there's no intermediate state while awaiting results.

To make a synchronous call from JavaScript to .NET in a client-side component, use `DotNet.invokeMethod` instead of `DotNet.invokeMethodAsync`.

Synchronous calls work if:

- The component is only rendered for execution on WebAssembly.
- The called function returns a value synchronously. The function isn't an `async` method and doesn't return a .NET Task or JavaScript Promise.

JavaScript location

Load JavaScript (JS) code using any of approaches described by the article on JavaScript location:

- Load a script in <head> markup (*Not generally recommended*)
- Load a script in <body> markup
- Load a script from an external JavaScript file (.js) collocated with a component
- Load a script from an external JavaScript file (.js)
- Inject a script before or after Blazor starts

Using JS modules to load JS is described in this article in the JavaScript isolation in JavaScript modules section.

> ⚠ **Warning**
>
> Only place a `<script>` tag in a component file (`.razor`) if the component is guaranteed to adopt static server-side rendering (static SSR) because the `<script>` tag can't be updated dynamically.

JavaScript isolation in JavaScript modules

Blazor enables JavaScript (JS) isolation in standard JavaScript modules (ECMAScript specification). JavaScript module loading works the same way in Blazor as it does for

other types of web apps, and you're free to customize how modules are defined in your app. For a guide on how to use JavaScript modules, see MDN Web Docs: JavaScript modules.

JS isolation provides the following benefits:

- Imported JS no longer pollutes the global namespace.
- Consumers of a library and components aren't required to import the related JS.

For more information, see Call JavaScript functions from .NET methods in ASP.NET Core Blazor.

Dynamic import with the import() operator is supported with ASP.NET Core and Blazor:

```javascript
if ({CONDITION}) import("/additionalModule.js");
```

In the preceding example, the `{CONDITION}` placeholder represents a conditional check to determine if the module should be loaded.

For browser compatibility, see Can I use: JavaScript modules: dynamic import.

Avoid circular object references

Objects that contain circular references can't be serialized on the client for either:

- .NET method calls.
- JavaScript method calls from C# when the return type has circular references.

Byte array support

Blazor supports optimized byte array JavaScript (JS) interop that avoids encoding/decoding byte arrays into Base64. The following example uses JS interop to pass a byte array to .NET.

Provide a `sendByteArray` JS function. The function is called statically, which includes the assembly name parameter in the `invokeMethodAsync` call, by a button in the component and doesn't return a value:

`CallDotnet8.razor.js`:

JavaScript

```
export function sendByteArray() {
  const data = new Uint8Array([0x45, 0x76, 0x65, 0x72, 0x79, 0x74, 0x68,
0x69,
    0x6e, 0x67, 0x27, 0x73, 0x20, 0x73, 0x68, 0x69, 0x6e, 0x79, 0x2c,
    0x20, 0x43, 0x61, 0x70, 0x74, 0x61, 0x69, 0x6e, 0x2e, 0x20, 0x4e,
    0x6f, 0x74, 0x20, 0x74, 0x6f, 0x20, 0x66, 0x72, 0x65, 0x74, 0x2e]);
  DotNet.invokeMethodAsync('BlazorSample', 'ReceiveByteArray', data)
    .then(str => {
      alert(str);
    });
}

export function addHandlers() {
  const btn = document.getElementById("btn");
  btn.addEventListener("click", sendByteArray);
}
```

> **Note**
>
> For general guidance on JS location and our recommendations for production apps, see JavaScript location in ASP.NET Core Blazor apps.

`CallDotnet8.razor`:

razor

```
@page "/call-dotnet-8"
@using System.Text
@implements IAsyncDisposable
@inject IJSRuntime JS

<PageTitle>Call .NET 8</PageTitle>

<h1>Call .NET Example 8</h1>

<p>
    <button id="btn">Send Bytes</button>
</p>

<p>
    Quote ©2005 <a href="https://www.uphe.com">Universal Pictures</a>:
    <a href="https://www.uphe.com/movies/serenity-2005">Serenity</a><br>
    <a href="https://www.imdb.com/name/nm0821612/">Jewel Staite on IMDB</a>
</p>

@code {
    private IJSObjectReference? module;
```

```
    protected override async Task OnAfterRenderAsync(bool firstRender)
    {
        if (firstRender)
        {
            module = await JS.InvokeAsync<IJSObjectReference>("import",
                "./Components/Pages/CallDotnet8.razor.js");

            await module.InvokeVoidAsync("addHandlers");
        }
    }

    [JSInvokable]
    public static Task<string> ReceiveByteArray(byte[] receivedBytes) =>
        Task.FromResult(Encoding.UTF8.GetString(receivedBytes, 0,
            receivedBytes.Length));

    async ValueTask IAsyncDisposable.DisposeAsync()
    {
        if (module is not null)
        {
            await module.DisposeAsync();
        }
    }
}
```

For information on using a byte array when calling JavaScript from .NET, see Call JavaScript functions from .NET methods in ASP.NET Core Blazor.

Stream from JavaScript to .NET

Blazor supports streaming data directly from JavaScript to .NET. Streams are requested using the `Microsoft.JSInterop.IJSStreamReference` interface.

`Microsoft.JSInterop.IJSStreamReference.OpenReadStreamAsync` returns a Stream and uses the following parameters:

- `maxAllowedSize`: Maximum number of bytes permitted for the read operation from JavaScript, which defaults to 512,000 bytes if not specified.
- `cancellationToken`: A CancellationToken for cancelling the read.

In JavaScript:

JavaScript

```
function streamToDotNet() {
  return new Uint8Array(10000000);
}
```

In C# code:

```C#
var dataReference =
    await JS.InvokeAsync<IJSStreamReference>("streamToDotNet");
using var dataReferenceStream =
    await dataReference.OpenReadStreamAsync(maxAllowedSize: 10_000_000);

var outputPath = Path.Combine(Path.GetTempPath(), "file.txt");
using var outputFileStream = File.OpenWrite(outputPath);
await dataReferenceStream.CopyToAsync(outputFileStream);
```

In the preceding example:

- `JS` is an injected IJSRuntime instance. IJSRuntime is registered by the Blazor framework.
- The `dataReferenceStream` is written to disk (`file.txt`) at the current user's temporary folder path (GetTempPath).

Call JavaScript functions from .NET methods in ASP.NET Core Blazor covers the reverse operation, streaming from .NET to JavaScript using a DotNetStreamReference.

ASP.NET Core Blazor file uploads covers how to upload a file in Blazor. For a forms example that streams `<textarea>` data in a server-side component, see Troubleshoot ASP.NET Core Blazor forms.

JavaScript `[JSImport]`/`[JSExport]` interop

This section applies to client-side components.

As an alternative to interacting with JavaScript (JS) in client-side components using Blazor's JS interop mechanism based on the IJSRuntime interface, a JS `[JSImport]`/`[JSExport]` interop API is available to apps targeting .NET 7 or later.

For more information, see JavaScript JSImport/JSExport interop with ASP.NET Core Blazor.

Disposal of JavaScript interop object references

Examples throughout the JavaScript (JS) interop articles demonstrate typical object disposal patterns:

- When calling .NET from JS, as described in this article, dispose of a created DotNetObjectReference either from .NET or from JS to avoid leaking .NET memory.
- When calling JS from .NET, as described in Call JavaScript functions from .NET methods in ASP.NET Core Blazor, dispose any created IJSObjectReference/IJSInProcessObjectReference/`JSObjectReference` either from .NET or from JS to avoid leaking JS memory.

JS interop object references are implemented as a map keyed by an identifier on the side of the JS interop call that creates the reference. When object disposal is initiated from either the .NET or JS side, Blazor removes the entry from the map, and the object can be garbage collected as long as no other strong reference to the object is present.

At a minimum, always dispose objects created on the .NET side to avoid leaking .NET managed memory.

DOM cleanup tasks during component disposal

For more information, see ASP.NET Core Blazor JavaScript interoperability (JS interop).

JavaScript interop calls without a circuit

For more information, see ASP.NET Core Blazor JavaScript interoperability (JS interop).

Additional resources

- Call JavaScript functions from .NET methods in ASP.NET Core Blazor
- InteropComponent.razor example (dotnet/AspNetCore GitHub repository main branch): The `main` branch represents the product unit's current development for the next release of ASP.NET Core. To select the branch for a different release (for example, `release/{VERSION}`, where the `{VERSION}` placeholder is the release version), use the **Switch branches or tags** dropdown list to select the branch. For a branch that no longer exists, use the **Tags** tab to find the API (for example, `v7.0.0`).

JavaScript `[JSImport]`/`[JSExport]` interop with ASP.NET Core Blazor

Article • 10/04/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article explains how to interact with JavaScript (JS) in client-side components using JavaScript (JS) `[JSImport]`/`[JSExport]` interop API. For additional information and examples, see JavaScript `[JSImport]`/`[JSExport]` interop in .NET WebAssembly.

For additional guidance, see the Configuring and hosting .NET WebAssembly applications guidance in the .NET Runtime (`dotnet/runtime`) GitHub repository.

Blazor provides its own JS interop mechanism based on the IJSRuntime interface. Blazor's JS interop is uniformly supported across Blazor render modes and for Blazor Hybrid apps. IJSRuntime also enables library authors to build JS interop libraries for sharing across the Blazor ecosystem and remains the recommended approach for JS interop in Blazor. See the following articles:

- Call JavaScript functions from .NET methods in ASP.NET Core Blazor
- Call .NET methods from JavaScript functions in ASP.NET Core Blazor

This article describes an alternative JS interop approach specific to client-side components executed on WebAssembly. These approaches are appropriate when you only expect to run on client-side WebAssembly. Library authors can use these approaches to optimize JS interop by checking during code execution if the app is running on WebAssembly in a browser (OperatingSystem.IsBrowser). The approaches described in this article should be used to replace the obsolete unmarshalled JS interop API when migrating to .NET 7 or later.

> **Note**
>
> This article focuses on JS interop in client-side components. For guidance on calling .NET in JavaScript apps, see **JavaScript `[JSImport]`/`[JSExport]` interop with a**

WebAssembly Browser App project.

Obsolete JavaScript interop API

Unmarshalled JS interop using IJSUnmarshalledRuntime API is obsolete in ASP.NET Core in .NET 7 or later. Follow the guidance in this article to replace the obsolete API.

Prerequisites

Visual Studio with the **ASP.NET and web development** workload.

No further tooling is required if you plan on implementing `[JSImport]`/`[JSExport]` interop in a Blazor WebAssembly app generated from the Blazor WebAssembly project template.

If you plan to use the WebAssembly Browser or WebAssembly Console app project templates, install the Microsoft.NET.Runtime.WebAssembly.Templates NuGet package with the following command:

.NET CLI

```
dotnet new install Microsoft.NET.Runtime.WebAssembly.Templates
```

For more information, see JavaScript `[JSImport]`/`[JSExport]` interop with a WebAssembly Browser App project.

Namespace

The JS interop API (JSHost.ImportAsync) described in this article is controlled by attributes in the System.Runtime.InteropServices.JavaScript namespace.

Enable unsafe blocks

Enable the AllowUnsafeBlocks property in app's project file, which permits the code generator in the Roslyn compiler to use pointers for JS interop:

XML

```
<PropertyGroup>
  <AllowUnsafeBlocks>true</AllowUnsafeBlocks>
```

```
</PropertyGroup>
```

> ⚠ **Warning**
>
> The JS interop API requires enabling AllowUnsafeBlocks. Be careful when implementing your own unsafe code in .NET apps, which can introduce security and stability risks. For more information, see Unsafe code, pointer types, and function pointers.

Razor class library (RCL) collocated JS is unsupported

Generally, the JS location support for IJSRuntime-based JS interop (JavaScript location in ASP.NET Core Blazor apps) is also present for the `[JSImport]`/`[JSExport]` interop described by this article. The only unsupported JS location feature is for *collocated JS in a Razor class library (RCL)*.

Instead of using collocated JS in an RCL, place the JS file in the RCL's `wwwroot` folder and reference it using the usual path for RCL static assets:

`_content/{PACKAGE ID}/{PATH}/{FILE NAME}.js`

- The `{PACKAGE ID}` placeholder is the RCL's package identifier (or library name for a class library).
- The `{PATH}` placeholder is the path to the file.
- The `{FILE NAME}` placeholder is the file name.

Although collocated JS in an RCL isn't supported by `[JSImport]`/`[JSExport]` interop, you can keep your JS files organized by taking either or both of the following approaches:

- Name the JS file the same as the component where the JS is used. For a component in the RCL named `CallJavaScriptFromLib` (`CallJavaScriptFromLib.razor`), name the file `CallJavaScriptFromLib.js` in the `wwwroot` folder.
- Place component-specific JS files in a `Components` folder inside the RCL's `wwwroot` folder and use "`Components`" in the path to the file: `_content/{PACKAGE ID}/Components/CallJavaScriptFromLib.js`.

Call JavaScript from .NET

This section explains how to call JS functions from .NET.

In the following `CallJavaScript1` component:

- The `CallJavaScript1` module is imported asynchronously from the collocated JS file with JSHost.ImportAsync.
- The imported `getMessage` JS function is called by `GetWelcomeMessage`.
- The returned welcome message string is displayed in the UI via the `message` field.

`CallJavaScript1.razor`:

razor

```razor
@page "/call-javascript-1"
@rendermode InteractiveWebAssembly
@using System.Runtime.InteropServices.JavaScript

<h1>
    JS <code>[JSImport]</code>/<code>[JSExport]</code> Interop
    (Call JS Example 1)
</h1>

@(message is not null ? message : string.Empty)

@code {
    private string? message;

    protected override async Task OnInitializedAsync()
    {
        await JSHost.ImportAsync("CallJavaScript1",
            "../Components/Pages/CallJavaScript1.razor.js");

        message = GetWelcomeMessage();
    }
}
```

> **Note**
>
> Include a conditional check in code with OperatingSystem.IsBrowser to ensure that the JS interop is only called by a component rendered on the client. This is important for libraries/NuGet packages that target server-side components, which can't execute the code provided by this JS interop API.

To import a JS function to call it from C#, use the [JSImport] attribute on a C# method signature that matches the JS function's signature. The first parameter to the `[JSImport]`

attribute is the name of the JS function to import, and the second parameter is the name of the JS module.

In the following example, `getMessage` is a JS function that returns a `string` for a module named `CallJavaScript1`. The C# method signature matches: No parameters are passed to the JS function, and the JS function returns a `string`. The JS function is called by `GetWelcomeMessage` in C# code.

`CallJavaScript1.razor.cs`:

C#

```
using System.Runtime.InteropServices.JavaScript;
using System.Runtime.Versioning;

namespace BlazorSample.Components.Pages;

[SupportedOSPlatform("browser")]
public partial class CallJavaScript1
{
    [JSImport("getMessage", "CallJavaScript1")]
    internal static partial string GetWelcomeMessage();
}
```

The app's namespace for the preceding `CallJavaScript1` partial class is `BlazorSample`. The component's namespace is `BlazorSample.Components.Pages`. If using the preceding component in a local test app, update the namespace to match the app. For example, the namespace is `ContosoApp.Components.Pages` if the app's namespace is `ContosoApp`. For more information, see ASP.NET Core Razor components.

In the imported method signature, you can use .NET types for parameters and return values, which are marshalled automatically by the runtime. Use JSMarshalAsAttribute<T> to control how the imported method parameters are marshalled. For example, you might choose to marshal a `long` as System.Runtime.InteropServices.JavaScript.JSType.Number or System.Runtime.InteropServices.JavaScript.JSType.BigInt. You can pass Action/Func<TResult> callbacks as parameters, which are marshalled as callable JS functions. You can pass both JS and managed object references, and they are marshaled as proxy objects, keeping the object alive across the boundary until the proxy is garbage collected. You can also import and export asynchronous methods with a Task result, which are marshaled as JS promises. Most of the marshalled types work in both directions, as parameters and as return values, on both imported and exported methods, which are covered in the Call .NET from JavaScript section later in this article.

For additional type mapping information and examples, see JavaScript `[JSImport]`/`[JSExport]` interop in .NET WebAssembly.

The module name in the `[JSImport]` attribute and the call to load the module in the component with JSHost.ImportAsync must match and be unique in the app. When authoring a library for deployment in a NuGet package, we recommend using the NuGet package namespace as a prefix in module names. In the following example, the module name reflects the `Contoso.InteropServices.JavaScript` package and a folder of user message interop classes (`UserMessages`):

C#

```
[JSImport("getMessage",
    "Contoso.InteropServices.JavaScript.UserMessages.CallJavaScript1")]
```

Functions accessible on the global namespace can be imported by using the globalThis prefix in the function name and by using the `[JSImport]` attribute without providing a module name. In the following example, console.log is prefixed with `globalThis`. The imported function is called by the C# `Log` method, which accepts a C# string message (`message`) and marshalls the C# string to a JS String for `console.log`:

C#

```
[JSImport("globalThis.console.log")]
internal static partial void Log([JSMarshalAs<JSType.String>] string
message);
```

Export scripts from a standard JavaScript module either collocated with a component or placed with other JavaScript static assets in a JS file (for example, `wwwroot/js/{FILE NAME}.js`, where JS static assets are maintained in a folder named `js` in the app's `wwwroot` folder and the `{FILE NAME}` placeholder is the file name).

In the following example, a JS function named `getMessage` is exported from a collocated JS file that returns a welcome message, "Hello from Blazor!" in Portuguese:

`CallJavaScript1.razor.js`:

JavaScript

```
export function getMessage() {
  return 'Olá do Blazor!';
}
```

Call .NET from JavaScript

This section explains how to call .NET methods from JS.

The following `CallDotNet1` component calls JS that directly interacts with the DOM to render the welcome message string:

- The `CallDotNet` JS module is imported asynchronously from the collocated JS file for this component.
- The imported `setMessage` JS function is called by `SetWelcomeMessage`.
- The returned welcome message is displayed by `setMessage` in the UI via the `message` field.

> **Important**
>
> In this section's example, JS interop is used to mutate a DOM element *purely for demonstration purposes* after the component is rendered in **OnAfterRender**. Typically, you should only mutate the DOM with JS when the object doesn't interact with Blazor. The approach shown in this section is similar to cases where a third-party JS library is used in a Razor component, where the component interacts with the JS library via JS interop, the third-party JS library interacts with part of the DOM, and Blazor isn't involved directly with the DOM updates to that part of the DOM. For more information, see **ASP.NET Core Blazor JavaScript interoperability (JS interop)**.

`CallDotNet1.razor`:

razor

```razor
@page "/call-dotnet-1"
@rendermode InteractiveWebAssembly
@using System.Runtime.InteropServices.JavaScript

<h1>
    JS <code>[JSImport]</code>/<code>[JSExport]</code> Interop
    (Call .NET Example 1)
</h1>

<p>
    <span id="result">.NET method not executed yet</span>
</p>

@code {
    protected override async Task OnAfterRenderAsync(bool firstRender)
    {
```

```
        if (firstRender)
        {
            await JSHost.ImportAsync("CallDotNet1",
                "../Components/Pages/CallDotNet1.razor.js");

            SetWelcomeMessage();
        }
    }
}
```

To export a .NET method so that it can be called from JS, use the [JSExport] attribute.

In the following example:

- `SetWelcomeMessage` calls a JS function named `setMessage`. The JS function calls into .NET to receive the welcome message from `GetMessageFromDotnet` and displays the message in the UI.
- `GetMessageFromDotnet` is a .NET method with the `[JSExport]` attribute that returns a welcome message, "Hello from Blazor!" in Portuguese.

`CallDotNet1.razor.cs`:

C#

```
using System.Runtime.InteropServices.JavaScript;
using System.Runtime.Versioning;

namespace BlazorSample.Components.Pages;

[SupportedOSPlatform("browser")]
public partial class CallDotNet1
{
    [JSImport("setMessage", "CallDotNet1")]
    internal static partial void SetWelcomeMessage();

    [JSExport]
    internal static string GetMessageFromDotnet() => "Olá do Blazor!";
}
```

The app's namespace for the preceding `CallDotNet1` partial class is `BlazorSample`. The component's namespace is `BlazorSample.Components.Pages`. If using the preceding component in a local test app, update the app's namespace to match the app. For example, the component namespace is `ContosoApp.Components.Pages` if the app's namespace is `ContosoApp`. For more information, see ASP.NET Core Razor components.

In the following example, a JS function named `setMessage` is imported from a collocated JS file.

The `setMessage` method:

- Calls `globalThis.getDotnetRuntime(0)` to expose the WebAssembly .NET runtime instance for calling exported .NET methods.
- Obtains the app assembly's JS exports. The name of the app's assembly in the following example is `BlazorSample`.
- Calls the `BlazorSample.Components.Pages.CallDotNet1.GetMessageFromDotnet` method from the exports (`exports`). The returned value, which is the welcome message, is assigned to the `CallDotNet1` component's `<span>` text. The app's namespace is `BlazorSample`, and the `CallDotNet1` component's namespace is `BlazorSample.Components.Pages`.

`CallDotNet1.razor.js`:

JavaScript

```
export async function setMessage() {
  const { getAssemblyExports } = await globalThis.getDotnetRuntime(0);
  var exports = await getAssemblyExports("BlazorSample.dll");

  document.getElementById("result").innerText =

exports.BlazorSample.Components.Pages.CallDotNet1.GetMessageFromDotnet();
}
```

> **Note**
>
> Calling `getAssemblyExports` to obtain the exports can occur in a JavaScript initializer for availability across the app.

Multiple module import calls

After a JS module is loaded, the module's JS functions are available to the app's components and classes as long as the app is running in the browser window or tab without the user manually reloading the app. JSHost.ImportAsync can be called multiple times on the same module without a significant performance penalty when:

- The user visits a component that calls JSHost.ImportAsync to import a module, navigates away from the component, and then returns to the component where JSHost.ImportAsync is called again for the same module import.
- The same module is used by different components and loaded by JSHost.ImportAsync in each of the components.

Use of a single JavaScript module across components

Before following the guidance in this section, read the Call JavaScript from .NET and Call .NET from JavaScript sections of this article, which provide general guidance on `[JSImport]`/`[JSExport]` interop.

The example in this section shows how to use JS interop from a shared JS module in a client-side app. The guidance in this section isn't applicable to Razor class libraries (RCLs).

The following components, classes, C# methods, and JS functions are used:

- `Interop` class (`Interop.cs`): Sets up import and export JS interop with the `[JSImport]` and `[JSExport]` attributes for a module named `Interop`.
  - `GetWelcomeMessage`: .NET method that calls the imported `getMessage` JS function.
  - `SetWelcomeMessage`: .NET method that calls the imported `setMessage` JS function.
  - `GetMessageFromDotnet`: An exported C# method that returns a welcome message string when called from JS.
- `wwwroot/js/interop.js` file: Contains the JS functions.
  - `getMessage`: Returns a welcome message when called by C# code in a component.
  - `setMessage`: Calls the `GetMessageFromDotnet` C# method and assigns the returned welcome message to a DOM `<span>` element.
- `Program.cs` calls JSHost.ImportAsync to load the module from `wwwroot/js/interop.js`.
- `CallJavaScript2` component (`CallJavaScript2.razor`): Calls `GetWelcomeMessage` and displays the returned welcome message in the component's UI.
- `CallDotNet2` component (`CallDotNet2.razor`): Calls `SetWelcomeMessage`.

`Interop.cs`:

C#

```
using System.Runtime.InteropServices.JavaScript;
using System.Runtime.Versioning;

namespace BlazorSample.JavaScriptInterop;

[SupportedOSPlatform("browser")]
public partial class Interop
{
    [JSImport("getMessage", "Interop")]
```

```
    internal static partial string GetWelcomeMessage();

    [JSImport("setMessage", "Interop")]
    internal static partial void SetWelcomeMessage();

    [JSExport]
    internal static string GetMessageFromDotnet() => "Olá do Blazor!";
}
```

In the preceding example, the app's namespace is `BlazorSample`, and the full namespace for C# interop classes is `BlazorSample.JavaScriptInterop`.

`wwwroot/js/interop.js`:

JavaScript

```
export function getMessage() {
  return 'Olá do Blazor!';
}

export async function setMessage() {
  const { getAssemblyExports } = await globalThis.getDotnetRuntime(0);
  var exports = await getAssemblyExports("BlazorSample.dll");

  document.getElementById("result").innerText =
    exports.BlazorSample.JavaScriptInterop.Interop.GetMessageFromDotnet();
}
```

Make the System.Runtime.InteropServices.JavaScript namespace available at the top of the `Program.cs` file:

C#

```
using System.Runtime.InteropServices.JavaScript;
```

Load the module in `Program.cs` before WebAssemblyHost.RunAsync is called:

C#

```
if (OperatingSystem.IsBrowser())
{
    await JSHost.ImportAsync("Interop", "../js/interop.js");
}
```

`CallJavaScript2.razor`:

razor

```razor
@page "/call-javascript-2"
@rendermode InteractiveWebAssembly
@using BlazorSample.JavaScriptInterop

<h1>
    JS <code>[JSImport]</code>/<code>[JSExport]</code> Interop
    (Call JS Example 2)
</h1>

@(message is not null ? message : string.Empty)

@code {
    private string? message;

    protected override void OnInitialized()
    {
        message = Interop.GetWelcomeMessage();
    }
}
```

`CallDotNet2.razor`:

razor

```razor
@page "/call-dotnet-2"
@rendermode InteractiveWebAssembly
@using BlazorSample.JavaScriptInterop

<h1>
    JS <code>[JSImport]</code>/<code>[JSExport]</code> Interop
    (Call .NET Example 2)
</h1>

<p>
    <span id="result">.NET method not executed</span>
</p>

@code {
    protected override void OnAfterRender(bool firstRender)
    {
        if (firstRender)
        {
            Interop.SetWelcomeMessage();
        }
    }
}
```

ⓘ Important

In this section's example, JS interop is used to mutate a DOM element *purely for demonstration purposes* after the component is rendered in **OnAfterRender**. Typically, you should only mutate the DOM with JS when the object doesn't interact with Blazor. The approach shown in this section is similar to cases where a third-party JS library is used in a Razor component, where the component interacts with the JS library via JS interop, the third-party JS library interacts with part of the DOM, and Blazor isn't involved directly with the DOM updates to that part of the DOM. For more information, see **ASP.NET Core Blazor JavaScript interoperability (JS interop)**.

ASP.NET Core Blazor JavaScript with static server-side rendering (static SSR)

Article • 04/11/2024

This article explains how to load JavaScript (JS) in a Blazor Web App with static server-side rendering (static SSR) and enhanced navigation.

Some apps depend on JS to perform initialization tasks that are specific to each page. When using Blazor's enhanced navigation feature, which allows the user to avoid reloading the entire page, page-specific JS may not be executed again as expected each time an enhanced page navigation occurs.

To avoid this problem, we don't recommended relying on page-specific `<script>` elements placed outside of the layout file applied to the component. Instead, scripts should register an afterWebStarted JS initializer to perform initialization logic and use an event listener (`blazor.addEventListener("enhancedload", callback)`) to listen for page updates caused by enhanced navigation.

The following example demonstrates one way to configure JS code to run when a statically-rendered page with enhanced navigation is initially loaded or updated.

The following `PageWithScript` component example is a component in the app that requires scripts to run with static SSR and enhanced navigation. The following component example includes a `PageScript` component from a Razor class library (RCL) that's added to the solution later in this article.

`Components/Pages/PageWithScript.razor`:

razor

```razor
@page "/page-with-script"
@using BlazorPageScript

<PageTitle>Enhanced Load Script Example</PageTitle>

<PageScript Src="./Components/Pages/PageWithScript.razor.js" />

Welcome to my page.
```

In the Blazor Web App, add the following collocated JS file:

- `onLoad` is called when the script is added to the page.

- `onUpdate` is called when the script still exists on the page after an enhanced update.
- `onDispose` is called when the script is removed from the page after an enhanced update.

`Components/Pages/PageWithScript.razor.js`:

JavaScript

```
export function onLoad() {
  console.log('Loaded');
}

export function onUpdate() {
  console.log('Updated');
}

export function onDispose() {
  console.log('Disposed');
}
```

In a Razor Class Library (RCL) (the example RCL is named `BlazorPageScript`), add the following module.

`wwwroot/BlazorPageScript.lib.module.js`:

JavaScript

```
const pageScriptInfoBySrc = new Map();

function registerPageScriptElement(src) {
  if (!src) {
    throw new Error('Must provide a non-empty value for the "src"
attribute.');
  }

  let pageScriptInfo = pageScriptInfoBySrc.get(src);

  if (pageScriptInfo) {
    pageScriptInfo.referenceCount++;
  } else {
    pageScriptInfo = { referenceCount: 1, module: null };
    pageScriptInfoBySrc.set(src, pageScriptInfo);
    initializePageScriptModule(src, pageScriptInfo);
  }
}

function unregisterPageScriptElement(src) {
  if (!src) {
    return;
```

```
  }

  const pageScriptInfo = pageScriptInfoBySrc.get(src);

  if (!pageScriptInfo) {
    return;
  }

  pageScriptInfo.referenceCount--;
}

async function initializePageScriptModule(src, pageScriptInfo) {
  if (src.startsWith("./")) {
    src = new URL(src.substr(2), document.baseURI).toString();
  }

  const module = await import(src);

  if (pageScriptInfo.referenceCount <= 0) {
    return;
  }

  pageScriptInfo.module = module;
  module.onLoad?.();
  module.onUpdate?.();
}

function onEnhancedLoad() {
  for (const [src, { module, referenceCount }] of pageScriptInfoBySrc) {
    if (referenceCount <= 0) {
      module?.onDispose?.();
      pageScriptInfoBySrc.delete(src);
    }
  }

  for (const { module } of pageScriptInfoBySrc.values()) {
    module?.onUpdate?.();
  }
}

export function afterWebStarted(blazor) {
  customElements.define('page-script', class extends HTMLElement {
    static observedAttributes = ['src'];

    attributeChangedCallback(name, oldValue, newValue) {
      if (name !== 'src') {
        return;
      }

      this.src = newValue;
      unregisterPageScriptElement(oldValue);
      registerPageScriptElement(newValue);
    }

    disconnectedCallback() {
```

```
      unregisterPageScriptElement(this.src);
    }
  });

  blazor.addEventListener('enhancedload', onEnhancedLoad);
}
```

In the RCL, add the following `PageScript` component.

`PageScript.razor`:

razor

```razor
<page-script src="@Src"></page-script>

@code {
    [Parameter]
    [EditorRequired]
    public string Src { get; set; } = default!;
}
```

The `PageScript` component functions normally on the top-level of a page.

If you place the `PageScript` component in an app's layout (for example, `MainLayout.razor`), which results in a shared `PageScript` among pages that use the layout, then the component only runs `onLoad` after a full page reload and `onUpdate` when any enhanced page update occurs, including enhanced navigation.

To reuse the same module among pages, but have the `onLoad` and `onDispose` callbacks invoked on each page change, append a query string to the end of the script so that it's recognized as a different module. An app could adopt the convention of using the component's name as the query string value. In the following example, the query string is "`counter`" because this `PageScript` component reference is placed in a `Counter` component. This is merely a suggestion, and you can use whatever query string scheme that you prefer.

razor

```razor
<PageScript Src="./Components/Pages/PageWithScript.razor.js?counter" />
```

To monitor changes in specific DOM elements, use the MutationObserver pattern in JS on the client. For more information, see ASP.NET Core Blazor JavaScript interoperability (JS interop).

Example implementation without using an RCL

The approach described in this article can be implemented directly in a Blazor Web App without using a Razor class library (RCL). For an example, see Enable QR code generation for TOTP authenticator apps in an ASP.NET Core Blazor Web App.

Call a web API from ASP.NET Core Blazor

Article • 10/21/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article describes how to call a web API from a Blazor app.

Package

The System.Net.Http.Json package provides extension methods for System.Net.Http.HttpClient and System.Net.Http.HttpContent that perform automatic serialization and deserialization using System.Text.Json. The `System.Net.Http.Json` package is provided by the .NET shared framework and doesn't require adding a package reference to the app.

Sample apps

See the sample apps in the dotnet/blazor-samples GitHub repository.

`BlazorWebAppCallWebApi`

Call an external (not in the Blazor Web App) todo list web API from a Blazor Web App:

- `Backend`: A web API app for maintaining a todo list, based on Minimal APIs. The web API app is a separate app from the Blazor Web App, possibly hosted on a different server.
- `BlazorApp`/`BlazorApp.Client`: A Blazor Web App that calls the web API app with an HttpClient for todo list operations, such as creating, reading, updating, and deleting (CRUD) items from the todo list.

For client-side rendering (CSR), which includes Interactive WebAssembly components and Auto components that have adopted CSR, calls are made with a preconfigured HttpClient registered in the `Program` file of the client project (`BlazorApp.Client`):

C#

```
builder.Services.AddScoped(sp =>
    new HttpClient
    {
        BaseAddress = new Uri(builder.Configuration["FrontendUrl"] ??
"https://localhost:5002")
    });
```

For server-side rendering (SSR), which includes prerendered and interactive Server components, prerendered WebAssembly components, and Auto components that are prerendered or have adopted SSR, calls are made with an HttpClient registered in the `Program` file of the server project (`BlazorApp`):

C#

```
builder.Services.AddHttpClient();
```

Call an internal (inside the Blazor Web App) movie list API, where the API resides in the server project of the Blazor Web App:

- `BlazorApp`: A Blazor Web App that maintains a movie list:
  - When operations are performed on the movie list within the app on the server, ordinary API calls are used.
  - When API calls are made by a web-based client, a web API is used for movie list operations, based on Minimal APIs.
- `BlazorApp.Client`: The client project of the Blazor Web App, which contains Interactive WebAssembly and Auto components for user management of the movie list.

For CSR, which includes Interactive WebAssembly components and Auto components that have adopted CSR, calls to the API are made via a client-based service (`ClientMovieService`) that uses a preconfigured HttpClient registered in the `Program` file of the client project (`BlazorApp.Client`). Because these calls are made over a public or private web, the movie list API is a *web API*.

The following example obtains a list of movies from the `/movies` endpoint:

C#

```
public class ClientMovieService(HttpClient http) : IMovieService
{
    public async Task<Movie[]> GetMoviesAsync(bool watchedMovies) =>
        await http.GetFromJsonAsync<Movie[]>("movies") ?? [];
}
```

For SSR, which includes prerendered and interactive Server components, prerendered WebAssembly components, and Auto components that are prerendered or have adopted SSR, calls are made directly via a server-based service (`ServerMovieService`). The API doesn't rely on a network, so it's a standard API for movie list CRUD operations.

The following example obtains a list of movies:

C#

```
public class ServerMovieService(MovieContext db) : IMovieService
{
    public async Task<Movie[]> GetMoviesAsync(bool watchedMovies) =>
        watchedMovies ?
        await db.Movies.Where(t => t.IsWatched).ToArrayAsync() :
        await db.Movies.ToArrayAsync();
}
```

`BlazorWebAppCallWebApi_Weather`

A weather data sample app that uses streaming rendering for weather data.

`BlazorWebAssemblyCallWebApi`

Calls a todo list web API from a Blazor WebAssembly app:

- `Backend`: A web API app for maintaining a todo list, based on Minimal APIs.
- `BlazorTodo`: A Blazor WebAssembly app that calls the web API with a preconfigured HttpClient for todo list CRUD operations.

Server-side scenarios for calling external web APIs

Server-based components call external web APIs using HttpClient instances, typically created using IHttpClientFactory. For guidance that applies to server-side apps, see Make HTTP requests using IHttpClientFactory in ASP.NET Core.

A server-side app doesn't include an HttpClient service. Provide an HttpClient to the app using the HttpClient factory infrastructure.

In the `Program` file:

C#

```
builder.Services.AddHttpClient();
```

The following Razor component makes a request to a web API for GitHub branches similar to the *Basic Usage* example in the Make HTTP requests using IHttpClientFactory in ASP.NET Core article.

`CallWebAPI.razor`:

razor

```
@page "/call-web-api"
@using System.Text.Json
@using System.Text.Json.Serialization
@inject IHttpClientFactory ClientFactory

<h1>Call web API from a Blazor Server Razor component</h1>

@if (getBranchesError || branches is null)
{
    <p>Unable to get branches from GitHub. Please try again later.</p>
}
else
{
    <ul>
        @foreach (var branch in branches)
        {
            <li>@branch.Name</li>
        }
    </ul>
}

@code {
    private IEnumerable<GitHubBranch>? branches = [];
    private bool getBranchesError;
    private bool shouldRender;

    protected override bool ShouldRender() => shouldRender;

    protected override async Task OnInitializedAsync()
    {
        var request = new HttpRequestMessage(HttpMethod.Get,
            "https://api.github.com/repos/dotnet/AspNetCore.Docs/branches");
        request.Headers.Add("Accept", "application/vnd.github.v3+json");
        request.Headers.Add("User-Agent", "HttpClientFactory-Sample");
```

```
        var client = ClientFactory.CreateClient();

        var response = await client.SendAsync(request);

        if (response.IsSuccessStatusCode)
        {
            using var responseStream = await
response.Content.ReadAsStreamAsync();
            branches = await JsonSerializer.DeserializeAsync
                <IEnumerable<GitHubBranch>>(responseStream);
        }
        else
        {
            getBranchesError = true;
        }

        shouldRender = true;
    }

    public class GitHubBranch
    {
        [JsonPropertyName("name")]
        public string? Name { get; set; }
    }
}
```

In the preceding example for C# 12 or later, an empty array (`[]`) is created for the `branches` variable. For earlier versions of C#, create an empty array (`Array.Empty<GitHubBranch>()`).

For an additional working example, see the server-side file upload example that uploads files to a web API controller in the ASP.NET Core Blazor file uploads article.

Service abstractions for web API calls

This section applies to Blazor Web Apps that maintain a web API in the server project or transform web API calls to an external web API.

When using the interactive WebAssembly and Auto render modes, components are prerendered by default. Auto components are also initially rendered interactively from the server before the Blazor bundle downloads to the client and the client-side runtime activates. This means that components using these render modes should be designed so that they run successfully from both the client and the server. If the component must call a server project-based API or transform a request to an external web API (one that's outside of the Blazor Web App) when running on the client, the recommended approach

is to abstract that API call behind a service interface and implement client and server versions of the service:

- The client version calls the web API with a preconfigured HttpClient.
- The server version can typically access the server-side resources directly. Injecting an HttpClient on the server that makes calls back to the server isn't recommended, as the network request is typically unnecessary. Alternatively, the API might be external to the server project, but a service abstraction for the server is required to transform the request in some way, for example to add an access token to a proxied request.

When using the WebAssembly render mode, you also have the option of disabling prerendering, so the components only render from the client. For more information, see ASP.NET Core Blazor render modes.

Examples (sample apps):

- Movie list web API in the `BlazorWebAppCallWebApi` sample app.
- Streaming rendering weather data web API in the `BlazorWebAppCallWebApi_Weather` sample app.
- Weather data returned to the client in either the `BlazorWebAppOidc` (non-BFF pattern) or `BlazorWebAppOidcBff` (BFF pattern) sample apps. These apps demonstrate secure (web) API calls. For more information, see Secure an ASP.NET Core Blazor Web App with OpenID Connect (OIDC).

Blazor Web App external web APIs

This section applies to Blazor Web Apps that call a web API maintained by a separate (external) project, possibly hosted on a different server.

Blazor Web Apps normally prerender client-side WebAssembly components, and Auto components render on the server during static or interactive server-side rendering (SSR). HttpClient services aren't registered by default in a Blazor Web App's main project. If the app is run with only the HttpClient services registered in the `.Client` project, as described in the Add the HttpClient service section, executing the app results in a runtime error:

> InvalidOperationException: Cannot provide a value for property 'Http' on type '...{COMPONENT}'. There is no registered service of type 'System.Net.Http.HttpClient'.

Use ***either*** of the following approaches:

- Add the HttpClient services to the server project to make the HttpClient available during SSR. Use the following service registration in the server project's `Program` file:

  ```
  C#

  builder.Services.AddHttpClient();
  ```

  HttpClient services are provided by the shared framework, so a package reference in the app's project file isn't required.

  Example: Todo list web API in the `BlazorWebAppCallWebApi` sample app

- If prerendering isn't required for a WebAssembly component that calls the web API, disable prerendering by following the guidance in ASP.NET Core Blazor render modes. If you adopt this approach, you don't need to add HttpClient services to the main project of the Blazor Web App because the component isn't prerendered on the server.

For more information, see Client-side services fail to resolve during prerendering.

Prerendered data

When prerendering, components render twice: first statically, then interactively. State doesn't automatically flow from the prerendered component to the interactive one. If a component performs asynchronous initialization operations and renders different content for different states during initialization, such as a "Loading..." progress indicator, you may see a flicker when the component renders twice.

You can address this by flowing prerendered state using the Persistent Component State API, which the `BlazorWebAppCallWebApi` and `BlazorWebAppCallWebApi_Weather` sample apps demonstrate. When the component renders interactively, it can render the same way using the same state. However, the API doesn't currently work with enhanced navigation, which you can work around by disabling enhanced navigation on links to the page (`data-enhanced-nav=false`). For more information, see the following resources:

- Prerender ASP.NET Core Razor components
- ASP.NET Core Blazor routing and navigation
- Support persistent component state across enhanced page navigations (dotnet/aspnetcore #51584)

Add the `HttpClient` service

The guidance in this section applies to client-side scenarios.

Client-side components call web APIs using a preconfigured HttpClient service, which is focused on making requests back to the server of origin. Additional HttpClient service configurations for other web APIs can be created in developer code. Requests are composed using Blazor JSON helpers or with HttpRequestMessage. Requests can include Fetch API option configuration.

The configuration examples in this section are only useful when a single web API is called for a single HttpClient instance in the app. When the app must call multiple web APIs, each with its own base address and configuration, you can adopt the following approaches, which are covered later in this article:

- Named HttpClient with IHttpClientFactory: Each web API is provided a unique name. When app code or a Razor component calls a web API, it uses a named HttpClient instance to make the call.
- Typed HttpClient: Each web API is typed. When app code or a Razor component calls a web API, it uses a typed HttpClient instance to make the call.

In the `Program` file, add an HttpClient service if it isn't already present from a Blazor project template used to create the app:

C#

```
builder.Services.AddScoped(sp =>
    new HttpClient
    {
        BaseAddress = new Uri(builder.HostEnvironment.BaseAddress)
    });
```

The preceding example sets the base address with `builder.HostEnvironment.BaseAddress` (IWebAssemblyHostEnvironment.BaseAddress), which gets the base address for the app and is typically derived from the `<base>` tag's `href` value in the host page.

The most common use cases for using the client's own base address are:

- The client project (`.Client`) of a Blazor Web App (.NET 8 or later) makes web API calls from WebAssembly components or code that runs on the client in WebAssembly to APIs in the server app.
- The client project (**Client**) of a hosted Blazor WebAssembly app makes web API calls to the server project (**Server**). Note that the hosted Blazor WebAssembly

project template is no longer available in .NET 8 or later. However, hosted Blazor WebAssembly apps remain supported for .NET 8.

If you're calling an external web API (not in the same URL space as the client app), set the URI to the web API's base address. The following example sets the base address of the web API to `https://localhost:5001`, where a separate web API app is running and ready to respond to requests from the client app:

C#

```
builder.Services.AddScoped(sp =>
    new HttpClient
    {
        BaseAddress = new Uri("https://localhost:5001")
    });
```

JSON helpers

HttpClient is available as a preconfigured service for making requests back to the origin server.

HttpClient and JSON helpers (System.Net.Http.Json.HttpClientJsonExtensions) are also used to call third-party web API endpoints. HttpClient is implemented using the browser's Fetch API and is subject to its limitations, including enforcement of the same-origin policy, which is discussed later in this article in the *Cross-Origin Resource Sharing (CORS)* section.

The client's base address is set to the originating server's address. Inject an HttpClient instance into a component using the @inject directive:

razor

```
@using System.Net.Http
@inject HttpClient Http
```

Use the System.Net.Http.Json namespace for access to HttpClientJsonExtensions, including GetFromJsonAsync, PutAsJsonAsync, and PostAsJsonAsync:

razor

```
@using System.Net.Http.Json
```

The following sections cover JSON helpers:

- GET
- POST
- PUT
- PATCH

System.Net.Http includes additional methods for sending HTTP requests and receiving HTTP responses, for example to send a DELETE request. For more information, see the DELETE and additional extension methods section.

GET from JSON (`GetFromJsonAsync`)

GetFromJsonAsync sends an HTTP GET request and parses the JSON response body to create an object.

In the following component code, the `todoItems` are displayed by the component. GetFromJsonAsync is called when the component is finished initializing (OnInitializedAsync).

```
C#

todoItems = await Http.GetFromJsonAsync<TodoItem[]>("todoitems");
```

POST as JSON (`PostAsJsonAsync`)

PostAsJsonAsync sends a POST request to the specified URI containing the value serialized as JSON in the request body.

In the following component code, `newItemName` is provided by a bound element of the component. The `AddItem` method is triggered by selecting a `<button>` element.

```
C#

await Http.PostAsJsonAsync("todoitems", addItem);
```

PostAsJsonAsync returns an HttpResponseMessage. To deserialize the JSON content from the response message, use the ReadFromJsonAsync extension method. The following example reads JSON weather data as an array:

```
C#

var content = await response.Content.ReadFromJsonAsync<WeatherForecast[]>()
??
```

```
    Array.Empty<WeatherForecast>();
```

PUT as JSON (`PutAsJsonAsync`)

PutAsJsonAsync sends an HTTP PUT request with JSON-encoded content.

In the following component code, `editItem` values for `Name` and `IsCompleted` are provided by bound elements of the component. The item's `Id` is set when the item is selected in another part of the UI (not shown) and `EditItem` is called. The `SaveItem` method is triggered by selecting the `<button>` element. The following example doesn't show loading `todoItems` for brevity. See the GET from JSON (GetFromJsonAsync) section for an example of loading items.

C#

```
await Http.PutAsJsonAsync($"todoitems/{editItem.Id}", editItem);
```

PutAsJsonAsync returns an HttpResponseMessage. To deserialize the JSON content from the response message, use the ReadFromJsonAsync extension method. The following example reads JSON weather data as an array:

C#

```
var content = await response.Content.ReadFromJsonAsync<WeatherForecast[]>()
??
    Array.Empty<WeatherForecast>();
```

PATCH as JSON (`PatchAsJsonAsync`)

PatchAsJsonAsync sends an HTTP PATCH request with JSON-encoded content.

> **Note**
>
> For more information, see JsonPatch in ASP.NET Core web API.

In the following example, PatchAsJsonAsync receives a JSON PATCH document as a plain text string with escaped quotes:

C#

```
await Http.PatchAsJsonAsync(
    $"todoitems/{id}",
    "
[{\"operationType\":2,\"path\":\"/IsComplete\",\"op\":\"replace\",\"value\":
true}]");
```

PatchAsJsonAsync returns an HttpResponseMessage. To deserialize the JSON content from the response message, use the ReadFromJsonAsync extension method. The following example reads JSON todo item data as an array. An empty array is created if no item data is returned by the method, so `content` isn't null after the statement executes:

C#

```
var response = await Http.PatchAsJsonAsync(...);
var content = await response.Content.ReadFromJsonAsync<TodoItem[]>() ??
    Array.Empty<TodoItem>();
```

Laid out with indentation, spacing, and unescaped quotes, the unencoded PATCH document appears as the following JSON:

JSON

```
[
  {
    "operationType": 2,
    "path": "/IsComplete",
    "op": "replace",
    "value": true
  }
]
```

To simplify the creation of PATCH documents in the app issuing PATCH requests, an app can use .NET JSON PATCH support, as the following guidance demonstrates.

Install the Microsoft.AspNetCore.JsonPatch NuGet package and use the API features of the package to compose a JsonPatchDocument for a PATCH request.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

Add `@using` directives for the System.Text.Json, System.Text.Json.Serialization, and Microsoft.AspNetCore.JsonPatch namespaces to the top of the Razor component:

razor

```
@using System.Text.Json
@using System.Text.Json.Serialization
@using Microsoft.AspNetCore.JsonPatch
```

Compose the JsonPatchDocument for a `TodoItem` with `IsComplete` set to `true` using the Replace method:

C#

```
var patchDocument = new JsonPatchDocument<TodoItem>()
    .Replace(p => p.IsComplete, true);
```

Pass the document's operations (`patchDocument.Operations`) to the PatchAsJsonAsync call:

C#

```
private async Task UpdateItem(long id)
{
    await Http.PatchAsJsonAsync(
        $"todoitems/{id}",
        patchDocument.Operations,
        new JsonSerializerOptions()
        {
            DefaultIgnoreCondition = JsonIgnoreCondition.WhenWritingDefault
        });
}
```

JsonSerializerOptions.DefaultIgnoreCondition is set to JsonIgnoreCondition.WhenWritingDefault to ignore a property only if it equals the default value for its type.

Add JsonSerializerOptions.WriteIndented set to `true` if you want to present the JSON payload in a pleasant format for display. Writing indented JSON has no bearing on processing PATCH requests and isn't typically performed in production apps for web API requests.

Follow the guidance in the JsonPatch in ASP.NET Core web API article to add a PATCH controller action to the web API. Alternatively, PATCH request processing can be implemented as a Minimal API with the following steps.

Add a package reference for the Microsoft.AspNetCore.Mvc.NewtonsoftJson NuGet package to the web API app.

> **Note**
>
> There's no need to add a package reference for the Microsoft.AspNetCore.JsonPatch package to the app because the reference to the `Microsoft.AspNetCore.Mvc.NewtonsoftJson` package automatically transitively adds a package reference for `Microsoft.AspNetCore.JsonPatch`.

In the `Program` file add an `@using` directive for the Microsoft.AspNetCore.JsonPatch namespace:

C#

```
using Microsoft.AspNetCore.JsonPatch;
```

Provide the endpoint to the request processing pipeline of the web API:

C#

```
app.MapPatch("/todoitems/{id}", async (long id, TodoContext db) =>
{
    if (await db.TodoItems.FindAsync(id) is TodoItem todo)
    {
        var patchDocument =
            new JsonPatchDocument<TodoItem>().Replace(p => p.IsComplete,
true);
        patchDocument.ApplyTo(todo);
        await db.SaveChangesAsync();

        return TypedResults.Ok(todo);
    }

    return TypedResults.NoContent();
});
```

> **⚠ Warning**
>
> As with the other examples in the JsonPatch in ASP.NET Core web API article, the preceding PATCH API doesn't protect the web API from over-posting attacks. For more information, see Tutorial: Create a web API with ASP.NET Core.

For a fully working PATCH experience, see the `BlazorWebAppCallWebApi` sample app.

DELETE (`DeleteAsync`) and additional extension methods

System.Net.Http includes additional extension methods for sending HTTP requests and receiving HTTP responses. HttpClient.DeleteAsync is used to send an HTTP DELETE request to a web API.

In the following component code, the `<button>` element calls the `DeleteItem` method. The bound `<input>` element supplies the `id` of the item to delete.

C#

```
await Http.DeleteAsync($"todoitems/{id}");
```

Named `HttpClient` with `IHttpClientFactory`

IHttpClientFactory services and the configuration of a named HttpClient are supported.

> **Note**
>
> An alternative to using a named HttpClient from an IHttpClientFactory is to use a typed HttpClient. For more information, see the Typed HttpClient section.

Add the Microsoft.Extensions.Http NuGet package to the app.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

In the `Program` file of a client project:

C#

```
builder.Services.AddHttpClient("WebAPI", client =>
    client.BaseAddress = new Uri(builder.HostEnvironment.BaseAddress));
```

If the named client is to be used by prerendered client-side components of a Blazor Web App, the preceding service registration should appear in both the server project

and the `.Client` project. On the server, `builder.HostEnvironment.BaseAddress` is replaced by the web API's base address, which is described further below.

The preceding client-side example sets the base address with `builder.HostEnvironment.BaseAddress` (IWebAssemblyHostEnvironment.BaseAddress), which gets the base address for the client-side app and is typically derived from the `<base>` tag's `href` value in the host page.

The most common use cases for using the client's own base address are:

- The client project (`.Client`) of a Blazor Web App that makes web API calls from WebAssembly/Auto components or code that runs on the client in WebAssembly to APIs in the server app at the same host address.
- The client project (**Client**) of a hosted Blazor WebAssembly app that makes web API calls to the server project (**Server**).

If you're calling an external web API (not in the same URL space as the client app) or you're configuring the services in a server-side app (for example to deal with prerendering of client-side components on the server), set the URI to the web API's base address. The following example sets the base address of the web API to `https://localhost:5001`, where a separate web API app is running and ready to respond to requests from the client app:

C#

```
builder.Services.AddHttpClient("WebAPI", client =>
    client.BaseAddress = new Uri("https://localhost:5001"));
```

In the following component code:

- An instance of IHttpClientFactory creates a named HttpClient.
- The named HttpClient is used to issue a GET request for JSON weather forecast data from the web API at `/forecast`.

razor

```
@inject IHttpClientFactory ClientFactory

...

@code {
    private Forecast[]? forecasts;

    protected override async Task OnInitializedAsync()
    {
        var client = ClientFactory.CreateClient("WebAPI");
```

```
        forecasts = await client.GetFromJsonAsync<Forecast[]>("forecast") ??
[];
    }
}
```

The `BlazorWebAppCallWebApi` sample app demonstrates calling a web API with a named HttpClient in its `CallTodoWebApiCsrNamedClient` component. For an additional working demonstration in a client app based on calling Microsoft Graph with a named HttpClient, see Use Graph API with ASP.NET Core Blazor WebAssembly.

Typed `HttpClient`

Typed HttpClient uses one or more of the app's HttpClient instances, default or named, to return data from one or more web API endpoints.

> **Note**
>
> An alternative to using a typed HttpClient is to use a named HttpClient from an IHttpClientFactory. For more information, see the Named HttpClient with IHttpClientFactory section.

Add the Microsoft.Extensions.Http NuGet package to the app.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

The following example issues a GET request for JSON weather forecast data from the web API at `/forecast`.

`ForecastHttpClient.cs`:

C#

```
using System.Net.Http.Json;

namespace BlazorSample.Client;

public class ForecastHttpClient(HttpClient http)
{
```

```
    public async Task<Forecast[]> GetForecastAsync() =>
        await http.GetFromJsonAsync<Forecast[]>("forecast") ?? [];
}
```

In the `Program` file of a client project:

C#

```
builder.Services.AddHttpClient<ForecastHttpClient>(client =>
    client.BaseAddress = new Uri(builder.HostEnvironment.BaseAddress));
```

If the typed client is to be used by prerendered client-side components of a Blazor Web App, the preceding service registration should appear in both the server project and the `.Client` project. On the server, `builder.HostEnvironment.BaseAddress` is replaced by the web API's base address, which is described further below.

The preceding example sets the base address with `builder.HostEnvironment.BaseAddress` (IWebAssemblyHostEnvironment.BaseAddress), which gets the base address for the client-side app and is typically derived from the `<base>` tag's `href` value in the host page.

The most common use cases for using the client's own base address are:

- The client project (`.Client`) of a Blazor Web App that makes web API calls from WebAssembly/Auto components or code that runs on the client in WebAssembly to APIs in the server app at the same host address.
- The client project (**Client**) of a hosted Blazor WebAssembly app that makes web API calls to the server project (**Server**).

If you're calling an external web API (not in the same URL space as the client app) or you're configuring the services in a server-side app (for example to deal with prerendering of client-side components on the server), set the URI to the web API's base address. The following example sets the base address of the web API to `https://localhost:5001`, where a separate web API app is running and ready to respond to requests from the client app:

C#

```
builder.Services.AddHttpClient<ForecastHttpClient>(client =>
    client.BaseAddress = new Uri("https://localhost:5001"));
```

Components inject the typed HttpClient to call the web API.

In the following component code:

- An instance of the preceding `ForecastHttpClient` is injected, which creates a typed HttpClient.
- The typed HttpClient is used to issue a GET request for JSON weather forecast data from the web API.

razor

```
@inject ForecastHttpClient Http

...

@code {
    private Forecast[]? forecasts;

    protected override async Task OnInitializedAsync()
    {
        forecasts = await Http.GetForecastAsync();
    }
}
```

The `BlazorWebAppCallWebApi` sample app demonstrates calling a web API with a typed HttpClient in its `CallTodoWebApiCsrTypedClient` component. Note that the component adopts and client-side rendering (CSR) (`InteractiveWebAssembly` render mode) ***with prerendering***, so the typed client service registration appears in the `Program` file of both the server project and the `.Client` project.

Cookie-based request credentials

The guidance in this section applies to client-side scenarios that rely upon an authentication cookie.

For cookie-based authentication, which is considered more secure than bearer token authentication, cookie credentials can be sent with each web API request by calling AddHttpMessageHandler with a DelegatingHandler on a preconfigured HttpClient. The handler configures SetBrowserRequestCredentials with BrowserRequestCredentials.Include, which advises the browser to send credentials with each request, such as cookies or HTTP authentication headers, including for cross-origin requests.

`CookieHandler.cs`:

C#

```
public class CookieHandler : DelegatingHandler
{
```

```
    protected override Task<HttpResponseMessage> SendAsync(
        HttpRequestMessage request, CancellationToken cancellationToken)
    {

request.SetBrowserRequestCredentials(BrowserRequestCredentials.Include);
        request.Headers.Add("X-Requested-With", ["XMLHttpRequest"]);

        return base.SendAsync(request, cancellationToken);
    }
}
```

The `CookieHandler` is registered in the `Program` file:

C#

```
builder.Services.AddTransient<CookieHandler>();
```

The message handler is added to any preconfigured HttpClient that requires cookie authentication:

C#

```
builder.Services.AddHttpClient(...)
    .AddHttpMessageHandler<CookieHandler>();
```

For a demonstration, see Secure ASP.NET Core Blazor WebAssembly with ASP.NET Core Identity.

When composing an HttpRequestMessage, set the browser request credentials and header directly:

C#

```
var requestMessage = new HttpRequestMessage() { ... };

requestMessage.SetBrowserRequestCredentials(BrowserRequestCredentials.Includ
e);
requestMessage.Headers.Add("X-Requested-With", ["XMLHttpRequest"]);
```

`HttpClient` and `HttpRequestMessage` with Fetch API request options

The guidance in this section applies to client-side scenarios that rely upon bearer token authentication.

HttpClient (API documentation) and HttpRequestMessage can be used to customize requests. For example, you can specify the HTTP method and request headers. The following component makes a `POST` request to a web API endpoint and shows the response body.

`TodoRequest.razor`:

razor

```razor
@page "/todo-request"
@using System.Net.Http.Headers
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@inject HttpClient Http
@inject IAccessTokenProvider TokenProvider

<h1>ToDo Request</h1>

<h1>ToDo Request Example</h1>

<button @onclick="PostRequest">Submit POST request</button>

<p>Response body returned by the server:</p>

<p>@responseBody</p>

@code {
    private string? responseBody;

    private async Task PostRequest()
    {
        var requestMessage = new HttpRequestMessage()
        {
            Method = new HttpMethod("POST"),
            RequestUri = new Uri("https://localhost:10000/todoitems"),
            Content =
                JsonContent.Create(new TodoItem
                {
                    Name = "My New Todo Item",
                    IsComplete = false
                })
        };

        var tokenResult = await TokenProvider.RequestAccessToken();

        if (tokenResult.TryGetToken(out var token))
        {
            requestMessage.Headers.Authorization =
                new AuthenticationHeaderValue("Bearer", token.Value);

            requestMessage.Content.Headers.TryAddWithoutValidation(
                "x-custom-header", "value");

            var response = await Http.SendAsync(requestMessage);
```

```
            var responseStatusCode = response.StatusCode;

            responseBody = await response.Content.ReadAsStringAsync();
        }
    }

    public class TodoItem
    {
        public long Id { get; set; }
        public string? Name { get; set; }
        public bool IsComplete { get; set; }
    }
}
```

Blazor's client-side implementation of HttpClient uses Fetch API and configures the underlying request-specific Fetch API options via HttpRequestMessage extension methods and WebAssemblyHttpRequestMessageExtensions. Set additional options using the generic SetBrowserRequestOption extension method. Blazor and the underlying Fetch API don't directly add or modify request headers. For more information on how user agents, such as browsers, interact with headers, consult external user agent documentation sets and other web resources.

The HTTP response is typically buffered to enable support for synchronous reads on the response content. To enable support for response streaming, use the SetBrowserResponseStreamingEnabled extension method on the request.

To include credentials in a cross-origin request, use the SetBrowserRequestCredentials extension method:

C#

```
requestMessage.SetBrowserRequestCredentials(BrowserRequestCredentials.Includ
e);
```

For more information on Fetch API options, see MDN web docs: WindowOrWorkerGlobalScope.fetch(): Parameters.

Handle errors

Handle web API response errors in developer code when they occur. For example, GetFromJsonAsync expects a JSON response from the web API with a `Content-Type` of `application/json`. If the response isn't in JSON format, content validation throws a NotSupportedException.

In the following example, the URI endpoint for the weather forecast data request is misspelled. The URI should be to `WeatherForecast` but appears in the call as `WeatherForcast`, which is missing the letter `e` in `Forecast`.

The GetFromJsonAsync call expects JSON to be returned, but the web API returns HTML for an unhandled exception with a `Content-Type` of `text/html`. The unhandled exception occurs because the path to `/WeatherForcast` isn't found and middleware can't serve a page or view for the request.

In OnInitializedAsync on the client, NotSupportedException is thrown when the response content is validated as non-JSON. The exception is caught in the `catch` block, where custom logic could log the error or present a friendly error message to the user.

`ReturnHTMLOnException.razor`:

razor

```
@page "/return-html-on-exception"
@using {PROJECT NAME}.Shared
@inject HttpClient Http

<h1>Fetch data but receive HTML on unhandled exception</h1>

@if (forecasts == null)
{
    <p><em>Loading...</em></p>
}
else
{
    <h2>Temperatures by Date</h2>

    <ul>
        @foreach (var forecast in forecasts)
        {
            <li>
                @forecast.Date.ToShortDateString():
                @forecast.TemperatureC &#8451;
                @forecast.TemperatureF &#8457;
            </li>
        }
    </ul>
}

<p>
    @exceptionMessage
</p>

@code {
    private WeatherForecast[]? forecasts;
    private string? exceptionMessage;
```

```
    protected override async Task OnInitializedAsync()
    {
        try
        {
            // The URI endpoint "WeatherForecast" is misspelled on purpose
on the
            // next line. See the preceding text for more information.
            forecasts = await Http.GetFromJsonAsync<WeatherForecast[]>
("WeatherForcast");
        }
        catch (NotSupportedException exception)
        {
            exceptionMessage = exception.Message;
        }
    }
}
```

> **Note**
>
> The preceding example is for demonstration purposes. A web API can be configured to return JSON even when an endpoint doesn't exist or an unhandled exception occurs on the server.

For more information, see Handle errors in ASP.NET Core Blazor apps.

Cross-Origin Resource Sharing (CORS)

Browser security restricts a webpage from making requests to a different domain than the one that served the webpage. This restriction is called the *same-origin policy*. The same-origin policy restricts (but doesn't prevent) a malicious site from reading sensitive data from another site. To make requests from the browser to an endpoint with a different origin, the *endpoint* must enable Cross-Origin Resource Sharing (CORS).

For more information on server-side CORS, see Enable Cross-Origin Requests (CORS) in ASP.NET Core. The article's examples don't pertain directly to Razor component scenarios, but the article is useful for learning general CORS concepts.

For information on client-side CORS requests, see ASP.NET Core Blazor WebAssembly additional security scenarios.

Antiforgery support

To add antiforgery support to an HTTP request, inject the `AntiforgeryStateProvider` and add a `RequestToken` to the headers collection as a `RequestVerificationToken`:

razor

```
@inject AntiforgeryStateProvider Antiforgery
```

C#

```
private async Task OnSubmit()
{
    var antiforgery = Antiforgery.GetAntiforgeryToken();
    var request = new HttpRequestMessage(HttpMethod.Post, "action");
    request.Headers.Add("RequestVerificationToken",
antiforgery.RequestToken);
    var response = await client.SendAsync(request);
    ...
}
```

For more information, see ASP.NET Core Blazor authentication and authorization.

Blazor framework component examples for testing web API access

Various network tools are publicly available for testing web API backend apps directly, such as Firefox Browser Developer. Blazor framework's reference source includes HttpClient test assets that are useful for testing:

HttpClientTest assets in the dotnet/aspnetcore GitHub repository

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Additional resources

General

- Cross-Origin Resource Sharing (CORS) at W3C
- Enable Cross-Origin Requests (CORS) in ASP.NET Core: Although the content applies to ASP.NET Core apps, not Razor components, the article covers general CORS concepts.

Mitigation of overposting attacks

Web APIs can be vulnerable to an *overposting* attack, also known as a *mass assignment* attack. An overposting attack occurs when a malicious user issues an HTML form POST to the server that processes data for properties that aren't part of the rendered form and that the developer doesn't wish to allow users to modify. The term "overposting" literally means that the malicious user has *over*-POSTed with the form.

For guidance on mitigating overposting attacks, see Tutorial: Create a web API with ASP.NET Core.

Server-side

- Server-side ASP.NET Core Blazor additional security scenarios: Includes coverage on using HttpClient to make secure web API requests.
- Make HTTP requests using IHttpClientFactory in ASP.NET Core
- Enforce HTTPS in ASP.NET Core
- Kestrel HTTPS endpoint configuration

Client-side

- ASP.NET Core Blazor WebAssembly additional security scenarios: Includes coverage on using HttpClient to make secure web API requests.
- Use Graph API with ASP.NET Core Blazor WebAssembly
- Fetch API

Display images and documents in ASP.NET Core Blazor

Article • 10/18/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article describes approaches for displaying images and documents in Blazor apps.

The examples in this article are available for inspection and use in the Blazor sample apps:

dotnet/blazor-samples GitHub repository: Navigate to the app named `BlazorSample_BlazorWebApp` (8.0 or later), `BlazorSample_Server` (7.0 or earlier), or `BlazorSample_WebAssembly`.

Dynamically set an image source

The following example demonstrates how to dynamically set an image's source with a C# field.

The example in this section uses three image files, named `image1.png`, `image2.png`, and `image3.png`. The images are placed in a folder named `images` in the app's web root (`wwwroot`). The use of the `images` folder is only for demonstration purposes. You can organize static assets in any folder layout that you prefer, including serving assets directly from the `wwwroot` folder.

In the following `ShowImage1` component:

- The image's source (`src`) is dynamically set to the value of `imageSource` in C#.
- The `ShowImage` method updates the `imageSource` field based on an image `id` argument passed to the method.
- Rendered buttons call the `ShowImage` method with an image argument for each of the three available images in the `images` folder. The file name is composed using

the argument passed to the method and matches one of the three images in the `images` folder.

`ShowImage1.razor`:

razor

```razor
@page "/show-image-1"

<PageTitle>Show Image 1</PageTitle>

<h1>Show Image Example 1</h1>

@if (imageSource is not null)
{
    <p>
        <img src="@imageSource" />
    </p>
}

@for (var i = 1; i <= 3; i++)
{
    var imageId = i;
    <button @onclick="() => ShowImage(imageId)">
        Image @imageId
    </button>
}

@code {
    private string? imageSource;

    private void ShowImage(int id) => imageSource = $"images/image{id}.png";
}
```

The preceding example uses a C# field to hold the image's source data, but you can also use a C# property to hold the data.

Avoid using a loop variable directly in a lambda expression, such as `i` in the preceding `for` loop example. Otherwise, the same variable is used by all lambda expressions, which results in use of the same value in all lambdas. Capture the variable's value in a local variable. In the preceding example:

- The loop variable `i` is assigned to `imageId`.
- `imageId` is used in the lambda expression.

Alternatively, use a `foreach` loop with Enumerable.Range, which doesn't suffer from the preceding problem:

razor

```
@foreach (var imageId in Enumerable.Range(1, 3))
{
    <button @onclick="() => ShowImage(imageId)">
        Image @imageId
    </button>
}
```

For more information on lambda expressions with event handling, see ASP.NET Core Blazor event handling.

Stream image or document data

An image or other document type, such as a PDF, can be directly transmitted to the client using Blazor's streaming interop features instead of hosting the file at a public URL.

The example in this section streams source data using JavaScript (JS) interop. The following `setSource` JS function:

- Can be used to stream content for the following elements: `<body>`, `<embed>`, `<iframe>`, `<img>`, `<link>`, `<object>`, `<script>`, `<style>`, and `<track>`.
- Accepts an element `id` to display the file's contents, a data stream for the document, the content type, and a title for the display element.

The function:

- Reads the provided stream into an ArrayBuffer.
- Creates a Blob to wrap the `ArrayBuffer`, setting the blob's content type.
- Creates an object URL to serve as the address for the document to be shown.
- Set's the element's title (`title`) from the `title` parameter and sets the element's source (`src`) from the created object URL.
- To prevent memory leaks, the function calls revokeObjectURL to dispose of the object URL after the element loads the resource (load event).

HTML

```
<script>
  window.setSource = async (elementId, stream, contentType, title) => {
    const arrayBuffer = await stream.arrayBuffer();
    let blobOptions = {};
    if (contentType) {
      blobOptions['type'] = contentType;
    }
    const blob = new Blob([arrayBuffer], blobOptions);
```

```
    const url = URL.createObjectURL(blob);
    const element = document.getElementById(elementId);
    element.title = title;
    element.onload = () => {
      URL.revokeObjectURL(url);
    }
    element.src = url;
  }
</script>
```

> **Note**
>
> For general guidance on JS location and our recommendations for production apps, see JavaScript location in ASP.NET Core Blazor apps.

The following `ShowImage2` component:

- Injects services for an System.Net.Http.HttpClient and Microsoft.JSInterop.IJSRuntime.
- Includes an `<img>` tag to display an image.
- Has a `GetImageStreamAsync` C# method to retrieve a Stream for an image. A production app may dynamically generate an image based on the specific user or retrieve an image from storage. The following example retrieves the .NET avatar for the `dotnet` GitHub repository.
- Has a `SetImageAsync` method that's triggered on the button's selection by the user. `SetImageAsync` performs the following steps:
  - Retrieves the Stream from `GetImageStreamAsync`.
  - Wraps the Stream in a DotNetStreamReference, which allows streaming the image data to the client.
  - Invokes the `setSource` JavaScript function, which accepts the data on the client.

> **Note**
>
> Server-side apps use a dedicated HttpClient service to make requests, so no action is required by the developer of a server-side Blazor app to register an HttpClient service. Client-side apps have a default HttpClient service registration when the app is created from a Blazor project template. If an HttpClient service registration isn't present in the `Program` file of a client-side app, provide one by adding `builder.Services.AddHttpClient();`. For more information, see Make HTTP requests using IHttpClientFactory in ASP.NET Core.

`ShowImage2.razor`:

razor

```razor
@page "/show-image-2"
@inject HttpClient Http
@inject IJSRuntime JS

<PageTitle>Show Image 2</PageTitle>

<h1>Show Image Example 2</h1>

<button @onclick="SetImageAsync">
    Set Image
</button>

<div class="p-3">
    <img id="avatar" />
</div>

@code {
    private async Task<Stream> GetImageStreamAsync() =>
        await
Http.GetStreamAsync("https://avatars.githubusercontent.com/u/9141961");

    private async Task SetImageAsync()
    {
        var imageStream = await GetImageStreamAsync();
        var strRef = new DotNetStreamReference(imageStream);
        await JS.InvokeVoidAsync("setSource", "avatar", strRef, "image/png",
            ".NET GitHub avatar");
    }
}
```

The following `ShowFile` component loads either a text file (`files/quote.txt`) or a PDF file (`files/quote.pdf`) into an <iframe> element (MDN documentation).

⊗ Caution

Use of the `<iframe>` element in the following example is safe and doesn't require **sandboxing** because content is loaded from the app, which is a trusted source.

When loading content from an untrusted source or user input, an improperly implemented `<iframe>` element risks creating security vulnerabilities.

`ShowFile.razor`:

razor

```razor
@page "/show-file"
@inject NavigationManager Navigation
@inject HttpClient Http
@inject IJSRuntime JS

<PageTitle>Show File</PageTitle>

<div class="d-flex flex-column">
    <h1>Show File Example</h1>
    <div class="mb-4">
        <button @onclick="@(() => ShowFileAsync("files/quote.txt",
                "General Ravon quote (text file)"))">
            Show text ('quote.txt')
        </button>
        <button @onclick="@(() => ShowFileAsync("files/quote.pdf",
                "General Ravon quote (PDF file)"))">
            Show PDF ('quote.pdf')
        </button>
    </div>
    <iframe id="iframe" style="height: calc(100vh - 200px)" />
</div>

@code
{
    private async Task<(Stream, string?)> DownloadFileAsync(string url)
    {
        var absoluteUrl = Navigation.ToAbsoluteUri(url);
        Console.WriteLine($"Downloading file from {absoluteUrl}");

        var response = await Http.GetAsync(absoluteUrl);
        string? contentType = null;

        if (response.Content.Headers.TryGetValues("Content-Type", out var
values))
        {
            contentType = values.FirstOrDefault();
        }

        return (await response.Content.ReadAsStreamAsync(), contentType);
    }

    private async Task ShowFileAsync(string url, string title)
    {
        var (fileStream, contentType) = await DownloadFileAsync(url);
        var strRef = new DotNetStreamReference(fileStream);
        await JS.InvokeVoidAsync("setSource", "iframe", strRef, contentType,
title);
    }
}
```

ASP.NET Core Blazor authentication and authorization

Article • 11/06/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article describes ASP.NET Core's support for the configuration and management of security in Blazor apps.

Security scenarios differ between authorization code running server-side and client-side in Blazor apps. For authorization code that runs on the server, authorization checks are able to enforce access rules for areas of the app and components. Because client-side code execution can be tampered with, authorization code executing on the client can't be trusted to absolutely enforce access rules or control the display of client-side content.

If authorization rule enforcement must be guaranteed, don't implement authorization checks in client-side code. Build a Blazor Web App that only relies on server-side rendering (SSR) for authorization checks and rule enforcement.

Razor Pages authorization conventions don't apply to routable Razor components. If a non-routable Razor component is embedded in a page of a Razor Pages app, the page's authorization conventions indirectly affect the Razor component along with the rest of the page's content.

> **Note**
>
> The code examples in this article adopt nullable reference types (NRTs) and .NET compiler null-state static analysis, which are supported in ASP.NET Core in .NET 6 or later. When targeting ASP.NET Core 5.0 or earlier, remove the null type designation (`?`) from examples in this article.

Securely maintain sensitive data and credentials

Don't store app secrets, connection strings, credentials, passwords, personal identification numbers (PINs), private .NET/C# code, or private keys/tokens in client-side code, which is ***always insecure***. Client-side Blazor code should access secure services and databases through a secure web API that you control.

In test/staging and production environments, server-side Blazor code and web APIs should use secure authentication flows that avoid maintaining credentials within project code or configuration files. Outside of local development testing, we recommend avoiding the use of environment variables to store sensitive data, as environment variables aren't the most secure approach. For local development testing, the Secret Manager tool is recommended for securing sensitive data. For more information, see the following resources:

- Secure authentication flows (ASP.NET Core documentation)
- Managed identities for Microsoft Azure services (this article)

For client-side and server-side local development and testing, use the Secret Manager tool to secure sensitive credentials.

Managed identities for Microsoft Azure services

For Microsoft Azure services, we recommend using *managed identities*. Managed identities securely authenticate to Azure services without storing credentials in app code. For more information, see the following resources:

- What are managed identities for Azure resources? (Microsoft Entra documentation)
- Azure services documentation
  - Managed identities in Microsoft Entra for Azure SQL
  - How to use managed identities for App Service and Azure Functions

Antiforgery support

The Blazor template:

- Adds antiforgery services automatically when AddRazorComponents is called in the `Program` file.

- Adds Antiforgery Middleware by calling UseAntiforgery in its request processing pipeline in the `Program` file and requires endpoint antiforgery protection to mitigate the threats of Cross-Site Request Forgery (CSRF/XSRF). UseAntiforgery is called after UseHttpsRedirection. A call to UseAntiforgery must be placed after calls, if present, to UseAuthentication and UseAuthorization.

The AntiforgeryToken component renders an antiforgery token as a hidden field, and this component is automatically added to form (EditForm) instances. For more information, see ASP.NET Core Blazor forms overview.

The AntiforgeryStateProvider service provides access to an antiforgery token associated with the current session. Inject the service and call its GetAntiforgeryToken() method to obtain the current AntiforgeryRequestToken. For more information, see Call a web API from an ASP.NET Core Blazor app.

Blazor stores request tokens in component state, which guarantees that antiforgery tokens are available to interactive components, even when they don't have access to the request.

> **Note**
>
> Antiforgery mitigation is only required when submitting form data to the server encoded as `application/x-www-form-urlencoded`, `multipart/form-data`, or `text/plain` since these are the only valid form enctypes.

For more information, see the following resources:

- Prevent Cross-Site Request Forgery (XSRF/CSRF) attacks in ASP.NET Core: This article is the primary ASP.NET Core article on the subject, which applies to server-side Blazor Server, the server project of Blazor Web Apps, and Blazor integration with MVC/Razor Pages.
- ASP.NET Core Blazor forms overview: The *Antiforgery support* section of the article pertains to Blazor forms antiforgery support.

Authentication

Blazor uses the existing ASP.NET Core authentication mechanisms to establish the user's identity. The exact mechanism depends on how the Blazor app is hosted, server-side or client-side.

Server-side Blazor authentication

Interactively-rendered server-side Blazor operates over a SignalR connection with the client. Authentication in SignalR-based apps is handled when the connection is established. Authentication can be based on a cookie or some other bearer token, but authentication is managed via the SignalR hub and entirely within the circuit.

The built-in or custom AuthenticationStateProvider service obtains authentication state data from ASP.NET Core's HttpContext.User. This is how authentication state integrates with existing ASP.NET Core authentication mechanisms.

For more information on server-side authentication, see Secure ASP.NET Core server-side Blazor apps.

`IHttpContextAccessor`/`HttpContext` in Razor components

IHttpContextAccessor must be avoided with interactive rendering because there isn't a valid `HttpContext` available.

IHttpContextAccessor can be used for components that are statically rendered on the server. **However, we recommend avoiding it if possible.**

HttpContext can be used as a cascading parameter only in *statically-rendered root components* for general tasks, such as inspecting and modifying headers or other properties in the `App` component (`Components/App.razor`). The value is always `null` for interactive rendering.

C#

```
[CascadingParameter]
public HttpContext? HttpContext { get; set; }
```

For scenarios where the HttpContext is required in interactive components, we recommend flowing the data via persistent component state from the server. For more information, see Server-side ASP.NET Core Blazor additional security scenarios.

Shared state

Server-side Blazor apps live in server memory, and multiple app sessions are hosted within the same process. For each app session, Blazor starts a circuit with its own dependency injection container scope, thus scoped services are unique per Blazor session.

> ⚠ **Warning**

> We don't recommend apps on the same server share state using singleton services unless extreme care is taken, as this can introduce security vulnerabilities, such as leaking user state across circuits.

You can use stateful singleton services in Blazor apps if they're specifically designed for it. For example, use of a singleton memory cache is acceptable because a memory cache requires a key to access a given entry. Assuming users don't have control over the cache keys that are used with the cache, state stored in the cache doesn't leak across circuits.

For general guidance on state management, see ASP.NET Core Blazor state management.

Client-side Blazor authentication

In client-side Blazor apps, client-side authentication checks can be bypassed because all client-side code can be modified by users. The same is true for all client-side app technologies, including JavaScript SPA frameworks and native apps for any operating system.

Add the following:

- A package reference for the Microsoft.AspNetCore.Components.Authorization NuGet package.

  > **Note**
  >
  > For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at **Package consumption workflow (NuGet documentation)**. Confirm correct package versions at **NuGet.org**.

- The Microsoft.AspNetCore.Components.Authorization namespace to the app's `_Imports.razor` file.

To handle authentication, use the built-in or custom AuthenticationStateProvider service.

For more information on client-side authentication, see Secure ASP.NET Core Blazor WebAssembly.

`AuthenticationStateProvider` service

AuthenticationStateProvider is the underlying service used by the AuthorizeView component and cascading authentication services to obtain the authentication state for a user.

You don't typically use AuthenticationStateProvider directly. Use the AuthorizeView component or Task<AuthenticationState> approaches described later in this article. The main drawback to using AuthenticationStateProvider directly is that the component isn't notified automatically if the underlying authentication state data changes.

To implement a custom AuthenticationStateProvider, see ASP.NET Core Blazor authentication state, which includes guidance on implementing user authentication state change notifications.

Obtain a user's claims principal data

The AuthenticationStateProvider service can provide the current user's ClaimsPrincipal data, as shown in the following example.

`ClaimsPrincipalData.razor`:

razor

```
@page "/claims-principal-data"
@using System.Security.Claims
@inject AuthenticationStateProvider AuthenticationStateProvider

<h1>ClaimsPrincipal Data</h1>

<button @onclick="GetClaimsPrincipalData">Get ClaimsPrincipal Data</button>

<p>@authMessage</p>

@if (claims.Any())
{
    <ul>
        @foreach (var claim in claims)
        {
            <li>@claim.Type: @claim.Value</li>
        }
    </ul>
}

<p>@surname</p>

@code {
    private string? authMessage;
    private string? surname;
    private IEnumerable<Claim> claims = Enumerable.Empty<Claim>();
```

```
    private async Task GetClaimsPrincipalData()
    {
        var authState = await AuthenticationStateProvider
            .GetAuthenticationStateAsync();
        var user = authState.User;

        if (user.Identity is not null && user.Identity.IsAuthenticated)
        {
            authMessage = $"{user.Identity.Name} is authenticated.";
            claims = user.Claims;
            surname = user.FindFirst(c => c.Type ==
ClaimTypes.Surname)?.Value;
        }
        else
        {
            authMessage = "The user is NOT authenticated.";
        }
    }
}
```

In the preceding example:

- ClaimsPrincipal.Claims returns the user's claims (`claims`) for display in the UI.
- The line that obtains the user's surname (`surname`) calls ClaimsPrincipal.FindAll with a predicate to filter the user's claims.

If `user.Identity.IsAuthenticated` is `true` and because the user is a ClaimsPrincipal, claims can be enumerated and membership in roles evaluated.

For more information on dependency injection (DI) and services, see ASP.NET Core Blazor dependency injection and Dependency injection in ASP.NET Core. For information on how to implement a custom AuthenticationStateProvider, see ASP.NET Core Blazor authentication state.

Expose the authentication state as a cascading parameter

If authentication state data is required for procedural logic, such as when performing an action triggered by the user, obtain the authentication state data by defining a cascading parameter of type `Task<AuthenticationState>`, as the following example demonstrates.

`CascadeAuthState.razor`:

```
razor
```

```razor
@page "/cascade-auth-state"

<h1>Cascade Auth State</h1>

<p>@authMessage</p>

@code {
    private string authMessage = "The user is NOT authenticated.";

    [CascadingParameter]
    private Task<AuthenticationState>? authenticationState { get; set; }

    protected override async Task OnInitializedAsync()
    {
        if (authenticationState is not null)
        {
            var authState = await authenticationState;
            var user = authState?.User;

            if (user?.Identity is not null && user.Identity.IsAuthenticated)
            {
                authMessage = $"{user.Identity.Name} is authenticated.";
            }
        }
    }
}
```

If `user.Identity.IsAuthenticated` is `true`, claims can be enumerated and membership in roles evaluated.

Set up the `Task<`AuthenticationState`>` cascading parameter using the AuthorizeRouteView and cascading authentication state services.

When you create a Blazor app from one of the Blazor project templates with authentication enabled, the app includes the AuthorizeRouteView and the call to AddCascadingAuthenticationState shown in the following example. A client-side Blazor app includes the required service registrations as well. Additional information is presented in the Customize unauthorized content with the Router component section.

razor

```razor
<Router ...>
    <Found ...>
        <AuthorizeRouteView RouteData="routeData"
            DefaultLayout="typeof(Layout.MainLayout)" />
        ...
    </Found>
</Router>
```

In the `Program` file, register cascading authentication state services:

```
C#

builder.Services.AddCascadingAuthenticationState();
```

In a client-side Blazor app, add authorization services to the `Program` file:

```
C#

builder.Services.AddAuthorizationCore();
```

In a server-side Blazor app, services for options and authorization are already present, so no further steps are required.

Authorization

After a user is authenticated, *authorization* rules are applied to control what the user can do.

Access is typically granted or denied based on whether:

- A user is authenticated (signed in).
- A user is in a *role*.
- A user has a *claim*.
- A *policy* is satisfied.

Each of these concepts is the same as in an ASP.NET Core MVC or Razor Pages app. For more information on ASP.NET Core security, see the articles under ASP.NET Core Security and Identity.

`AuthorizeView` component

The AuthorizeView component selectively displays UI content depending on whether the user is authorized. This approach is useful when you only need to *display* data for the user and don't need to use the user's identity in procedural logic.

The component exposes a `context` variable of type AuthenticationState (`@context` in Razor syntax), which you can use to access information about the signed-in user:

```
razor
```

```razor
<AuthorizeView>
    <p>Hello, @context.User.Identity?.Name!</p>
</AuthorizeView>
```

You can also supply different content for display if the user isn't authorized with a combination of the Authorized and NotAuthorized parameters:

razor

```razor
<AuthorizeView>
    <Authorized>
        <p>Hello, @context.User.Identity?.Name!</p>
        <p><button @onclick="HandleClick">Authorized Only Button</button>
</p>
    </Authorized>
    <NotAuthorized>
        <p>You're not authorized.</p>
    </NotAuthorized>
</AuthorizeView>

@code {
    private void HandleClick() { ... }
}
```

Although the AuthorizeView component controls the visibility of elements based on the user's authorization status, it doesn't enforce security on the event handler itself. In the preceding example, the `HandleClick` method is only associated with a button visible to authorized users, but nothing prevents invoking this method from other places. To ensure method-level security, implement additional authorization logic within the handler itself or in the relevant API.

Razor components of Blazor Web Apps never display `<NotAuthorized>` content when authorization fails server-side during static server-side rendering (static SSR). The server-side ASP.NET Core pipeline processes authorization on the server. Use server-side techniques to handle unauthorized requests. For more information, see ASP.NET Core Blazor render modes.

> ⚠ **Warning**
>
> Client-side markup and methods associated with an AuthorizeView are only protected from view and execution in the ***rendered UI*** in client-side Blazor apps. In order to protect authorized content and secure methods in client-side Blazor, the content is usually supplied by a secure, authorized web API call to a server API and never stored in the app. For more information, see Call a web API from an ASP.NET

Core Blazor app and ASP.NET Core Blazor WebAssembly additional security scenarios.

The content of Authorized and NotAuthorized can include arbitrary items, such as other interactive components.

Authorization conditions, such as roles or policies that control UI options or access, are covered in the Authorization section.

If authorization conditions aren't specified, AuthorizeView uses a default policy:

- Authenticated (signed-in) users are authorized.
- Unauthenticated (signed-out) users are unauthorized.

The AuthorizeView component can be used in the `NavMenu` component (`Shared/NavMenu.razor`) to display a NavLink component (NavLink), but note that this approach only removes the list item from the rendered output. It doesn't prevent the user from navigating to the component. Implement authorization separately in the destination component.

Role-based and policy-based authorization

The AuthorizeView component supports *role-based* or *policy-based* authorization.

For role-based authorization, use the Roles parameter. In the following example, the user must have a role claim for either the `Admin` or `Superuser` roles:

razor

```
<AuthorizeView Roles="Admin, Superuser">
    <p>You have an 'Admin' or 'Superuser' role claim.</p>
</AuthorizeView>
```

To require a user have both `Admin` and `Superuser` role claims, nest AuthorizeView components:

razor

```
<AuthorizeView Roles="Admin">
    <p>User: @context.User</p>
    <p>You have the 'Admin' role claim.</p>
    <AuthorizeView Roles="Superuser" Context="innerContext">
        <p>User: @innerContext.User</p>
        <p>You have both 'Admin' and 'Superuser' role claims.</p>
```

```
    </AuthorizeView>
</AuthorizeView>
```

The preceding code establishes a `Context` for the inner AuthorizeView component to prevent an AuthenticationState context collision. The AuthenticationState context is accessed in the outer AuthorizeView with the standard approach for accessing the context (`@context.User`). The context is accessed in the inner AuthorizeView with the named `innerContext` context (`@innerContext.User`).

For more information, including configuration guidance, see Role-based authorization in ASP.NET Core.

For policy-based authorization, use the Policy parameter with a single policy name:

razor

```
<AuthorizeView Policy="Over21">
    <p>You satisfy the 'Over21' policy.</p>
</AuthorizeView>
```

To handle the case where the user should satisfy one of several policies, create a policy that confirms that the user satisfies other policies.

To handle the case where the user must satisfy several policies simultaneously, take *either* of the following approaches:

- Create a policy for AuthorizeView that confirms that the user satisfies several other policies.
- Nest the policies in multiple AuthorizeView components:

  razor

  ```
  <AuthorizeView Policy="Over21">
      <AuthorizeView Policy="LivesInCalifornia">
          <p>You satisfy the 'Over21' and 'LivesInCalifornia' policies.
  </p>
      </AuthorizeView>
  </AuthorizeView>
  ```

Claims-based authorization is a special case of policy-based authorization. For example, you can define a policy that requires users to have a certain claim. For more information, see Policy-based authorization in ASP.NET Core.

If neither Roles nor Policy is specified, AuthorizeView uses the default policy:

- Authenticated (signed-in) users are authorized.
- Unauthenticated (signed-out) users are unauthorized.

Because .NET string comparisons are case-sensitive, matching role and policy names is also case-sensitive. For example, `Admin` (uppercase `A`) is not treated as the same role as `admin` (lowercase `a`).

Pascal case is typically used for role and policy names (for example, `BillingAdministrator`), but the use of Pascal case isn't a strict requirement. Different casing schemes, such as camel case, kebab case, and snake case, are permitted. Using spaces in role and policy names is unusual but permitted by the framework. For example, `billing administrator` is an unusual role or policy name format in .NET apps, but it's a valid role or policy name.

Content displayed during asynchronous authentication

Blazor allows for authentication state to be determined *asynchronously*. The primary scenario for this approach is in client-side Blazor apps that make a request to an external endpoint for authentication.

While authentication is in progress, AuthorizeView displays no content. To display content while authentication occurs, assign content to the Authorizing parameter:

razor

```
<AuthorizeView>
    <Authorized>
        <p>Hello, @context.User.Identity?.Name!</p>
    </Authorized>
    <Authorizing>
        <p>You can only see this content while authentication is in
progress.</p>
    </Authorizing>
</AuthorizeView>
```

This approach isn't normally applicable to server-side Blazor apps. Server-side Blazor apps know the authentication state as soon as the state is established. Authorizing content can be provided in an app's AuthorizeView component, but the content is never displayed.

`[Authorize]` attribute

The [Authorize] attribute is available in Razor components:

razor

```
@page "/"
@attribute [Authorize]

You can only see this if you're signed in.
```

> **Important**
>
> Only use **[Authorize]** on `@page` components reached via the Blazor router. Authorization is only performed as an aspect of routing and *not* for child components rendered within a page. To authorize the display of specific parts within a page, use **AuthorizeView** instead.

The [Authorize] attribute also supports role-based or policy-based authorization. For role-based authorization, use the Roles parameter:

razor

```
@page "/"
@attribute [Authorize(Roles = "Admin, Superuser")]

<p>You can only see this if you're in the 'Admin' or 'Superuser' role.</p>
```

For policy-based authorization, use the Policy parameter:

razor

```
@page "/"
@attribute [Authorize(Policy = "Over21")]

<p>You can only see this if you satisfy the 'Over21' policy.</p>
```

If neither Roles nor Policy is specified, [Authorize] uses the default policy:

- Authenticated (signed-in) users are authorized.
- Unauthenticated (signed-out) users are unauthorized.

When the user isn't authorized and if the app doesn't customize unauthorized content with the Router component, the framework automatically displays the following fallback message:

HTML

```
Not authorized.
```

Resource authorization

To authorize users for resources, pass the request's route data to the Resource parameter of AuthorizeRouteView.

In the Router.Found content for a requested route:

razor

```
<AuthorizeRouteView Resource="routeData" RouteData="routeData"
    DefaultLayout="typeof(MainLayout)" />
```

For more information on how authorization state data is passed and used in procedural logic, see the Expose the authentication state as a cascading parameter section.

When the AuthorizeRouteView receives the route data for the resource, authorization policies have access to RouteData.PageType and RouteData.RouteValues that permit custom logic to make authorization decisions.

In the following example, an `EditUser` policy is created in AuthorizationOptions for the app's authorization service configuration (AddAuthorizationCore) with the following logic:

- Determine if a route value exists with a key of `id`. If the key exists, the route value is stored in `value`.
- In a variable named `id`, store `value` as a string or set an empty string value (`string.Empty`).
- If `id` isn't an empty string, assert that the policy is satisfied (return `true`) if the string's value starts with `EMP`. Otherwise, assert that the policy fails (return `false`).

In the `Program` file:

- Add namespaces for Microsoft.AspNetCore.Components and System.Linq:

  C#

  ```
  using Microsoft.AspNetCore.Components;
  using System.Linq;
  ```

- Add the policy:

C#

```
options.AddPolicy("EditUser", policy =>
    policy.RequireAssertion(context =>
    {
        if (context.Resource is RouteData rd)
        {
            var routeValue = rd.RouteValues.TryGetValue("id", out var
value);
            var id = Convert.ToString(value,
                System.Globalization.CultureInfo.InvariantCulture) ??
string.Empty;

            if (!string.IsNullOrEmpty(id))
            {
                return id.StartsWith("EMP",
StringComparison.InvariantCulture);
            }
        }

        return false;
    })
);
```

The preceding example is an oversimplified authorization policy, merely used to demonstrate the concept with a working example. For more information on creating and configuring authorization policies, see Policy-based authorization in ASP.NET Core.

In the following `EditUser` component, the resource at `/users/{id}/edit` has a route parameter for the user's identifier (`{id}`). The component uses the preceding `EditUser` authorization policy to determine if the route value for `id` starts with `EMP`. If `id` starts with `EMP`, the policy succeeds and access to the component is authorized. If `id` starts with a value other than `EMP` or if `id` is an empty string, the policy fails, and the component doesn't load.

`EditUser.razor`:

razor

```
@page "/users/{id}/edit"
@using Microsoft.AspNetCore.Authorization
@attribute [Authorize(Policy = "EditUser")]

<h1>Edit User</h1>

<p>The "EditUser" policy is satisfied! <code>Id</code> starts with 'EMP'.
</p>

@code {
```

```
    [Parameter]
    public string? Id { get; set; }
}
```

Customize unauthorized content with the `Router` component

The Router component, in conjunction with the AuthorizeRouteView component, allows the app to specify custom content if:

- The user fails an [Authorize] condition applied to the component. The markup of the <NotAuthorized> element is displayed. The [Authorize] attribute is covered in the [Authorize] attribute section.
- Asynchronous authorization is in progress, which usually means that the process of authenticating the user is in progress. The markup of the <Authorizing> element is displayed.

> **Important**
>
> Blazor router features that display `<NotAuthorized>` and `<NotFound>` content aren't operational during static server-side rendering (static SSR) because request processing is entirely handled by ASP.NET Core middleware pipeline request processing and Razor components aren't rendered at all for unauthorized or bad requests. Use server-side techniques to handle unauthorized and bad requests during static SSR. For more information, see **ASP.NET Core Blazor render modes**.

razor

```
<Router ...>
    <Found ...>
        <AuthorizeRouteView ...>
            <NotAuthorized>
                ...
            </NotAuthorized>
            <Authorizing>
                ...
            </Authorizing>
        </AuthorizeRouteView>
    </Found>
</Router>
```

The content of Authorized and NotAuthorized can include arbitrary items, such as other interactive components.

> **Note**
>
> The preceding requires cascading authentication state services registration in the app's `Program` file:
>
> ```
> C#
> builder.Services.AddCascadingAuthenticationState();
> ```

If NotAuthorized content isn't specified, the AuthorizeRouteView uses the following fallback message:

```
HTML
Not authorized.
```

An app created from the Blazor WebAssembly project template with authentication enabled includes a `RedirectToLogin` component, which is positioned in the `<NotAuthorized>` content of the Router component. When a user isn't authenticated (`context.User.Identity?.IsAuthenticated != true`), the `RedirectToLogin` component redirects the browser to the `authentication/login` endpoint for authentication. The user is returned to the requested URL after authenticating with the identity provider.

Procedural logic

If the app is required to check authorization rules as part of procedural logic, use a cascaded parameter of type `Task<`AuthenticationState`>` to obtain the user's ClaimsPrincipal. `Task<`AuthenticationState`>` can be combined with other services, such as `IAuthorizationService`, to evaluate policies.

In the following example:

- The `user.Identity.IsAuthenticated` executes code for authenticated (signed-in) users.
- The `user.IsInRole("admin")` executes code for users in the 'Admin' role.
- The `(await AuthorizationService.AuthorizeAsync(user, "content-editor")).Succeeded` executes code for users satisfying the 'content-editor' policy.

A server-side Blazor app includes the appropriate namespaces when created from the project template. In a client-side Blazor app, confirm the presence of the

Microsoft.AspNetCore.Authorization and Microsoft.AspNetCore.Components.Authorization namespaces either in the component or in the app's `_Imports.razor` file:

razor

```
@using Microsoft.AspNetCore.Authorization
@using Microsoft.AspNetCore.Components.Authorization
```

`ProceduralLogic.razor`:

razor

```
@page "/procedural-logic"
@inject IAuthorizationService AuthorizationService

<h1>Procedural Logic Example</h1>

<button @onclick="@DoSomething">Do something important</button>

@code {
    [CascadingParameter]
    private Task<AuthenticationState>? authenticationState { get; set; }

    private async Task DoSomething()
    {
        if (authenticationState is not null)
        {
            var authState = await authenticationState;
            var user = authState?.User;

            if (user is not null)
            {
                if (user.Identity is not null &&
user.Identity.IsAuthenticated)
                {
                    // ...
                }

                if (user.IsInRole("Admin"))
                {
                    // ...
                }

                if ((await AuthorizationService.AuthorizeAsync(user,
"content-editor"))
                    .Succeeded)
                {
                    // ...
                }
            }
        }
```

```
    }
}
```

Troubleshoot errors

Common errors:

- **Authorization requires a cascading parameter of type `Task<AuthenticationState>`. Consider using `CascadingAuthenticationState` to supply this.**
- **`null` value is received for `authenticationStateTask`**

It's likely that the project wasn't created using a server-side Blazor template with authentication enabled.

In .NET 7 or earlier, wrap a `<CascadingAuthenticationState>` around some part of the UI tree, for example around the Blazor router:

razor

```
<CascadingAuthenticationState>
    <Router ...>
        ...
    </Router>
</CascadingAuthenticationState>
```

In .NET 8 or later, don't use the CascadingAuthenticationState component:

diff

```
- <CascadingAuthenticationState>
      <Router ...>
          ...
      </Router>
- </CascadingAuthenticationState>
```

Instead, add cascading authentication state services to the service collection in the `Program` file:

C#

```
builder.Services.AddCascadingAuthenticationState();
```

The CascadingAuthenticationState component (.NET 7 or earlier) or services provided by AddCascadingAuthenticationState (.NET 8 or later) supplies the `Task<AuthenticationState>` cascading parameter, which in turn it receives from the underlying AuthenticationStateProvider dependency injection service.

Personally Identifiable Information (PII)

Microsoft uses the GDPR definition for 'personal data' (GDPR 4.1) when documentation discusses Personally Identifiable Information (PII).

PII refers any information relating to an identified or identifiable natural person. An identifiable natural person is one who can be identified, directly or indirectly, with any of the following:

- Name
- Identification number
- Location coordinates
- Online identifier
- Other specific factors
  - Physical
  - Physiological
  - Genetic
  - Mental (psychological)
  - Economic
  - Cultural
  - Social identity

ASP.NET Core Blazor authentication state

Article • 09/23/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article explains how to create a custom authentication state provider and receive user authentication state change notifications in code.

The general approaches taken for server-side and client-side Blazor apps are similar but differ in their exact implementations, so this article pivots between server-side Blazor apps and client-side Blazor apps. Use the pivot selector at the top of the article to change the article's pivot to match the type of Blazor project that you're working with:

- Server-side Blazor apps (**Server** pivot): Blazor Server for .NET 7 or earlier and the server project of a Blazor Web App for .NET 8 or later.
- Client-side Blazor apps (**Blazor WebAssembly** pivot): Blazor WebAssembly for all versions of .NET or the `.Client` project of a Blazor Web App for .NET 8 or later.

Abstract `AuthenticationStateProvider` class

The Blazor framework includes an abstract AuthenticationStateProvider class to provide information about the authentication state of the current user with the following members:

- GetAuthenticationStateAsync: Asynchronously gets the authentication state of the current user.
- AuthenticationStateChanged: An event that provides notification when the authentication state has changed. For example, this event may be raised if a user signs in or out of the app.
- NotifyAuthenticationStateChanged: Raises an authentication state changed event.

Implement a custom `AuthenticationStateProvider`

The app must reference the Microsoft.AspNetCore.Components.Authorization NuGet package, which provides authentication and authorization support for Blazor apps.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

Configure the following authentication, authorization, and cascading authentication state services in the `Program` file.

When you create a Blazor app from one of the Blazor project templates with authentication enabled, the app is preconfigured with the following service registrations, which includes exposing the authentication state as a cascading parameter. For more information, see ASP.NET Core Blazor authentication and authorization with additional information presented in the article's Customize unauthorized content with the Router component section.

C#

```
using Microsoft.AspNetCore.Components.Authorization;

...

builder.Services.AddAuthorization();
builder.Services.AddCascadingAuthenticationState();
```

Subclass AuthenticationStateProvider and override GetAuthenticationStateAsync to create the user's authentication state. In the following example, all users are authenticated with the username `mrfibuli`.

`CustomAuthStateProvider.cs`:

C#

```
using System.Security.Claims;
using Microsoft.AspNetCore.Components.Authorization;

public class CustomAuthStateProvider : AuthenticationStateProvider
{
```

```
    public override Task<AuthenticationState> GetAuthenticationStateAsync()
    {
        var identity = new ClaimsIdentity(
        [
            new Claim(ClaimTypes.Name, "mrfibuli"),
        ], "Custom Authentication");

        var user = new ClaimsPrincipal(identity);

        return Task.FromResult(new AuthenticationState(user));
    }
}
```

> **Note**
>
> The preceding code that creates a new ClaimsIdentity uses simplified collection initialization introduced with C# 12 (.NET 8). For more information, see Collection expressions - C# language reference.

The `CustomAuthStateProvider` service is registered in the `Program` file. Register the service *scoped* with AddScoped:

C#

```
builder.Services.AddScoped<AuthenticationStateProvider,
CustomAuthStateProvider>();
```

If it isn't present, add an @using statement to the `_Imports.razor` file to make the Microsoft.AspNetCore.Components.Authorization namespace available across components:

razor

```
@using Microsoft.AspNetCore.Components.Authorization;
```

Confirm or change the route view component to an AuthorizeRouteView in the Router component definition. The location of the `Router` component differs depending on the type of app. Use search to locate the component if you're unaware of its location in the project.

razor

```
<Router ...>
    <Found ...>
        <AuthorizeRouteView RouteData="routeData"
```

```
            DefaultLayout="typeof(Layout.MainLayout)" />
        ...
    </Found>
</Router>
```

> **Note**
>
> When you create a Blazor app from one of the Blazor project templates with authentication enabled, the app includes the AuthorizeRouteView component. For more information, see ASP.NET Core Blazor authentication and authorization with additional information presented in the article's Customize unauthorized content with the Router component section.

The following example AuthorizeView component demonstrates the authenticated user's name:

razor

```
<AuthorizeView>
    <Authorized>
        <p>Hello, @context.User.Identity?.Name!</p>
    </Authorized>
    <NotAuthorized>
        <p>You're not authorized.</p>
    </NotAuthorized>
</AuthorizeView>
```

For guidance on the use of AuthorizeView, see ASP.NET Core Blazor authentication and authorization.

Authentication state change notifications

A custom AuthenticationStateProvider can invoke NotifyAuthenticationStateChanged on the AuthenticationStateProvider base class to notify consumers of the authentication state change to rerender.

The following example is based on implementing a custom AuthenticationStateProvider by following the guidance in the Implement a custom AuthenticationStateProvider section earlier in this article. If you already followed the guidance in that section, the following `CustomAuthStateProvider` replaces the one shown in the section.

The following `CustomAuthStateProvider` implementation exposes a custom method, `AuthenticateUser`, to sign in a user and notify consumers of the authentication state

change.

`CustomAuthStateProvider.cs`:

C#

```
using System.Security.Claims;
using Microsoft.AspNetCore.Components.Authorization;

public class CustomAuthStateProvider : AuthenticationStateProvider
{
    public override Task<AuthenticationState> GetAuthenticationStateAsync()
    {
        var identity = new ClaimsIdentity();
        var user = new ClaimsPrincipal(identity);

        return Task.FromResult(new AuthenticationState(user));
    }

    public void AuthenticateUser(string userIdentifier)
    {
        var identity = new ClaimsIdentity(
        [
            new Claim(ClaimTypes.Name, userIdentifier),
        ], "Custom Authentication");

        var user = new ClaimsPrincipal(identity);

        NotifyAuthenticationStateChanged(
            Task.FromResult(new AuthenticationState(user)));
    }
}
```

> **Note**
>
> The preceding code that creates a new ClaimsIdentity uses simplified collection initialization introduced with C# 12 (.NET 8). For more information, see Collection expressions - C# language reference.

In a component:

- Inject AuthenticationStateProvider.
- Add a field to hold the user's identifier.
- Add a button and a method to cast the AuthenticationStateProvider to `CustomAuthStateProvider` and call `AuthenticateUser` with the user's identifier.

razor

```
@inject AuthenticationStateProvider AuthenticationStateProvider

<input @bind="userIdentifier" />
<button @onclick="SignIn">Sign in</button>

<AuthorizeView>
    <Authorized>
        <p>Hello, @context.User.Identity?.Name!</p>
    </Authorized>
    <NotAuthorized>
        <p>You're not authorized.</p>
    </NotAuthorized>
</AuthorizeView>

@code {
    public string userIdentifier = string.Empty;

    private void SignIn()
    {
        ((CustomAuthStateProvider)AuthenticationStateProvider)
            .AuthenticateUser(userIdentifier);
    }
}
```

The preceding approach can be enhanced to trigger notifications of authentication state changes via a custom service. The following `CustomAuthenticationService` class maintains the current user's claims principal in a backing field (`currentUser`) with an event (`UserChanged`) that the authentication state provider can subscribe to, where the event invokes NotifyAuthenticationStateChanged. With the additional configuration later in this section, the `CustomAuthenticationService` can be injected into a component with logic that sets the `CurrentUser` to trigger the `UserChanged` event.

`CustomAuthenticationService.cs`:

C#

```
using System.Security.Claims;

public class CustomAuthenticationService
{
    public event Action<ClaimsPrincipal>? UserChanged;
    private ClaimsPrincipal? currentUser;

    public ClaimsPrincipal CurrentUser
    {
        get { return currentUser ?? new(); }
        set
        {
            currentUser = value;
```

```
            if (UserChanged is not null)
            {
                UserChanged(currentUser);
            }
        }
    }
}
```

In the `Program` file, register the `CustomAuthenticationService` in the dependency injection container:

C#

```
builder.Services.AddScoped<CustomAuthenticationService>();
```

The following `CustomAuthStateProvider` subscribes to the `CustomAuthenticationService.UserChanged` event. The `GetAuthenticationStateAsync` method returns the user's authentication state. Initially, the authentication state is based on the value of the `CustomAuthenticationService.CurrentUser`. When the user changes, a new authentication state is created for the new user (`new AuthenticationState(newUser)`) for calls to `GetAuthenticationStateAsync`:

C#

```
using Microsoft.AspNetCore.Components.Authorization;

public class CustomAuthStateProvider : AuthenticationStateProvider
{
    private AuthenticationState authenticationState;

    public CustomAuthStateProvider(CustomAuthenticationService service)
    {
        authenticationState = new AuthenticationState(service.CurrentUser);

        service.UserChanged += (newUser) =>
        {
            authenticationState = new AuthenticationState(newUser);

NotifyAuthenticationStateChanged(Task.FromResult(authenticationState));
        };
    }

    public override Task<AuthenticationState> GetAuthenticationStateAsync()
=>
        Task.FromResult(authenticationState);
}
```

The following component's `SignIn` method creates a claims principal for the user's identifier to set on `CustomAuthenticationService.CurrentUser`:

razor

```razor
@using System.Security.Claims
@inject CustomAuthenticationService AuthService

<input @bind="userIdentifier" />
<button @onclick="SignIn">Sign in</button>

<AuthorizeView>
    <Authorized>
        <p>Hello, @context.User.Identity?.Name!</p>
    </Authorized>
    <NotAuthorized>
        <p>You're not authorized.</p>
    </NotAuthorized>
</AuthorizeView>

@code {
    public string userIdentifier = string.Empty;

    private void SignIn()
    {
        var currentUser = AuthService.CurrentUser;

        var identity = new ClaimsIdentity(
            [
                new Claim(ClaimTypes.Name, userIdentifier),
            ],
            "Custom Authentication");

        var newUser = new ClaimsPrincipal(identity);

        AuthService.CurrentUser = newUser;
    }
}
```

> ⓘ Note
>
> The preceding code that creates a new ClaimsIdentity uses simplified collection initialization introduced with C# 12 (.NET 8). For more information, see Collection expressions - C# language reference.

Secure ASP.NET Core server-side Blazor apps

Article • 10/08/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article explains how to secure server-side Blazor apps as ASP.NET Core applications.

Server-side Blazor apps are configured for security in the same manner as ASP.NET Core apps. For more information, see the articles under ASP.NET Core security topics.

The authentication context is only established when the app starts, which is when the app first connects to the WebSocket. The authentication context is maintained for the lifetime of the circuit. Apps periodically revalidate the user's authentication state every 30 minutes.

If the app must capture users for custom services or react to updates to the user, see Server-side ASP.NET Core Blazor additional security scenarios.

Blazor differs from a traditional server-rendered web apps that make new HTTP requests with cookies on every page navigation. Authentication is checked during navigation events. However, cookies aren't involved. Cookies are only sent when making an HTTP request to a server, which isn't what happens when the user navigates in a Blazor app. During navigation, the user's authentication state is checked within the Blazor circuit, which you can update at any time on the server using a revalidating `AuthenticationStateProvider`](#additional-authentication-state-providers).

> **ⓘ Important**
>
> Implementing a custom `NavigationManager` to achieve authentication validation during navigation isn't recommended. If the app must execute custom authentication state logic during navigation, use a **custom AuthenticationStateProvider**.

> **Note**
>
> The code examples in this article adopt nullable reference types (NRTs) and .NET compiler null-state static analysis, which are supported in ASP.NET Core in .NET 6 or later. When targeting ASP.NET Core 5.0 or earlier, remove the null type designation (`?`) from the examples in this article.

Server-side security of sensitive data and credentials

In test/staging and production environments, server-side Blazor code and web APIs should use secure authentication flows that avoid maintaining credentials within project code or configuration files. Outside of local development testing, we recommend avoiding the use of environment variables to store sensitive data, as environment variables aren't the most secure approach. For local development testing, the Secret Manager tool is recommended for securing sensitive data. For more information, see the following resources:

- Secure authentication flows (ASP.NET Core documentation)
- Managed identities for Microsoft Azure services (Blazor documentation)

For client-side and server-side local development and testing, use the Secret Manager tool to secure sensitive credentials.

Project template

Create a new server-side Blazor app by following the guidance in Tooling for ASP.NET Core Blazor.

Visual Studio

After choosing the server-side app template and configuring the project, select the app's authentication under **Authentication type**:

- **None** (default): No authentication.
- **Individual Accounts**: User accounts are stored within the app using ASP.NET Core Identity.

Blazor Identity UI (Individual Accounts)

Blazor supports generating a full Blazor-based Identity UI when you choose the authentication option for *Individual Accounts*.

The Blazor Web App template scaffolds Identity code for a SQL Server database. The command line version uses SQLite and includes a SQLite database for Identity.

The template:

- Supports interactive server-side rendering (interactive SSR) and client-side rendering (CSR) scenarios with authenticated users.
- Adds Identity Razor components and related logic for routine authentication tasks, such as signing users in and out. The Identity components also support advanced Identity features, such as account confirmation and password recovery and multifactor authentication using a third-party app. Note that the Identity components themselves don't support interactivity.
- Adds the Identity-related packages and dependencies.
- References the Identity packages in `_Imports.razor`.
- Creates a custom user Identity class (`ApplicationUser`).
- Creates and registers an EF Core database context (`ApplicationDbContext`).
- Configures routing for the built-in Identity endpoints.
- Includes Identity validation and business logic.

To inspect the Blazor framework's Identity components, access them in the `Pages` and `Shared` folders of the Account folder in the Blazor Web App project template (reference source).

When you choose the Interactive WebAssembly or Interactive Auto render modes, the server handles all authentication and authorization requests, and the Identity components render statically on the server in the Blazor Web App's main project.

The framework provides a custom AuthenticationStateProvider in both the server and client (`.Client`) projects to flow the user's authentication state to the browser. The server project calls `AddAuthenticationStateSerialization`, while the client project calls `AddAuthenticationStateDeserialization`. Authenticating on the server rather than the client allows the app to access authentication state during prerendering and before the .NET WebAssembly runtime is initialized. The custom AuthenticationStateProvider implementations use the Persistent Component State service (PersistentComponentState) to serialize the authentication state into HTML comments and then read it back from WebAssembly to create a new AuthenticationState instance. For more information, see the Manage authentication state in Blazor Web Apps section.

Only for Interactive Server solutions, IdentityRevalidatingAuthenticationStateProvider (reference source) is a server-side AuthenticationStateProvider that revalidates the security stamp for the connected user every 30 minutes an interactive circuit is connected.

Blazor Identity depends on DbContext instances not created by a factory, which is intentional because DbContext is sufficient for the project template's Identity components to render statically without supporting interactivity.

For a description on how global interactive render modes are applied to non-Identity components while at the same time enforcing static SSR for the Identity components, see ASP.NET Core Blazor render modes.

For more information on persisting prerendered state, see Prerender ASP.NET Core Razor components.

For more information on the Blazor Identity UI and guidance on integrating external logins through social websites, see What's new with identity in .NET 8.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Manage authentication state in Blazor Web Apps

This section applies to Blazor Web Apps that adopt:

- Individual Accounts
- *Client-side rendering (CSR, WebAssembly-based interactivity).*

A client-side authentication state provider is only used within Blazor and isn't integrated with the ASP.NET Core authentication system. During prerendering, Blazor respects the metadata defined on the page and uses the ASP.NET Core authentication system to determine if the user is authenticated. When a user navigates from one page to another, a client-side authentication provider is used. When the user refreshes the page (full-page reload), the client-side authentication state provider isn't involved in the

authentication decision on the server. Since the user's state isn't persisted by the server, any authentication state maintained client-side is lost.

To address this, the best approach is to perform authentication within the ASP.NET Core authentication system. The client-side authentication state provider only takes care of reflecting the user's authentication state. Examples for how to accomplish this with authentication state providers are demonstrated by the Blazor Web App project template and described below.

In the server project's `Program` file, call `AddAuthenticationStateSerialization`, which serializes the AuthenticationState returned by the server-side AuthenticationStateProvider using the Persistent Component State service (PersistentComponentState):

C#

```
builder.Services.AddRazorComponents()
    .AddInteractiveWebAssemblyComponents()
    .AddAuthenticationStateSerialization();
```

The API only serializes the server-side name and role claims for access in the browser. To include all claims, set `SerializeAllClaims` to `true` in the server-side call to `AddAuthenticationStateSerialization`:

C#

```
builder.Services.AddRazorComponents()
    .AddInteractiveWebAssemblyComponents()
    .AddAuthenticationStateSerialization(
        options => options.SerializeAllClaims = true);
```

In the client (`.Client`) project's `Program` file, call `AddAuthenticationStateDeserialization`, which adds an AuthenticationStateProvider where the AuthenticationState is deserialized from the server using `AuthenticationStateData` and the Persistent Component State service (PersistentComponentState). There should be a corresponding call to `AddAuthenticationStateSerialization` in the server project.

C#

```
builder.Services.AddAuthorizationCore();
builder.Services.AddCascadingAuthenticationState();
builder.Services.AddAuthenticationStateDeserialization();
```

Additional claims and tokens from external providers

To store additional claims from external providers, see Persist additional claims and tokens from external providers in ASP.NET Core.

Azure App Service on Linux with Identity Server

Specify the issuer explicitly when deploying to Azure App Service on Linux with Identity Server. For more information, see Use Identity to secure a Web API backend for SPAs.

Inject `AuthenticationStateProvider` for services scoped to a component

Don't attempt to resolve AuthenticationStateProvider within a custom scope because it results in the creation of a new instance of the AuthenticationStateProvider that isn't correctly initialized.

To access the AuthenticationStateProvider within a service scoped to a component, inject the AuthenticationStateProvider with the @inject directive or the [Inject] attribute and pass it to the service as a parameter. This approach ensures that the correct, initialized instance of the AuthenticationStateProvider is used for each user app instance.

`ExampleService.cs`:

C#

```
public class ExampleService
{
    public async Task<string> ExampleMethod(AuthenticationStateProvider
authStateProvider)
    {
        var authState = await
authStateProvider.GetAuthenticationStateAsync();
        var user = authState.User;

        if (user.Identity is not null && user.Identity.IsAuthenticated)
        {
            return $"{user.Identity.Name} is authenticated.";
        }
        else
        {
            return "The user is NOT authenticated.";
        }
```

```
    }
}
```

Register the service as scoped. In a server-side Blazor app, scoped services have a lifetime equal to the duration of the client connection circuit.

In the `Program` file:

C#

```
builder.Services.AddScoped<ExampleService>();
```

In the following `InjectAuthStateProvider` component:

- The component inherits OwningComponentBase.
- The AuthenticationStateProvider is injected and passed to `ExampleService.ExampleMethod`.
- `ExampleService` is resolved with OwningComponentBase.ScopedServices and GetRequiredService, which returns the correct, initialized instance of `ExampleService` that exists for the lifetime of the user's circuit.

`InjectAuthStateProvider.razor`:

razor

```
@page "/inject-auth-state-provider"
@inherits OwningComponentBase
@inject AuthenticationStateProvider AuthenticationStateProvider

<h1>Inject <code>AuthenticationStateProvider</code> Example</h1>

<p>@message</p>

@code {
    private string? message;
    private ExampleService? ExampleService { get; set; }

    protected override async Task OnInitializedAsync()
    {
        ExampleService = ScopedServices.GetRequiredService<ExampleService>
();

        message = await
ExampleService.ExampleMethod(AuthenticationStateProvider);
    }
}
```

For more information, see the guidance on OwningComponentBase in ASP.NET Core Blazor dependency injection.

Unauthorized content display while prerendering with a custom `AuthenticationStateProvider`

To avoid showing unauthorized content, for example content in an AuthorizeView component, while prerendering with a custom AuthenticationStateProvider, adopt ***one*** of the following approaches:

- Implement IHostEnvironmentAuthenticationStateProvider for the custom AuthenticationStateProvider to support prerendering: For an example implementation of IHostEnvironmentAuthenticationStateProvider, see the Blazor framework's ServerAuthenticationStateProvider implementation in ServerAuthenticationStateProvider.cs (reference source).

  > **Note**
  >
  > Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

- Disable prerendering: Indicate the render mode with the `prerender` parameter set to `false` at the highest-level component in the app's component hierarchy that isn't a root component.

  > **Note**
  >
  > Making a root component interactive, such as the `App` component, isn't supported. Therefore, prerendering can't be disabled directly by the `App` component.

  For apps based on the Blazor Web App project template, prerendering is typically disabled where the `Routes` component is used in the `App` component (`Components/App.razor`):

```razor
<Routes @rendermode="new InteractiveServerRenderMode(prerender: false)"
/>
```

Also, disable prerendering for the `HeadOutlet` component:

```razor
<HeadOutlet @rendermode="new InteractiveServerRenderMode(prerender:
false)" />
```

You can also selectively control the render mode applied to the `Routes` component instance. For example, see ASP.NET Core Blazor render modes.

- Authenticate the user on the server before the app starts: To adopt this approach, the app must respond to a user's initial request with the Identity-based sign-in page or view and prevent any requests to Blazor endpoints until they're authenticated. For more information, see Create an ASP.NET Core app with user data protected by authorization. After authentication, unauthorized content in prerendered Razor components is only shown when the user is truly unauthorized to view the content.

User state management

In spite of the word "state" in the name, AuthenticationStateProvider isn't for storing *general user state*. AuthenticationStateProvider only indicates the user's authentication state to the app, whether they are signed into the app and who they are signed in as.

Authentication uses the same ASP.NET Core Identity authentication as Razor Pages and MVC apps. The user state stored for ASP.NET Core Identity flows to Blazor without adding additional code to the app. Follow the guidance in the ASP.NET Core Identity articles and tutorials for the Identity features to take effect in the Blazor parts of the app.

For guidance on general state management outside of ASP.NET Core Identity, see ASP.NET Core Blazor state management.

Additional authentication state providers

Two additional classes derived from AuthenticationStateProvider help with managing authentication state on the server:

- ServerAuthenticationStateProvider (reference source): A default AuthenticationStateProvider used by the Blazor framework to manage authentication state on the server when a more specific provider isn't registered.
- RevalidatingServerAuthenticationStateProvider (reference source): A base class for AuthenticationStateProvider services that receive an authentication state from the host environment and revalidate it at regular intervals. See the Blazor Web App project template for an example implementation. Override RevalidationInterval to change the default 30 minute revalidation interval.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Authentication state management at sign out

Server-side Blazor persists user authentication state for the lifetime of the circuit, including across browser tabs. To proactively sign off a user across browser tabs when the user signs out on one tab, you must implement a RevalidatingServerAuthenticationStateProvider (reference source) with a short RevalidationInterval.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Temporary redirection URL validity duration

This section applies to Blazor Web Apps.

Use the RazorComponentsServiceOptions.TemporaryRedirectionUrlValidityDuration option to get or set the lifetime of ASP.NET Core Data Protection validity for temporary redirection URLs emitted by Blazor server-side rendering. These are only used transiently, so the lifetime only needs to be long enough for a client to receive the URL and begin navigation to it. However, it should also be long enough to allow for clock skew across servers. The default value is five minutes.

In the following example the value is extended to seven minutes:

C#

```
builder.Services.AddRazorComponents(options =>
    options.TemporaryRedirectionUrlValidityDuration =
        TimeSpan.FromMinutes(7));
```

Threat mitigation guidance for ASP.NET Core Blazor static server-side rendering

Article • 09/27/2024

This article explains the security considerations that developers should take into account when developing Blazor Web Apps with static server-side rendering.

Blazor combines three different models in one for writing interactive web apps. Traditional server-side rendering, which is a request/response model based on HTTP. Interactive server-side rendering, which is a rendering model based on SignalR. Finally, client-side rendering, which is a rendering model based on WebAssembly.

All of the general security considerations defined for the interactive rendering modes apply to Blazor Web Apps when there are interactive components rendering in one of the supported render modes. The following sections explain the security considerations specific to non-interactive server-side rendering in Blazor Web Apps and the specific aspects that apply when render modes interact with each other.

General considerations for server-side rendering

The server-side rendering (SSR) model is based on the traditional request/response model of HTTP. As such, there are common areas of concern between SSR and request/response HTTP. General security considerations and specific threats must be successfully mitigated. The framework provides built-in mechanisms for managing some of these threats, but other threats are specific to app code and must be handled by the app. These threats can be categorized as follows:

- Authentication and authorization: The app must ensure that the user is authenticated and authorized to access the app and the resources it exposes. The framework provides built-in mechanisms for authentication and authorization, but the app must ensure that the mechanisms are properly configured and used. The built-in mechanisms for authentication and authorization are covered in the Blazor documentation's *Server* security node and in the ASP.NET Core documentation's *Security and Identity* node, so they won't be covered here.

- Input validation and sanitization: All input arriving from a client must be validated and sanitized before use. Otherwise, the app might be exposed to attacks, such as SQL injection, cross-site scripting, cross-site request forgery, open redirection, and other forms of attacks. The input might come from anywhere in the request.

- Session management: Properly managing user sessions is critical to ensure that the app isn't exposed to attacks, such as session fixation, session hijacking, and other attacks. Information stored in the session must be properly protected and encrypted, and the app's code must prevent a malicious user from guessing or manipulating sessions.

- Error handling and logging: The app must ensure that errors are properly handled and logged. Otherwise, the app might be exposed to attacks, such as information disclosure. This can happen when the app returns sensitive information in the response or when the app returns detailed error messages with data that can be used to attack the app.

- Data protection: Sensitive data must be properly protected, which includes app logic when running on WebAssembly, since it can be easily reverse-engineered.

- Denial of service: The app must ensure that it isn't exposed to attacks, such as denial of service. This happens for example, when the app isn't properly protected against brute force attacks or when an action can cause the app to consume too many resources.

Input validation and sanitization

All input arriving from the client must be considered untrusted unless its information was generated and protected on the server, such as a CSRF token, an authentication cookie, a session identifier, or any other payload that's protected with authenticated encryption.

Input is normally available to the app through a binding process, for example via the [SupplyParameterFromQuery] attribute or [SupplyParameterFromForm] attribute. Before processing this input, the app must make sure that the data is valid. For example, the app must confirm that there were no binding errors when mapping the form data to a component property. Otherwise, the app might process invalid data.

If the input is used to perform a redirect, the app must make sure that the input is valid and that it isn't pointing to a domain considered invalid or to an invalid subpath within the app base path. Otherwise, the app may be exposed to open redirection attacks, where a cyberattacker can craft a link that redirects the user to a malicious site.

If the input is used to perform a database query, app must confirm that the input is valid and that it isn't exposing the app to SQL injection attacks. Otherwise, a cyberattacker might be able to craft a malicious query that can be used to extract information from the database or to modify the database.

Data that might have come from user input also must be sanitized before included in a response. For example, the input might contain HTML or JavaScript that can be used to perform cross-site scripting attacks, which can be used to extract information from the user or to perform actions on behalf of the user.

The framework provides the following mechanisms to help with input validation and sanitization:

- All bound form data is validated for basic correctness. If an input can't be parsed, the binding process reports an error that the app can discover before taking any action with the data. The built-in EditForm component takes this into account before invoking the OnValidSubmit form callback. Blazor avoids executing the callback if there are one or more binding errors.
- The framework uses an antiforgery token to protect against cross-site request forgery attacks. For more information, see ASP.NET Core Blazor authentication and authorization and ASP.NET Core Blazor forms overview.

All input and permissions must be validated on the server at the time of performing a given action to ensure that the data is valid and accurate at that time and that the user is allowed to perform the action. This approach is consistent with the security guidance provided for interactive server-side rendering.

Session management

Session management is handled by the framework. The framework uses a session cookie to identify the user session. The session cookie is protected using the ASP.NET Core Data Protection APIs. The session cookie isn't accessible to JavaScript code running on the browser and it can't be easily guessed or manipulated by a user.

With regard to other session data, such as data stored within services, the session data should be stored within scoped services, as scoped services are unique per a given user session, as opposed to singleton services which are shared across all user sessions in a given process instance.

When it comes to SSR, there's not much difference between scoped and transient services in most cases, as the lifetime of the service is limited to a single request. There's a difference in two scenarios:

- If the service is injected in more than one location or at different times during the request.
- If the service might be used in an interactive server context, where it survives multiple renders and its fundamental that the service is scoped to the user session.

Error handling and logging

The framework provides built-in logging for the app at the framework level. The framework logs important events, such as when the antiforgery token for a form fails to validate, when a root component starts to render, and when an action is dispatched. The app is responsible for logging any other events that might be important to record.

The framework provides built-in error handling for the app at the framework level. The framework handles errors that happen during the rendering of a component and either uses the error boundary mechanism to display a friendly error message or allows the error to bubble up to the exception handling middleware, which is configured to render the error page.

Errors that occur during streaming rendering after the response has started to be sent to the client are displayed in the final response as a generic error message. Details about the cause of the error are only included during development.

ASP.NET Core Data Protection

The framework offers mechanisms for protecting sensitive information for a given user session and ensures that the built-in components use these mechanisms to protect sensitive information, such as protecting user identity when using cookie authentication. Outside of scenarios handled by the framework, developer code is responsible for protecting other app-specific information. The most common way of doing this is via the ASP.NET Core Data Protection (DP) APIs or any other form of encryption. As a general rule, the app is responsible for:

- Making sure that a user can't inspect or modify the private information of another user.
- Making sure that a user can't modify user data of another user, such as an internal identifier.

With regard to DP, you must clearly understand where the code is executing. For the static server-side rendering (static SSR) and interactive server-side rendering (interactive SSR), code is stored on the server and never reaches the client. For the Interactive WebAssembly render mode, the app code *always reaches the client*, which means that any sensitive information stored in the app code is available to anyone with access to the app. Obfuscation and other similar technique to "protect" the code isn't effective. Once the code reaches the client, it can be reverse-engineered to extract the sensitive information.

Denial of service

At the server level, the framework provides limits on request/response parameters, such as the maximum size of the request and the header size. In regard to app code, Blazor's form mapping system defines limits similar to those defined by the MVC model binding system:

- Limit on the maximum number of errors.
- Limit on the maximum recursion depth for the binder.
- Limit on the maximum number of elements bound in a collection.

In addition, there are limits defined for the form, such as the maximum form key size and value size and the maximum number of entries.

In general, the app must evaluate when there's a chance that a request triggers an asymmetric amount of work by the server. Examples of this include when the user sends a request parameterized by N and the server performs an operation in response that is N times as expensive, where N is a parameter that a user controls and can grow indefinitely. Normally, the app must either impose a limit on the maximum N that it's willing to process or ensure that any operation is either less, equal, or more expensive than the request by a constant factor.

This aspect has more to do with the difference in growth between the work the client performs and the work the server performs than with a specific 1→N comparison. For example, a client might submit a work item (inserting elements into a list) that takes N units of time to perform, but the server needs N^2^ to process (because it might be doing something very naive). It's the difference between N and N^2^ that matters.

As such, there's a limit on how much work the server must be willing to do, which is specific to the app. This aspect applies to server-side workloads, since the resources are on the server, but doesn't necessarily apply to WebAssembly workloads on the client in most cases.

The other important aspect is that this isn't only reserved to CPU time. It also applies to any resources, such as memory, network, and space on disk.

For WebAssembly workloads, there's usually little concern over the amount of work the client performs, since the client is normally limited by the resources available on the client. However, there are some scenarios where the client might be impacted, if for example, an app displays data from other users and one user is capable of adding data to the system that forces the clients that display the data to perform an amount of work that isn't proportional to the amount of data added by the user.

Recommended (non-exhaustive) check list

- Ensure that the user is authenticated and authorized to access the app and the resources it exposes.
- Validate and sanitize all input coming from a client before using it.
- Properly manage user sessions to ensure that state isn't mistakenly shared across users.
- Handle and log errors properly to avoid exposing sensitive information.
- Log important events in the app to identify potential issues and audit actions performed by users.
- Protect sensitive information using the ASP.NET Core Data Protection APIs or one of the available components (Microsoft.AspNetCore.Components.Server.ProtectedBrowserStorage, PersistentComponentState).
- Ensure that the app understands the resources that can be consumed by a given request and has limits in place to avoid denial of service attacks.

Threat mitigation guidance for ASP.NET Core Blazor interactive server-side rendering

Article • 09/27/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article explains how to mitigate security threats in interactive server-side Blazor.

Apps adopt a *stateful* data processing model, where the server and client maintain a long-lived relationship. The persistent state is maintained by a circuit, which can span connections that are also potentially long-lived.

When a user visits a site, the server creates a circuit in the server's memory. The circuit indicates to the browser what content to render and responds to events, such as when the user selects a button in the UI. To perform these actions, a circuit invokes JavaScript functions in the user's browser and .NET methods on the server. This two-way JavaScript-based interaction is referred to as JavaScript interop (JS interop).

Because JS interop occurs over the Internet and the client uses a remote browser, apps share most web app security concerns. This topic describes common threats to server-side Blazor apps and provides threat mitigation guidance focused on Internet-facing apps.

In constrained environments, such as inside corporate networks or intranets, some of the mitigation guidance either:

- Doesn't apply in the constrained environment.
- Isn't worth the cost to implement because the security risk is low in a constrained environment.

Interactive Server Components with WebSocket compression enabled

Compression can expose the app to side-channel attacks against the TLS encryption of the connection, such as CRIME and BREACH attacks. These types of attacks require that the cyberattacker:

- Force a browser to issue requests with a payload the cyberattacker controls to a vulnerable site via cross-site form posting or by embedding the site inside an iframe of another site.
- Observe the length of the compressed and encrypted response over the network.

For the app to be vulnerable, it must reflect the payload from the cyberattacker in the response, for example, by writing out the path or the query string into the response. Using the length of the response, the cyberattacker can "guess" any information on the response, bypassing the encryption of the connection.

Generally speaking, Blazor apps can enable compression over the WebSocket connection with appropriate security measures:

- The app can be vulnerable when it takes content from the request (for example, the path or query string) that can be influenced by a cyberattacker and reproduces it into the HTML of the page or otherwise makes it part of the response.
- Blazor applies the following security measures automatically:
  - When compression is configured, Blazor automatically blocks embedding the app into an iframe, which blocks the initial (uncompressed) response from the server from rendering and precludes the WebSocket connection from ever starting.
  - The restriction on embedding the app into an iframe can be relaxed. However, relaxing the restriction exposes the app to attack if the embedding document becomes compromised via a cross-site scripting vulnerability, as that gives the cyberattacker a way to execute the attack.
- Normally for this type of attack to take place, the app must repeatedly reproduce the content in the responses so that the cyberattacker can guess the response. Given how Blazor renders (it renders once and then produces diffs of the content only for the elements that changed) this is hard for a cyberattacker to accomplish. However, it isn't impossible for a cyberattacker, so care must be taken to avoid rendering sensitive information alongside external information that can be manipulated by a cyberattacker. Some examples of this are:
  - Render Personally Identifiable Information (PII) on the page at the same time as rendering database data that was added by another user.

- Rendering PII information on to the page at the same time as data coming from another user via JS interop or a local singleton service on the server.

In general, we recommend that you avoid rendering components that contain sensitive information alongside components that can render data from untrusted sources as part of the same render batch. Untrusted sources include route parameters, query strings, data from JS interop, and any other source of data that a third-party user can control (databases, external services).

Shared state

Server-side Blazor apps live in server memory, and multiple app sessions are hosted within the same process. For each app session, Blazor starts a circuit with its own dependency injection container scope, thus scoped services are unique per Blazor session.

> ⚠ **Warning**
>
> We don't recommend apps on the same server share state using singleton services unless extreme care is taken, as this can introduce security vulnerabilities, such as leaking user state across circuits.

You can use stateful singleton services in Blazor apps if they're specifically designed for it. For example, use of a singleton memory cache is acceptable because a memory cache requires a key to access a given entry. Assuming users don't have control over the cache keys that are used with the cache, state stored in the cache doesn't leak across circuits.

For general guidance on state management, see ASP.NET Core Blazor state management.

`IHttpContextAccessor` / `HttpContext` in Razor components

IHttpContextAccessor must be avoided with interactive rendering because there isn't a valid `HttpContext` available.

IHttpContextAccessor can be used for components that are statically rendered on the server. **However, we recommend avoiding it if possible.**

HttpContext can be used as a cascading parameter only in *statically-rendered root components* for general tasks, such as inspecting and modifying headers or other

properties in the `App` component (`Components/App.razor`). The value is always `null` for interactive rendering.

```
C#

[CascadingParameter]
public HttpContext? HttpContext { get; set; }
```

For scenarios where the HttpContext is required in interactive components, we recommend flowing the data via persistent component state from the server. For more information, see Server-side ASP.NET Core Blazor additional security scenarios.

Resource exhaustion

Resource exhaustion can occur when a client interacts with the server and causes the server to consume excessive resources. Excessive resource consumption primarily affects:

- CPU
- Memory
- Client connections

Denial of Service (DoS) attacks usually seek to exhaust an app or server's resources. However, resource exhaustion isn't necessarily the result of an attack on the system. For example, finite resources can be exhausted due to high user demand. DoS is covered further in the DoS section.

Resources external to the Blazor framework, such as databases and file handles (used to read and write files), may also experience resource exhaustion. For more information, see ASP.NET Core Best Practices.

CPU

CPU exhaustion can occur when one or more clients force the server to perform intensive CPU work.

For example, consider an app that calculates a *Fibonnacci number*. A Fibonnacci number is produced from a Fibonnacci sequence, where each number in the sequence is the sum of the two preceding numbers. The amount of work required to reach the answer depends on the length of the sequence and the size of the initial value. If the app doesn't place limits on a client's request, the CPU-intensive calculations may dominate

the CPU's time and diminish the performance of other tasks. Excessive resource consumption is a security concern impacting availability.

CPU exhaustion is a concern for all public-facing apps. In regular web apps, requests and connections time out as a safeguard, but Blazor apps don't provide the same safeguards. Blazor apps must include appropriate checks and limits before performing potentially CPU-intensive work.

Memory

Memory exhaustion can occur when one or more clients force the server to consume a large amount of memory.

For example, consider an app with a component that accepts and displays a list of items. If the Blazor app doesn't place limits on the number of items allowed or the number of items rendered back to the client, the memory-intensive processing and rendering may dominate the server's memory to the point where performance of the server suffers. The server may crash or slow to the point that it appears to have crashed.

Consider the following scenario for maintaining and displaying a list of items that pertain to a potential memory exhaustion scenario on the server:

- The items in a `List<T>` property or field use the server's memory. If the app allows the list of items to grow unbounded, there's a risk of the server running out of memory. Running out of memory causes the current session to end (crash) and all of the concurrent sessions in that server instance receive an out-of-memory exception. To prevent this scenario from occurring, the app must use a data structure that imposes an item limit on concurrent users.
- If a paging scheme isn't used for rendering, the server uses additional memory for objects that aren't visible in the UI. Without a limit on the number of items, memory demands may exhaust the available server memory. To prevent this scenario, use one of the following approaches:
  - Use paginated lists when rendering.
  - Only display the first 100 to 1,000 items and require the user to enter search criteria to find items beyond the items displayed.
  - For a more advanced rendering scenario, implement lists or grids that support *virtualization*. Using virtualization, lists only render a subset of items currently visible to the user. When the user interacts with the scrollbar in the UI, the component renders only those items required for display. The items that aren't currently required for display can be held in secondary storage, which is the ideal approach. Undisplayed items can also be held in memory, which is less ideal.

> **Note**
>
> Blazor has built-in support for virtualization. For more information, see ASP.NET Core Razor component virtualization.

Blazor apps offer a similar programming model to other UI frameworks for stateful apps, such as WPF, Windows Forms, or Blazor WebAssembly. The main difference is that in several of the UI frameworks the memory consumed by the app belongs to the client and only affects that individual client. For example, a Blazor WebAssembly app runs entirely on the client and only uses client memory resources. For a server-side Blazor app, the memory consumed by the app belongs to the server and is shared among clients on the server instance.

Server-side memory demands are a consideration for all server-side Blazor apps. However, most web apps are stateless, and the memory used while processing a request is released when the response is returned. As a general recommendation, don't permit clients to allocate an unbound amount of memory as in any other server-side app that persists client connections. The memory consumed by a server-side Blazor app persists for a longer time than a single request.

> **Note**
>
> During development, a profiler can be used or a trace captured to assess memory demands of clients. A profiler or trace won't capture the memory allocated to a specific client. To capture the memory use of a specific client during development, capture a dump and examine the memory demand of all the objects rooted at a user's circuit.

Client connections

Connection exhaustion can occur when one or more clients open too many concurrent connections to the server, preventing other clients from establishing new connections.

Blazor clients establish a single connection per session and keep the connection open for as long as the browser window is open. Given the persistent nature of the connections and the stateful nature of server-side Blazor apps, connection exhaustion is a greater risk to availability of the app.

There's no limit on the number of connections per user for an app. If the app requires a connection limit, take one or more of the following approaches:

- Require authentication, which naturally limits the ability of unauthorized users to connect to the app. For this scenario to be effective, users must be prevented from provisioning new users on demand.
- Limit the number of connections per user. Limiting connections can be accomplished via the following approaches. Exercise care to allow legitimate users to access the app (for example, when a connection limit is established based on the client's IP address).
  - Application level
    - Endpoint routing extensibility.
    - Require authentication to connect to the app and keep track of the active sessions per user.
    - Reject new sessions upon reaching a limit.
    - Proxy WebSocket connections to an app through the use of a proxy, such as the Azure SignalR Service that multiplexes connections from clients to an app. This provides an app with greater connection capacity than a single client can establish, preventing a client from exhausting the connections to the server.
  - Server level
    - Use a proxy/gateway in front of the app. For example, Azure Application Gateway is a web traffic (OSI layer 7) load balancer that enables you to manage traffic to your web applications. For more information, see Overview of WebSocket support in Application Gateway.
    - Although Long Polling is supported for Blazor apps, which would permit the adoption of Azure Front Door, WebSockets is the recommended transport protocol. As of September, 2024, Azure Front Door doesn't support WebSockets, but support for WebSockets is under consideration. For more information, see Support WebSocket connections on Azure Front Door.

Denial of Service (DoS) attacks

Denial of Service (DoS) attacks involve a client causing the server to exhaust one or more of its resources making the app unavailable. Blazor apps include default limits and rely on other ASP.NET Core and SignalR limits that are set on CircuitOptions to protect against DoS attacks:

- CircuitOptions.DisconnectedCircuitMaxRetained
- CircuitOptions.DisconnectedCircuitRetentionPeriod
- CircuitOptions.JSInteropDefaultCallTimeout
- CircuitOptions.MaxBufferedUnacknowledgedRenderBatches
- HubConnectionContextOptions.MaximumReceiveMessageSize

For more information and configuration coding examples, see the following articles:

- ASP.NET Core Blazor SignalR guidance
- ASP.NET Core SignalR configuration

Interactions with the browser (client)

A client interacts with the server through JS interop event dispatching and render completion. JS interop communication goes both ways between JavaScript and .NET:

- Browser events are dispatched from the client to the server in an asynchronous fashion.
- The server responds asynchronously rerendering the UI as necessary.

JavaScript functions invoked from .NET

For calls from .NET methods to JavaScript:
